at an early, critical time, and to Carol Ann (né Andree) Wetzel
for her unending understanding and support

Preface to the Third Edition

Limnology is currently experiencing a period of introspection. Such criticism is healthy if done constructively and the causes of underlying deficiencies are recognized and addressed. Many problems have arisen, however, in part because of the purported necessity to respond rapidly to governmental and societal demands without an in-depth scientific underpinning. A root cause is our continuing inability to properly educate and train students and the public. Society must recognize that intellectual creativity is essential to excellence in science and that excellence in science is essential to the most effective and cost-efficient management of our resources.

Improvements in science education and training are critically needed. A fundamental requirement of scientific education is to obtain comprehensive background information prior to interpretation and synthesis. One observes an increasing erroneous reliance upon uninformed excuses that old perceptions have little foundation or relevance for modern interpretations. Additional nonsense arguments emerge that too much information exists to integrate. With modern search and organization capabilities, such ignorance of past research is much more than laziness; it represents a deficiency in the teaching of how science is properly conducted. Bibliographic negligence is more than a lack of responsible scholarship because it leads to increasing scientific redundancy and inefficient use of intellectual and financial resources. A result is an increasing tendency to promote old ideas and interpretations under the guise of new and invariably ambiguous "buzz word" terms. These redundant ideas are actively promoted as inspiration among noncritical peers, science writers, and even granting agency administrators who are unfamiliar with the background development of the subdiscipline. Many contemporary topical reviews are incredibly naive, biased, and incomplete, and parts are simply wrong. Such deficiencies in scholarship must be

severely condemned and can be countered by more rigorous preparatory study.

There is an increasing tendency, particularly in the United States, to capitulate to the masses of information on any subject and accept, even promote, superficial understanding of ecological subjects. That level of inquiry may be acceptable for the lay public but is not acceptable for professional limnologists, aquatic ecologists, and water resource managers. A superficial level of understanding is unacceptable in all rigorous disciplines that contemplate systems of equal complexity to natural ecosystems. For example, the great strides made in human medicine are the direct result of concerted, systematic evaluation and rigorous experimental investigations of the mechanisms controlling human and pathogen physiology.

In ecology, as in many other disciplines, the "cop out" deference strategy to the information glut is increasingly to specialize in a small area and to then aggregate teams of specialists to attempt to understand how all of the pieces fit and operate together. The present emphasis on interdisciplinary studies is little more than an expansion of the identical process that has been carried on for decades by competent ecosystem scientists. Emphasis, particularly by nonscientist administrators, on forced collaboration, regardless of expertise, either directly or by fiscal coercion is an increasing problem. Such realities of collaborations reinforce the need for participants to be versed on some comprehensive introductory understanding of the whole.

I argue that one cannot manage aquatic ecosystems effectively without understanding how they operate in response to interactions of physical, chemical, and biotic environmental variables. This insistence is analogous to the statement that one cannot effectively manage human health without understanding human physiological and biochemical interactions with environmental variables. Superficial or biased training in limnology can only lead to superficial and biased understanding. There is a need for rigorous limnological training, even at the introductory level. The U.S. National Academy of Sciences (1996) also emphasized that need in the recent thorough evaluation of limnological education.

The first edition of this book, initiated in the early 1970s, resulted from my frustration with the available texts at the time, which, at best, offered interesting but superficial analyses of inland aquatic ecosystems. The initial edition, issued in 1975, was well received as an alternative. The second edition, published in 1983, represented an extensive updating with new findings, appreciable reorganization, and clarifications based on experience in my own classes and constructive inputs from many students and colleagues. Again the book was well received; it has been widely cited as a source work (e.g., ISI Citation Classic) and has been translated into several other languages.

Since the appearance of these editions, a number of other general treatments of limnology have appeared in English, French, German, Spanish, Portuguese, and other languages. Essentially all of these works are directed at providing general overviews of the subject, and some accomplish this objective very well. Some of these books are simple but interesting overviews of the subject that can be assimilated in a long evening of reading, whereas others are more involved and clearly are intended to accompany instructional programs in initial introductory courses in limnology.

Such general books introduce students at college and university levels to the fascinating subject of inland aquatic ecology. These accomplishments assist in fulfilling an enormously important responsibility of educators: the general public, particularly those obtaining higher education, should be aware of the magnitude, general operation, and management problems of inland waters upon which so much of their well-being depends. The information presented in these works need not include details underlying certain basics of the operation and should be presented in an interesting, scientifically correct manner.

There are different levels of training in any subject. The gap is large between general texts suitable for the general public and nonspecialist students and detailed research-level treatments, such as G. E. Hutchinson's four-volume *A Treatise on Limnology*. Somewhere in between is the need for a more detailed *introductory instructional* text for students interested in becoming professionals in this discipline and desiring greater depth of inquiry and understanding. For nearly a decade, among other responsibilities, I have been revising this general limnology text for a third edition for this introductory instructional objective.

Those persons familiar with the past editions of *Limnology* will recognize marked differences in the present *Limnology: Lake and River Ecosystems*. The basic format of previous editions is maintained, although the parts are completely reorganized, modified, and updated with recent advances in understanding. A number of introductory texts have taken the tack of presenting an ecosystem overview initially, in some cases constituting half the text, and then presenting a somewhat hackneyed discussion of the parts of the ecosystems thereafter that may influence the biota within the ecosystem. In *Limnology: Lake and River Ecosystems* I opine first that, apart from the structure of water and a few physical properties, aquatic ecosystem structure, energy flow, and productivity are regulated by biogeochemical cycling. One

cannot talk effectively about chemical cycles, for example, without treating microbial mediation of those cycles. Thus, it is essential to comprehend these ecosystem components before discussing the integration of the entire ecosystem. Nonetheless, a very general discussion of aquatic ecosystem structure and productivity appears early in the text, largely in order to introduce the terms used throughout the subsequent topical treatments. True ecosystem integration follows in the individual community treatments and then finally in the important synthesis chapter on organic carbon.

Second, I make major attempts to present data supporting conceptual relationships among biota and the environment in a realistic and unbiased manner. I have been accused of being biased against the roles that animals play in aquatic ecosystem structure and energetic transfer. Nothing could be further from the truth. Evaluation of the data, however, simply does not support some of the entrenched dogma that prevails in contemporary limnological writings, including many textbooks. I do present historical developments of some of those ideas even if new findings demonstrate them to be erroneous. Alternative explanations and hypotheses are then presented. I recognize that some colleagues will have difficulty with these conclusions, although I believe my conclusions accurately represent reality.

Throughout the development of our understanding of limnology, emphasis has been on differences among lakes and rivers, differences among the physical and chemical characteristics of waters of various geomorphological regions, and the diversity of different biota and their growth characteristics. That differentiation among lakes and rivers and their physical, chemical, and biological properties was the impetus behind a half century of lake and river classification studies. A major evolution of my syntheses in *Limnology: Lake and River Ecosystems* is the comparative treatment of topics across lake, reservoir, and river ecosystems. These analyses do indeed indicate differences among the properties of lakes, land–water interface regions, reservoirs, and rivers. Importantly, these analyses also indicate marked commonality in function.

It is essential that we search for commonality, in addition to differences, among these aquatic ecosystems (Wetzel, 2000). Because of the dynamic properties of metabolism, growth, and reproductive capacities of organisms as they respond to the bewildering array of dynamic environmental factors influencing growth and development, variability is enormous and often difficult to fathom. Modeling at the present level of understanding is unable to cope with so many nonlinear variables that are changing rapidly. Although reductionism is essential to provide information on the properties involved, I argue that regulatory generality prevails across the individual species and diversity of processes. Regulation of metabolic rates among different communities is where generality emerges. From both theoretical relationships and management methods of controlling the effects of disturbances, integration of quantitative process rates of metabolism, energy fluxes, and material fluxes is where commonality emerges among highly disparate and complex interacting parameters within ecosystems.

Combining lacustrine, reservoir, and running water limnology in one integrated synthesis volume on this discipline immediately causes manifold increases in the published literature to be evaluated. Indeed, the literature on certain subjects, such as stream invertebrate ecology, is both formidable and intimidating. Yet, amid the maze of individual detail, commonality of processes and regulatory mechanisms emerges. I make no pretense to being comprehensive in coverage, and among the stream and river literature in particular I relied heavily on many thorough reviews of topical subjects.

Saline lakes constitute approximately half of inland waters. Again, chemical and biological characteristics of saline lakes are not treated separately but rather are integrated within topical discussions with fresh waters. The chemistry and biota of saline lakes are fascinating and of great evolutionary significance. The mineral and biotic values of contemporary saline lakes, however, are dwarfed by the collective values of freshwater surface and groundwater repositories to humankind. As a result, treatment here has been subordinate to freshwater ecosystems. Hammer (1986) and Williams (1988, 1996) have summarized well selective characteristics of saline lakes.

Many persons have been generous and helpful with suggestions for improving this edition. In addition to persons cited in the preface to the second edition, numerous colleagues and friends offered constructive criticism on portions of this book: Vernon Ahmadjian, Hartmut Arndt, Michael T. Arts, Arthur C. Benke, Riccardo de Bernardi, J. Marie Boavida, Nina Caraco, Robert Carlson, Perry Churchill, Daniel Conley, G. D. Cooke, Clifford Dahm, Anthony Davis, Stanley Dodson, Eric Espeland, Steven Francoeur, Walter Geller, Chris E. Gibson, Alex Huryn, Frank M. D'Itri, Eileen Jokinen, Klaus Jürgens, Mark Johnson, Susan S. Kilham, Joachim Kleiner, Reiner Koschel, Winfried Lampert, Richard C. Lathrop, Gene E. Likens, S. MacIntyre, Robert P. McIntosh, Jürgen Marxsen, William J. Matthews, R. Michael McKay, J. Melack, Robert E. Moeller, Walter T. Momot, Roland Psenner, Peter H. Rich, Eric E. Roden, Philippe Ross, Mark R. D. Seaward, Arthur J. Stewart, Ruben Sommaruga, Eugene Stoermer, Raymond G. Stross, Keller Suberkropp,

Nancy C. Tuchman, A. Vähätalo, Jack R. Vallentyne, Anthony E. Walsby, Amelia K. Ward, G. Milton Ward, William D. Williams, and Edward O. Wilson. Deborah Cook has patiently sustained my constant barrage of manuscript drafts, tabular materials, endless organization of thousands of references, and requests for help with figure preparations. Her uncompromising attention to detail has assisted me enormously in the preparation of this work. Mark Dedmon also assisted with preparation of many figures. My wife, Carol, continues to exude unending patience and understanding of the siren call of my limnological mistress. Portions of unpublished results cited in the text were supported by subventions of the National Science Foundation. Regardless of the assistance of the persons mentioned and many unnamed, the responsibility for the synthesis and interpretations rests with me.

VI. Search for Commonality, Not Only Differences
VII. Altered Perspectives
VIII. Summary

A basic feature of the earth is an abundance of water, which extends over 71% of its surface to an average depth of 3800 m. Over 99% of this immense hydrosphere is deposited in ocean depressions (Table 1-1). The relatively small amounts of water that occur in freshwater lakes and rivers belie their fundamental importance in the maintenance and survival of terrestrial life.

I. OUR FRESHWATER RESOURCES

Any analysis of inland water resources must address the preeminence of exponential human growth and utilization of fresh water. Humans must be recognized for what they are: an animal whose population growth is in an exponential phase. In spite of its absurdity, a belief prevails that the earth's supply of finite water resources can be increased constantly to meet exponential demands. Fresh waters are a finite resource that can be increased only slightly. For example, desalinization of ocean water requires tremendous energy expenditures for the treatment process and distribution of the product once obtained. That distribution is energetically prohibitive within only short distances from marine sources. Society as a whole, and many freshwater ecologists, have tended to ignore humans, and their use and misuse of fresh waters, as influential factors in the maintenance of lake and river ecosystems. Freshwater utilization is governed by the spiraling relationships in which supply is constantly expanded in response to growing demands. The unfortunate effect of essentially uncontrolled growth is that consumption increases in response to rising supply. Every increase in supply is met by a corresponding increase in consumption, because in contemporary society, voluntary control of consumption is ineffective unless economically advantageous.

II. DEMOTECHNIC GROWTH

The impending environmental problems are not only the result of population growth (Vallentyne, 1972, 1988). They result also from technological growth, both directly in the sense of increased per capita production and consumption and indirectly in that technology has furthered the growth of population and urbanization. This **demotechnic** concept of growth encompasses the combined effects of population in a biological sense as well as of production-consumption in a technological sense. The importance of the concept of demotechnic growth lies in its emphasis on both production and consumption. It describes the cycle in which degradation of the biosphere occurs as a result of utilization of the environment for production and consumption of technological products. Both processes lead to pollution of water resources. In demotechnic growth, attention is correctly focused on all aspects of technological growth, that is, the technological metabolism of humans.

TABLE 1-1 Water in the Biosphere

	Volume (thousands of km³)	*Percentage of total*	*Renewal time*
Oceans	1,370,000	97.61	3100 years†
Polar ice, glaciers	29,000	2.08	16,000 years
Ground water (actively exchanged)‡	4067	0.295	300 years
Freshwater lakes	126	0.009	1–100 years)§
Saline lakes	104	0.008	10–1000 years)§
Soil and subsoil moisture	67	0.005	280 days
Rivers	1.2	0.00009	12–20 days)¶
Atmospheric water vapor	14	0.0009	9 days

* Modified from Vallentyne (1972), after Kalinin and Bykov. *In:* The Environmental Future, London, Macmillan Publishers, Ltd. Reprinted by permission of Macmillan London and Basingstoke. Slightly different values are given by Shiklomanov (1990), but ratios are similar.

† Based on net evaporation from the oceans.

‡ Kalinin and Bykov (1969) estimated that the total ground water to a depth of 5 km in the Earth's crust amounts to 60×10^6 km³. This is much greater than the estimate by the U.S. Geological Survey of 8.3×10^6 km³ to a depth of 4 km. Only the volume of the upper, actively exchanged ground water is included here.

§ Renewal times for lakes vary directly with volume and mean depth and inversely with rate of discharge. The absolute range for saline lakes is from days to thousands of years.

¶ Twelve days for rivers with relatively small catchment areas of less than 100,000 km²; 20 days for major rivers that drain directly to the sea.

The demands that demotechnic growth have imposed upon freshwater resources are monumental. Although about 105,000 km³ of precipitation, the ultimate source of the freshwater supply, fall on the land surface per year, only about one-third of it (ca. 37,500 km³ year^{-1}) reaches the oceans as river discharge (Vallentyne, 1972). About two-thirds of the annual water supply is returned to the atmosphere by evaporation and plant transpiration. If the potential water supply of 37,500 km³ year^{-1} were divided evenly among some 5.5 billion humans now existing on Earth (2000), each person would have potentially 6800 m³ year^{-1} or 18,680 liters day^{-1}. These values would be halved at a projected population level of 10 billion humans by approximately the year 2050. Even though these quantities seem large in comparison to the human physiological requirement of 2 liters person^{-1} day^{-1}, they are insufficient in view of modern technological demands. Domestic consumption averages 250 liters person^{-1} day^{-1}, the average industrial consumption is 1500 liters person^{-1} day^{-1} in developed countries, and agriculture uses up to several thousand liters person^{-1} day^{-1} in countries with hot, dry climates (Vallentyne, 1972).

Historical patterns of environmental resource utilization have resulted in a series of crises, particularly among populations of developed countries (Fig. 1-1). As the human population increases, the severity of the crises increases. Particular resource-related problems are confronted with various actions by humans (Francko and Wetzel, 1983). Most of these actions are therapeutic adaptations and adjustments rather than true corrective, prophylactic measures. As a result, stress levels increase. The margin between coping successfully with environmental resource limitations and disastrous situations of overexploitation decreases continually. Stability becomes increasingly tenuous.

Vagaries in climate (e.g., Bryson and Murray, 1977) are superimposed upon the immediate demotechnic pressures of resource utilization. Fluctuations in climate have resulted in catastrophic crises both in the availability of resources and effective resource utilization. Rapid climatic changes affect not only the availability of adequate food resources but availability of fresh water as well; the two are inexorably coupled. Although major climatic changes are difficult to predict, such changes are certain and, on the

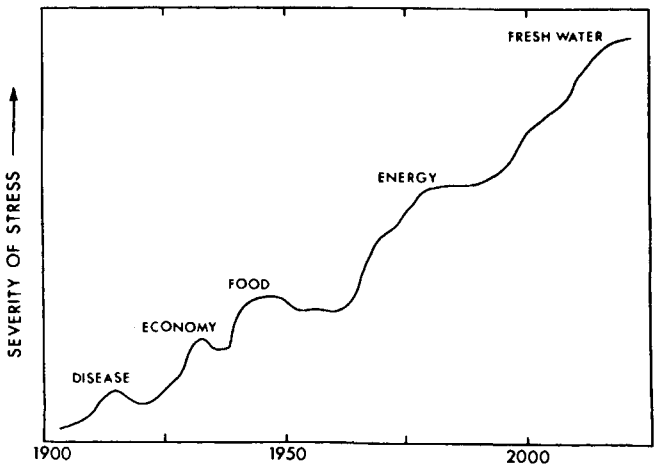

FIGURE 1-1 Stresses of increasing severity imposed upon human populations of developed countries resulting largely from excessive demotechnic growth. (Modified from Wetzel, 1978.)

basis of long-term trends, significant changes are imminent (Silver and DeFries, 1990; Schlesinger, 1991; Firth and Fisher, 1992; Cushing, 1997). In order to cope effectively with these natural and induced climatic changes, we must maintain sufficient flexibility in our use of freshwater resources and an adequate margin below the maximum carrying capacity.

III. HUMAN IMPACT ON FRESHWATER ECOSYSTEMS

The real freshwater supply is in reality much smaller than the potential total because of many factors. First, rainfall is not evenly distributed over land surfaces, and humans themselves are not distributed over land in proportion to water availability. This disparity results in a great expense of resources and energy for distribution systems to move water from places of water abundance to places where it is inadequate to support human activities. Second, total consumption has increased exponentially with demotechnic growth. Expansion of distribution systems to areas of low precipitation, such as for irrigation of semiarid regions, results in disproportionately high use of water because of very high losses by evapotranspiration. Third, potentially the most serious factor stemming from demotechnic growth is the severe degradation from contaminants of water quality. The effect is a severe reduction of the water supply available for other purposes.

Fresh waters of the world are collectively experiencing markedly accelerating rates of qualitative and quantitative degradation (Wetzel, 1992). Certain societies can cope, at least temporarily, with pollution and availability constraints and can even reduce freshwater degradation. In most of the world, however, human population growth continues without significant reduction of rates. Until human growth and consumption is stabilized, one hopes by the mid-twenty-first century, either by intelligence or catastrophes, further losses and degradation of fresh waters can be controlled only partially on a global basis. Control and reversal of degradation requires a proper economic and social valuation of fresh waters. With proper valuation, methods for effective utilization of existing, finite supplies can be applied to agricultural, industrial, and residential uses.

Fresh waters still serve purposes other than water supply, such as recreation, transportation systems, aesthetics, and others. However, the demands of exponential demotechnic growth clearly receive total precedence over uses of fresh waters for other purposes. The most fundamental laws of resource utilization may be recognized by most agencies and industries, but they are not being implemented significantly. The fuel "crisis" of 1973–1974, one of many consequences of demotechnic growth, demonstrated prevailing human behavioral patterns of virtually ignoring all diagnoses or prognostications of impending imbalances. When the crisis finally occurs, the public response is not to seek corrective measures that address the root of the problem, such as stabilization of population and technological growth, but rather to expand the distribution system to acquire more remote sources of energy. Only when disaster is imminent, when risk of survival of a large segment of the population is glaringly obvious to the majority, does a unified global response occur to save humankind from itself.

The remarks above, although pessimistic, accurately assess existing patterns of utilization of our water resources. It is clear that demotechnic growth will continue to impose increasing demands upon freshwater supplies either until inefficient utilization creates a disastrous situation threatening the survival of a major segment of the human race or until the expenditures of energy needed to obtain water exceed tolerable operational levels (Wetzel, 1992). Looking back at the repetitious history of responses to impending environmental disasters, we can be optimistic about the future only until such time as our understanding of the operation of the biosphere, and our knowledge of freshwater ecosystems in particular, is adequate to allow us to recognize the point of irreversibility (Bilsky, 1980; Francko and Wetzel, 1983; Wetzel, 1992). As one reflects on the progress that has been made in limnology since its inception a century ago, it becomes apparent that the time available for understanding fresh waters is disconcertingly limited. We need to intensify study of and time to understand freshwater ecosystems sufficiently to judge their resiliency and capacity for change in response to exponential demotechnic utilization and loading of contaminants. Existing understanding of freshwater ecosystems must be extended to a greater percentage of the population being educated so that this information can be effectively infused into the population at all levels.

It is of the utmost importance, therefore, that we understand the structure and function of freshwater ecosystems. Humans are a component of these ecosystems, and their effects on them will increase markedly until demotechnic growth is stabilized. Emotionalism and alarmist reactions to the momentum of exploitation of the finite biosphere by the technological system accomplish little and, as has been demonstrated repeatedly, are often antagonistic to improvement. Strict conservation and isolation of resource parcels, in the belief that such areas are exempt from technological alterations of the atmosphere and water supply, are naive

and likewise contribute little to solution of the overall problem.

Understanding the metabolic responses of aquatic ecosystems is essential in order to confront and offset the effects of these alterations and in order to achieve maximum, effective management of freshwater resources. All waters, of course, cannot be managed directly. Rather, an integration of human growth and utilization with the metabolism of fresh waters is required to minimize detrimental changes. A well-documented effect of human impact upon aquatic ecosystems is *eutrophication,* a multifaceted term associated with increased productivity, simplification of biotic communities, and a reduction in the ability of the metabolism of the organisms to adapt to the imposed loading of nutrients. These conditions lead to reduced stability of the ecosystem. In this condition of eutrophication, excessive inputs often exceed the capacity of the ecosystem to be balanced. In reality, however, the ecosystems are out of equilibrium only with respect to the freshwater chemical and biotic characteristics that are desired by humans for specific purposes. In order to have any hope of effectively integrating humans as a component of aquatic ecosystems, and of monitoring their utilization of these resources, it is mandatory that we comprehend in some detail the functional properties of fresh waters. Only then can we evaluate and predict, with reasonable certainty, the influence human activities will have on the metabolic characteristics of these ecosystems.

IV. THE STUDY OF LIMNOLOGY

Limnology can be defined in several ways, but it is important to recognize that the discipline involves the study of both freshwater and saline inland waters. As noted in Table 1-1 and discussed in detail throughout this synthesis, some 45% of the inland surface waters of the land masses of the world are saline. Although saline lakes are of less practical importance to human activities, they nonetheless are major constituents of our biosphere with a number of unique characteristics (Hammer, 1986; Williams, 1996). The following definitions emphasize several important distinctions:

***Limnology** is the study of the structural and functional interrelationships of organisms of inland waters as they are affected by their dynamic physical, chemical, and biotic environments.*

***Freshwater ecology** is the study of the structural and functional interrelationships of organisms of fresh waters as they are affected by their dynamic physical, chemical, and biotic environments.* Saline waters (e.g., $>0.3‰$ or 3 g/liter^{-1}) are excluded from this definition.

***Freshwater biology** is the study of the biological characteristics and interactions of organisms of fresh waters.* This study is largely restricted to the organisms themselves, such as their biology, life histories, populations, or, occasionally, communities.

It is important to emphasize that **limnology** correctly encompasses an integration of physical, chemical, and biological components of inland aquatic ecosystems of the drainage basin, movements of water through the drainage basins, and biogeochemical changes that occur en route, and within standing (**lentic**) waters. The lake ecosystem is a system that is intimately coupled with the land surrounding it in its drainage area and its running (lotic) waters that transport, and metabolize en route, components of the land to the lake. The analyses and syntheses of topics that follow address standing waters, as in previous editions, but have been expanded to include comparative syntheses of reservoir and stream ecosystems. The limnology of running waters was reviewed masterfully by Hynes (1970), but much new information and understanding has emerged since then. I summarize characteristics of running waters and compare them to those of standing water in this edition. Readers will recognize that this running water limnology is a true subdiscipline of limnology that is correctly receiving well over half of the research attention at the present time.

Many lakes of the world are of glacial origins. Because most limnological research has been concentrated in northern temperate regions, a strong bias occurs in current instruction of limnology by the disproportionate knowledge of natural temperate lakes. Most humans reside in nonglaciated regions in which reservoir and river ecosystems are the predominant surface waters. Understanding of tropical and warm water lake and reservoir ecosystems is increasing rapidly, and I have attempted to integrate their structural and functional differences and similarities into the evaluations of temperate inland waters. Furthermore, the number of human-made reservoirs has increased to the point where very few river systems are not impounded to some extent. Although reservoirs can possess many characteristics that differ from those of lakes, a firm grasp of the dynamics of natural lakes permits a relatively easy transition to an understanding of the more variable and individual characteristics of reservoir ecosystems. Underlying all of these ecosystems are basic metabolic similarities. In this treatment of inland aquatic ecosystems, I attempt to introduce fundamental, functional similarities without becoming mired in the plethora of individual detail.

Minimal background detail is required to appreciate even the rudiments of the discipline of limnology. The

selection of material and examples to include in such a synthesis is difficult not only because of individual biases but because there is incomplete understanding of many subjects. I hope that, in the end, the examples presented here are balanced and provide a basic overview of contemporary comparative limnology and a basic minimal understanding of limnology and freshwater ecology at the undergraduate level. A serious major in limnology will realize that he or she needs much greater depth of understanding to comprehend the subject thoroughly. Many of the reference works cited, such as G. E. Hutchinson's classical, perceptive treatise (1957, 1967, 1975, 1993), are only initial introductory summaries of specialized subjects. In the ensuing discussions I often point out forefronts of contemporary limnology as well as gaps in need of intensive investigation.

V. SCIENTIFIC APPROACHES

Hegel (1807) stated, "*Das Wahre ist das Ganze*" (The truth is the whole). Holism alone, however, is inadequate for a comprehensive understanding of limnology. Integration of our knowledge about the individual operational components and environmental factors that regulate the metabolism and productivity of aquatic ecosystems is fundamental. Other treatments of limnology have been deficient in this respect and almost totally directed toward the open-water pelagic communities of standing waters. Other major *operational* components of aquatic ecosystems are largely neglected (i.e., microbial decomposition of dissolved and particulate detritus; the intensive metabolism and biogeochemical cycling that occurs in the littoral zone and adjacent wetlands; metabolism in the sediments; influxes of nutrients and organic matter from outside the lake; the rapidity of nutrient cycling, particularly associated with surfaces). An integrated study of the dynamics of all components of inland aquatic ecosystems requires major alterations in former perspectives on limnology.

Understanding of the causal mechanisms operating in and controlling our natural world is a primary objective in any science, and it is certainly true in limnology because of its premier position for the well-being of humankind. The greater our understanding is, the higher is the probability that we can predict with reasonable accuracy patterns of events within aquatic ecosystems in response to human manipulations and disturbances. How we acquire that understanding is accomplished with a combination of analytical techniques.

1. *Descriptive observations of patterns of biological processes and communities in relation to dynamic patterns of environmental properties.* Such descriptive empirical analyses allow the generation of a hypothesis, that is, a *conceptual* predictive "model" of relationships among observed patterns. These relationships may be compared statistically with correlations of the strength of co-occurrence of two variables. Such regressional correlations are only an extension of descriptions and indicate relationships within a certain statistical probability. The correlations only generate a hypothesis. Correlations do not show the accuracy of relationships, even though the probability of the relationship of patterns may be high, and they do not provide any direct evidence of causality. Comparative correlations can suggest relationships and pattern, but they cannot evaluate or test general patterns of cause and effect. Positive correlations can narrow the search for controlling factors of observed patterns, but spurious and erroneous positive correlations can also obfuscate the analyses.

2. *Experimental examination and evaluation of quantitative response data to selected disturbances imposed on the system.* Great insight about controlling parameters can be gained from experimental manipulation or imposing known, controlled disturbances of specific environmental or community parameters on specific components of the community or ecosystem. Quantitative response data include changes in growth, productivity, reproduction, competition, metabolic adaptations, and other processes of populations and communities as ecosystem components are exposed to the manipulation or disturbance and compared to components not exposed to the treatment.

3. *Application of quantitative predictive models based on experimentally established, not random, governing variables.* Models allow expansion of *experimentally understood* quantitative relationships, that is, one can insert hypothetical data of various parameters and theoretically estimate system responses to these variables. Models cannot predict anything that was not built into them from the beginning (Lehman, 1986). Even "counterintuitive results" are simply unrecognized consequences of initial assumptions. Models are a tool. Most models greatly overestimate understanding and falsely and naively generate confidence.

Some hypotheses about cause-and-effect regulators of biological phenomena cannot be tested experimentally because the ecosystems cannot be replicated or perturbed. For example, the effects of increased carbon dioxide (CO_2) concentrations in the atmosphere or reductions in ozone concentrations in the stratosphere cannot be replicated at the global scale. However, the effects of increased CO_2 or ozone can be tested experimentally very rigorously at smaller species or

community scales, from which strong inferences of cause and effect can be coupled to observations of community changes in biological productivity, diversity, and other factors. These observational comparisons, however, are still correlations of relationships of certain probability, not demonstrations of regulating mechanisms. Although not ideal, such correlations can be highly instructive and useful in the management of ecosystems and aquatic resources even though the underlying causal mechanisms are unknown.

In the ensuing summaries and syntheses of contemporary understanding of the limnology of lakes, reservoirs, and streams, much of the information is presented in a comparative manner based on many, often hundreds, of observations and measurements. Patterns of differences and similarities emerge among the diverse ecosystems. Contemporary comprehension of why inland aquatic ecosystems operate as they do has emanated from experimentally controlled disturbances and manipulations to parts of or to whole ecosystems. These experimental approaches require integration of physiological and biochemical understanding with observed population and community responses to experimental and natural changes (Wetzel, 2000a).

VI. SEARCH FOR COMMONALITY, NOT ONLY DIFFERENCES

Throughout the development of our understanding of limnology, emphasis has been on the differences among lakes and rivers, physical and chemical characteristics among different waters of various geomorphologic regions, and the diversity of different biota and their growth characteristics. That differentiation among lakes and rivers and their physical, chemical, and biological properties was the impetus underlying the half century of lake classification studies. Subsequent comparative analyses attempted to demonstrate functional relationships among different groups but again were less successful than hoped because of the inherent limitations of correlation analyses. Progress has now extended to detailed examination of physiological, biochemical, and molecular variations among biota, commonly coupling these differences to variations in the environmental habitats in which the organisms reside. Some of this continued differentiation of species at the molecular level is most important from evolutionary, biogeographic, and systematic viewpoints, particularly in relation to biodiversity and losses of biodiversity.

Variability is enormous and often difficult to fathom because of the dynamic properties of metabolism, growth, and reproductive capacities of organisms as they respond to the bewildering array of dynamic environmental factors influencing growth and development. Modeling at the present level of understanding is unable to cope with so many nonlinear variables that are changing rapidly. Although reductionism is essential to provide information on the properties involved, regulatory generality prevails across the individual species and diversity of processes (Wetzel, 2000a). Regulation of quantitative rates of metabolism among the different communities is where generality emerges. Consolidation of quantitative process rates of metabolism, energy fluxes, and material fluxes is where commonality emerges among highly disparate and complex interacting parameters within ecosystems. That understanding is essential in terms of both theoretical relationships and in the management of controlling the effects of disturbances.

VII. ALTERED PERSPECTIVES

Fresh waters are biological systems, and biogeochemical processes control the quality of fresh waters. As will be evident in the following pages, we have a reasonable understanding of the "anatomy," that is, the structure, of inland waters; it is essential that we now achieve an understanding of the "physiology," that is, the functional metabolism, of fresh waters and controlling factors of the regulation of that physiology. That understanding is essential for effective management and addressing practical problems of water quality and how water quality is influenced by human-induced changes.

For decades, the operation of aquatic ecosystems has been treated mostly in terms of the higher trophic levels and couplings among largely the animal biota. Many fundamentals of modern ecology are founded on the superbly detailed study of interactions among animals and their supporting resources. This perspective is quite inadequate, however, as we find it essential to evaluate entire ecosystems, not just a small portion of them of potential interest to human culture, for effective management and utilization of the whole. Primary areas of that integrative perspective include: (a) Emphasis on *rates of metabolism and regulation of rates of biogeochemical cycling by that metabolism.* It is essential to understand how species interactions alter rates of energetic flows and storage and of biogeochemical cycling, rather than maintain the prevailing focus on how feeding relationships influence individual population or community growth and reproduction. Of course the processes are related and coupled, but present imbalances of understanding are conspicuous. (b) It will be apparent that *material and energy flows and cycling are regulated largely at the biochemical and*

microbial levels. Although many voids exist in understanding at these latter levels, their roles are dominant at the ecosystem level. The ensuing syntheses represent an initial synopsis.

VIII. SUMMARY

1. Over 99% of the immense amount of water of the biosphere occurs in the oceans and polar ice deposits. The turnover time of this water is very long (i.e., the rate of renewal is very slow).
2. Much of the remaining water occurs in inland waters, where renewal times are much shorter than in marine systems (Table 1-1).
3. Finite water resources are being exploited and degraded at an accelerating rate by the activities of humankind.
   a. Demands upon surface and groundwater supplies result from both population growth and the expanding utilization and consumption because of technological growth. This demotechnic growth results in expanded utilization of freshwater and other finite environmental resources. Biospheric degradation results from both biological population expansion and growth of technological production and consumption.
   b. Unless the demands of exponential demotechnic growth upon fresh waters are rapidly controlled, a freshwater crisis at a global level is imminent. The severity of the freshwater crisis will exceed that of past and contemporary resource-utilization problems. The problems are acutely apparent in many parts of the world and will accentuate in the twenty-first century.
4. *Limnology* is the study of the structural and functional relationships and productivity of organisms of inland aquatic ecosystems as they are regulated by the dynamics of their physical, chemical, and biotic environments.
5. Examination of limnological understanding can be approached by an examination of differences in physical and biotic properties among different lake, reservoir, and river ecosystems. However, among the array of dynamic environmental factors influencing metabolism, growth, and reproductive capacities of organisms, functional commonality is found amidst process rates and controls of metabolism, energy fluxes, and material cycling.

2 WATER AS A SUBSTANCE

I. The Characteristics of Water

  E. Viscosity–Density Relationships
  F. Surface Tension
II. Summary

I. THE CHARACTERISTICS OF WATER

Water is the essence of life on earth and totally dominates the chemical composition of all organisms. The ubiquity of water in biota, as the fulcrum of biochemical metabolism, rests on its unique physical and chemical properties.

The characteristics of water regulate lake metabolism. The unique thermal–density properties, high specific heat, and liquid–solid characteristics of water allow the formation of a stratified environment that controls extensively the chemical and biotic properties of lakes. Water provides a tempered milieu in which extreme fluctuations in water availability and temperatures are ameliorated relative to conditions faced by biota in aerial life. Coupled with a relatively high degree of viscosity, these characteristics have enabled biota to develop many adaptations that improve sustained productivity.

A. Molecular Structure and Properties

The unique properties of water center upon its atomic structure and bonding and the unusual association of water molecules in solid, liquid, and gaseous phases. In equilibrium, the nuclei of a water molecule form an isosceles triangle, with a slightly obtuse bond angle of 104.5° at the oxygen nucleus (Eisenberg and Kauzmann, 1969). The bond length from the center of the oxygen atom to that of each hydrogen atom is 0.96×10^{-8} cm. The nuclei of the molecules are in a continual state of vibration. As the molecule resonates, an electrical dipole moment occurs, such that a complex wave function results in a valence electron density pattern in which electron density is highest near the atoms and along the bonds (Fig. 2-1). The electronic charge of the molecule is not restricted to the planar configuration depicted, but is distributed in multiple directions.

Although most (ca. 56%) water molecules have balanced valances, excitation and ionization do occur. The most common ionized state is characterized by removal of one of the hydrogen atoms, which is charged positively and is functioning essentially as a proton. Higher ionization potentials (energy needed to remove electrons from the molecule) are needed to reach further ionization states of water and occur less frequently. The weak coulombic characteristics of the bonding of hydrogen atoms to the weakly electronegative oxygen atom result in both ionized and covalent states that simultaneously maintain the integrity of water. Water is nearly the only known compound that possesses these characteristics.

The density properties of water that are so germane to limnology and life in water result from the aggregation and bonding characteristics of the water molecules. It is instructive to look first at the structure of ice, whose physical properties are understood better than those of liquid water. Every oxygen atom is at the center of a tetrahedron formed by four oxygen atoms, each about 2.76×10^{-8} cm distant (Eisenberg and Kauzmann, 1969; Horne, 1972). Every water molecule

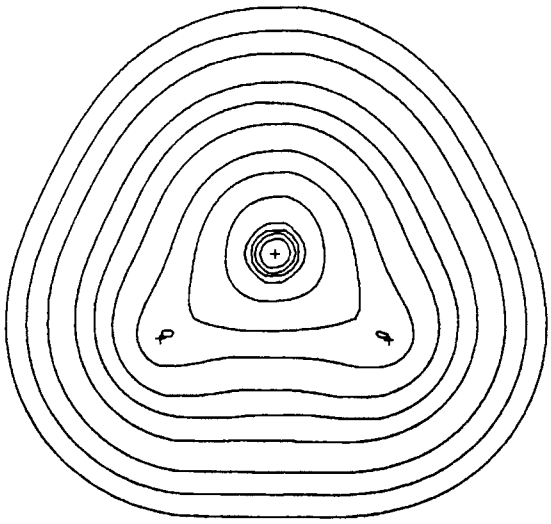

FIGURE 2-1 Contour map of the electronic charge distribution of the water molecule in the plane of the nuclei (positions indicated by crosses). Contours increase in value of atomic units (au) (1 au = 67 e^- per nm^3) from the outermost contour in steps of 2×10^n, 4×10^n, 8×10^n. The smallest contour value is 0.002, with n increasing in steps of unity to yield a maximum value of 20. (Unpublished figure courtesy of Dr. R. F. W. Bader, Department of Chemistry, McMaster University.)

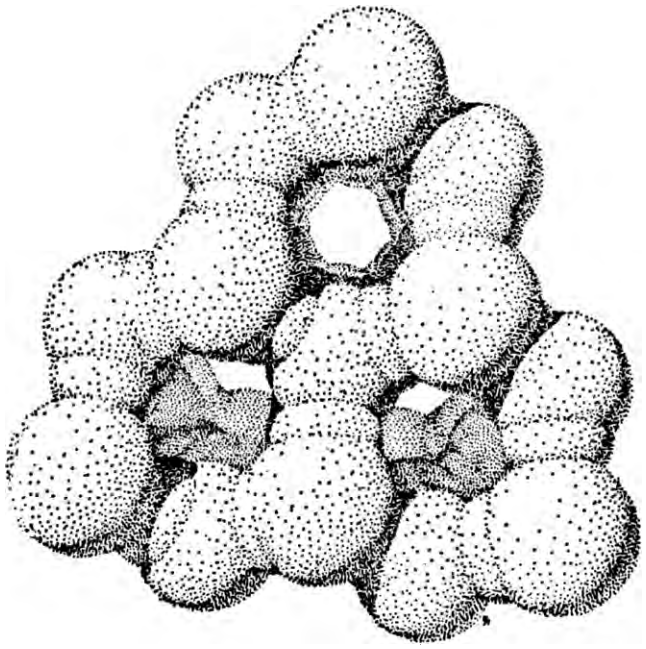

FIGURE 2-2 A diagrammatic representation of an ice crystal showing the van der Waals radii of the atoms and open voids between the aggregated molecules. (From Pimental, G. C., and McClellan, A. L.: *The Hydrogen Bond.* San Francisco, W. H. Freeman and Co., copyright © 1960.)

is hydrogen-bonded to its four nearest neighbors; its O—H bonds are directed toward lone pairs of electrons on two of these adjacent molecules and form two O—H—O hydrogen bonds. In turn, each of its lone pairs is directed toward an O—H bond on one of the other adjacent molecules and forms two O—H—O hydrogen bonds. This arrangement leads to an open lattice in which intermolecular cohesion is great (Fig. 2-2). This structure results in both parallel and perpendicular voids among the molecules and creates an open tetrahedral structure that permits ice to float upon liquid water.

Molecules in liquid water near 0°C experience about 10^{11} to 10^{12} reorientational and translational movements per second, whereas ice molecules near 0°C experience only about 10^5 to 10^6 movements per second. Increasing the temperature of water increases the rate of reorientations and molecular displacements and results in decreased viscosity, decreased molecular relaxation times, and increased rates of self-diffusion. By virtue of their dipolar nature, water molecules interact to form quasi-stable polymers.

We have viewed here water molecules as diffusionally averaged structures both in vibrational time and in space between molecules. However, variations in temperature change the intermolecular distances. Thermal increases result in increased agitation of the molecules, which distorts and breaks down the hydrogen-bonded networks. As the ice melts, increased bond dislocation and rupture occur, which disrupt and fill in the open spaces of the ice lattice structure. The result is an increase in density, and this effect predominates and reaches a maximum at 4°C. As water is heated above 4°C, intermolecular vibrations increase in amplitude and increase interatomic distances. The result is expansion of the liquid and decreased density. It is a characteristic of water that minimum volume, hence maximum density of water, occurs at 3.98°C. At this point, competition between the negative configurational contribution of hydrogen bonding and its positive vibrational contribution is maximized.

B. Isotopic Content of Water

Known isotopes of hydrogen are ^1H, ^2H or D (deuterium), and ^3H (tritium). Tritium is radioactive, with a half-life of 12.5 years, sufficiently short that after its decay to ^3He, most of which is lost from the atmosphere into space, concentrations of tritium in uncontaminated natural water are very low (approximately 1 ^3H atom per 10^{18} ^1H atoms) and do not accumulate. Six isotopes of oxygen are known: ^{14}O, ^{15}O, ^{16}O, ^{17}O, ^{18}O, and ^{19}O. The isotopes ^{14}O, ^{15}O, and ^{19}O are

radioactive but are short-lived and do not occur significantly in natural water. The precise isotopic content of natural water depends on the origin of the sample but, within limits of variation, the abundances of $H_2{}^{18}O$, $H_2{}^{17}O$, and $HD^{16}O$ are 0.20, 0.04, and 0.03 mole percent, respectively (Eisenberg and Kauzmann, 1969). Other isotopic combinations are exceedingly rare in natural water (Hutchinson, 1957).

Changes in the ratios of these isotopes in compounds and in remains of organisms formed within a lake over geological time permit an estimation of paleotemperatures. The technique is based on the temperature dependence of fractionation of the oxygen isotopes in the carbon dioxide–water–carbonate system (Stuiver, 1968). During slow precipitation of the carbonate, the temperature of the solution is reflected in the ratio of ^{18}O to ^{16}O in the carbonates of sediments and mollusks. The ratio of oxygen isotopes in the precipitated carbonates depends not only on the temperature but also on the ratio of ^{18}O to ^{16}O isotopes in the water in which carbonate is formed. The measured difference in the ratio of ^{18}O to ^{16}O isotopes between a carbonate fossil and a contemporaneous sample is the result of changes in both temperature and composition of water isotopes. Before paleotemperature determinations can be made, an estimate of the changes in ratio of oxygen isotopes of the water is needed. This measurement is more difficult to make in lakes, where variations over time are greater than in the oceans. However, estimates can be made with reasonable precision.

C. Specific Heat

Specific heat[1] of liquid water is very high (1.0) and is exceeded only by a few substances, such as liquid ammonia (1.23), liquid hydrogen (3.4), and lithium at high temperatures. Other substances of the biosphere, such as many rocks, have much lower specific heats (approximately 0.2). The high specific heat of water, as well as a high latent heat of evaporation (see below), is a function of the relatively large amounts of heat energy required to disrupt the hydrogen bonding of liquid water molecules.

These heat-requiring and heat-retaining properties of water provide a much more stable environment than is found in terrestrial situations. Fluctuations in water temperature occur very gradually. Daily and seasonal extremes in temperature are small in comparison to those of aerial habitats. The high specific heat of water can also have profound effects on climatic conditions of adjacent air and land masses. This ***thermal inertia*** of the hydrosphere (Hutchinson, 1957) occurs on both large and small scales, in relation to the volume of water bodies. Examples are many. The warm Gulf Stream currents of the Atlantic Ocean increase the prevailing temperatures and improve the climate of Western Europe. The prevailing air movements across the Laurentian Great Lakes moderate the climate of Michigan and other states adjacent to and east of the lakes (Leighly, 1942). Milder winters with higher precipitation rates are found in these areas than in the interiors of continents, because the water masses cool and yield heat to the air more slowly than do land masses. Similarly, areas adjacent to large water masses experience moist, cool summer periods. Fall fogs are common over and adjacent to lakes and large rivers, where water vapor from evaporation of the warm lake or river water condenses and stagnates in the cold overlying air. That the lake or river "is steaming" is the description of this phenomenon in common parlance.

The specific heat (thermal capacity) of ice below 0°C is about half (0.5 g^{-1} $°C^{-1}$) that of water and decreases progressively at temperatures below 0°C. The amount of heat required, however, to change ice to liquid water is large (***latent heat of melting*** = 79.72 cal g^{-1}) and is very much larger for disruption of hydrogen bonding in evaporation of water (***latent heat of evaporation*** = 540 cal g^{-1}) or for direct sublimation of ice to water vapor (***latent heat of sublimation*** = 679 cal g^{-1}). Conversely but similarly, a large amount of heat must be lost for the fusion of molecules of 0°C water to ice (***latent heat of fusion*** = 79.72 cal g^{-1}). Because of these properties, large energy inputs are required to melt ice in the spring, and large energy losses are required in order to form ice cover in the winter.

D. Density Relationships

The entire physical and chemical dynamics of lakes and reservoirs and resultant metabolism within them are regulated to a very great extent by differences in density. Throughout the remaining chapters of this book, we will refer repeatedly to the fundamental importance of the unique density properties of water.

The density or specific gravity of pure ice at 0°C is 0.9168 g ml^{-1}, about 8.5% lighter than that of liquid water at 0°C (0.99987). The density of water increases to a maximum of 1.0000 at 3.98°C, beyond which molecular expansion and decreasing density occur at a progressively increasing rate (Fig. 2-3). The density differences are small but highly significant. It is important to examine the difference in density between water at a given temperature and water at a temperature 1°C lower, referred to as the ***density difference per degree lowering*** (Vallentyne, 1957). The magnitudes of this

[1] Specific heat is the amount of heat in calories that is required to raise the temperature 1°C of 1 g mass of a substance.

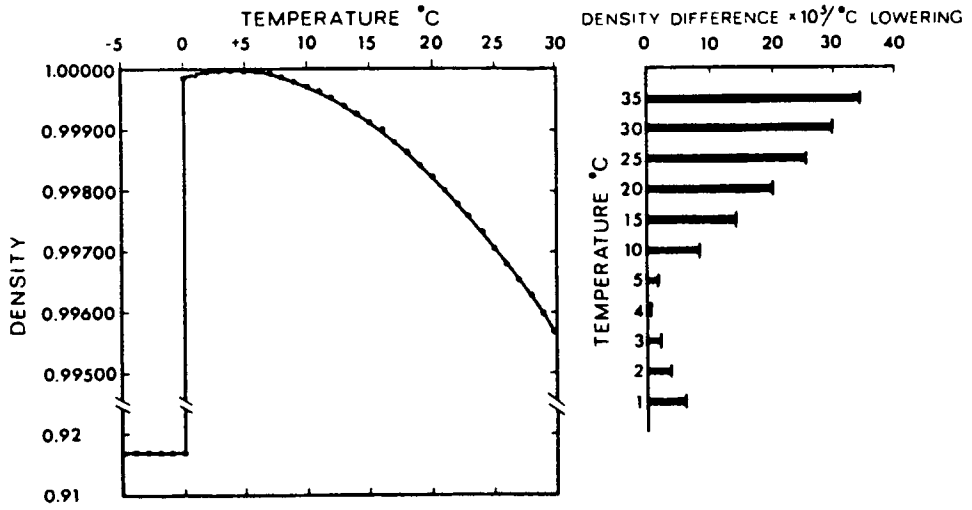

FIGURE 2-3 Density (g ml^{-1}) as a function of temperature for distilled water at 1 atm. The density difference per °C lowering is shown in the right-hand portion of the figure at various temperatures. (Modified from Vallentyne, 1957.)

density difference for water of different temperatures are shown on the right side of Figure 2-3. The density difference per degree lowering increases markedly as the temperature goes above or below 4°C. Physical work is required to mix fluids of differing density, for example, when mixing cream into milk, and the amount of energy input required is proportional to the difference in density. The amount of work required to mix layered water masses between 29 and 30°C is 40 times, and between 24 and 25°C 30 times, that required for the same masses of water between 4 and 5°C.

Density also increases with increasing concentrations of dissolved salts in an approximately linear fashion (Table 2-1). The salinity of most inland waters is within a range of 0.01 and 1.0 g $liter^{-1}$, and usually between 0.1 and 0.5 g $liter^{-1}$. Inorganic salinity of highly saline lakes can commonly exceeds 60 g $liter^{-1}$ and exhibits great seasonal variations (e.g., Rawson and Moore, 1944; International Association of Limnology, 1959; Wetzel, 1964; Eugster and Hardie, 1978; Hammer, 1990; Williams, 1996). In most lakes, however, salinity is very low and varies less than 0.1 g $liter^{-1}$ spatially and seasonally. Salinity-induced variations in density may be small, but they cannot be ignored. Under certain conditions of lake stratification, inorganic salts can accumulate temporarily or permanently (cf. Chap. 6).

TABLE 2-1 Approximate Changes in the Density (g ml^{-1}) of Water with Salt Content

Salinity (parts per thousand, ‰)	*Density (at 4°C)*
0	1.00000
1	1.00085
2	1.00169
3	1.00251
10	1.00818
35 (mean, seawater)	1.02822

After Ruttner (1963).

Salinity also decreases the temperature of maximum density of water at a rate of approximately 0.2°C g^{-1} $liter^{-1}$(‰) increase. The temperature of maximum density of sea water (mean 35 g $liter^{-1}$) is −3.52°C, which does not occur at surface pressures and is below the freezing point (−1.91°C). In most fresh waters, however, changes in the maximum density of water from salinity are very small.

Hydrostatic pressure can be sufficient to compress water and thereby lower the temperature of maximum density. Pressure increases 1 atmosphere per 10 m of depth. The temperature of maximum density decreases about 0.1°C per 100 m of depth (Strøm, 1945). In very deep lakes, temperatures below 4°C are found to be partially, but not totally, related to the relatively high pressures encountered at great depth (Eklund, 1963, 1965; Johnson, 1964, 1966; Bjerke *et al.*, 1979).

E. Viscosity–Density Relationships

The density of water is 775 times greater than that of air at standard temperature and pressure (0°C, 760 mm Hg). The high density of water makes aquatic organisms relatively buoyant against gravitational pull and consequently reduces the amount of energy that an organism must expend to support or maintain its

position in the water. Reduction of supporting tissue has occurred in many freshwater animals, particularly among the lower invertebrates, but these adaptations are particularly conspicuous among aquatic vascular plants. Truly submersed angiosperms are good examples; these plants are almost totally limited to fresh waters and have immigrated and adapted to aquatic conditions relatively recently. Modifications have led to marked reductions in vascular tissues, particularly by reduction of the extent of lignification of the xylem and supporting elements, and most of the vascular strands are condensed into a weakly developed central cylinder. Supportive tissues of these hydrophytes develop strongly only in those plants or plant parts that are adapted to aerial existence as surface-floating or emergent forms.

Water viscosity decreases as temperature increases. Water viscosity doubles as the temperature is lowered from 25 to 0°C. The viscosity of water offers approximately 100 times more frictional resistance to a moving organism or particle than air does and is dependent upon the surface exposure area, the speed, and the temperature and chemical composition of the fluid. As will be discussed further on, organisms with locomotion must expend considerable energy to overcome changes in viscosity. Sinking rates and distribution of passive organisms, such as planktonic algae or sedimenting particles, are influenced by density-related changes in viscosity.

F. Surface Tension

The quasi-polymeric bonding properties of liquid water molecules discussed earlier are disturbed at the interface with air. At the interface plane, the molecular attractions are unbalanced and exert an inward adhesion to the liquid phase. The result is an interface surface or film under tension. The surface tension at the air–water interface of pure water is higher than that for any other liquid except mercury. Surface tension decreases with increasing temperature and increases slightly with dissolved salts (Table 2-2).

The surface tension of water is reduced markedly by the addition of dissolved organic compounds. This phenomenon is seen in aquatic habitats wherever dissolved organic matter concentrates (Table 2-2). For example, surface tensions of relatively pristine waters containing few microorganisms differ little from those of distilled water. Bog lakes, which are heavily stained with dissolved organic compounds, exhibit depressions in surface tensions of 6 to 7 dynes cm^{-1} (range 0–20). Where growth of floating algae or of higher aquatic plants is particularly great, the surface tension is depressed by about 20 dynes cm^{-1}. Later on, we will demonstrate that concentrations of dissolved organic compounds are high in more productive waters. Moreover, natural populations of algae and submersed angiosperms secrete large quantities of organic compounds during active photosynthesis, as well as during senescence and lysis. The effects of these organic compounds on surface tension can vary with the dominance of photosynthetic organisms. For example, extracellular organic compounds released from green algae and cyanobacteria lowered surface tensions to a greater extent than those from diatoms (Nägeli and Schanz, 1991). Organic pollutants introduced into fresh waters can also markedly lower surface tensions (Jarvis, 1967; Jarvis *et al.*, 1967).

TABLE 2-2 Surface Tension of Water with Changes in Temperature and Its Depression in Natural Waters under Various Conditions

Temp. (°C)	*Water tension (dynes cm^{-1})*	*Condition*	*Depression of surface tension range (dynes cm^{-1})*
Pure water			
0	75.6	Oligotrophic lakes	0–2
5	74.9	Eutrophic lakes	0–20
10	74.4	Bog lakes	0–20
15	73.5	Lake water with foam	2–9
20	72.7	Near floating-leaved angiosperms	5–20
25	72.0	Near submersed angiosperms	1–2
30	71.2	During a cyanobacterial bloom	0–20
35	70.4	Open sea	< 1
40	69.6	Plymouth Sound, near muddy beach	6–20
		Harbor, heavy boat traffic	$15 \geq 20$
Sea water			
ca. 5	75.0		

From data of Adam (1937), Hardman (1941), and Goldacre (1949).

The air–water interface forms a special habitat for organisms adapted to living in or on the surface film. This community is collectively referred to as ***neuston*** and will be discussed in some detail further on (Ch. 8). The surface tension is sufficient to serve as a supporting surface for many organisms of considerable size (e.g., gyrinid and other beetles) and can destroy others, such as cladoceran microcrustacea, that happen to become caught in the interface through wave action and cannot reenter their normal submersed habitat.

II. SUMMARY

1. Water is a unique substance. Its thermal–density properties, high specific heat, and liquid–solid characteristics influence extensively the physical, chemical, and metabolic properties and dynamics of freshwater ecosystems.
2. The molecular aggregation and bonding characteristics of water result in unique density properties that permit water molecules to form quasi-stable polymers.
   a. The maximum density of water (1.00000 g ml^{-1}) occurs at 3.98°C. Molecular expansion and decreasing density occur at progressively increasing rates both above and below 4°C. The density of ice at 0°C (0.9168 g ml^{-1}) is significantly less than that of liquid water at 0°C, and ice consequently floats.
   b. The density difference between water at a given temperature and 1°C lower increases markedly at temperatures above and below 4°C. The amount of energy required to mix water of differing densities increases proportionally to the density differences.
3. The specific heat of liquid water is very high. As a result, thermal conditions within standing waters change slowly, are more stable, and permit a longer growing season than is commonly found in aerial habitats. The heat-absorbing and heat-retaining properties of bodies of water also modify the climate of adjacent land masses.
4. Water viscosity is far greater than the viscosity of air and is inversely proportional to temperature. Aquatic organisms have adapted to the more buoyant aquatic environment and to the resistance water imposed on locomotion; their distribution is often influenced by thermally induced stratification of water masses of differing density and viscosity.
5. High surface tension occurs at the air–water interface. Surface tension decreases with increasing temperature, salinity, and concentrations of organic compounds.

IX. Summary

The amount of fresh water on earth is very small in comparison to the water of the oceans, but the fresh waters have much more rapid renewal times (cf. Table 1-1). On a volumetric basis, fresh water is concentrated in large, deep basins of several great lakes. About 20% of surface fresh water is contained in Lake Baikal of Siberian Russia. The number of individual depressions of smaller lakes and reservoirs is extremely large, however, and most of these lakes are located in temperate and subarctic regions of the Northern Hemisphere. Most lakes are shallow and geologically very transient.

Catastrophic events of glacial, volcanic, and tectonic activities have aggregated many freshwater lakes into lake districts. The morphometry and geological substrata of the drainage basins are very important because these properties influence sediment–water interactions, the resultant productivity, and the significance of littoral productivity to that of the river and entire lake ecosystem. Shallow lakes, which have more sediment area per unit of water volume, are generally more productive than deep lakes, and a greater proportion of their total productivity is attributable to communities of the littoral and wetland areas of the land–water interface.

I. DISTRIBUTION OF FRESH WATERS

Inland waters cover less than 2% of the earth's surface, approximately 2.5×10^6 km^2. About 20 lakes are extremely deep (in excess of 400 m), and a significant portion of the world's fresh water is contained in Lake Baikal, Siberian Russia (A = 31,500 km^2; z_m = 1620 m; $\bar{z}$ = 740 m), the deepest lake of enormous volume (23,000 km^3). Like Lake Baikal, nearly all other extremely deep lakes are tectonic or volcanic in origin or have formed from fjords that have subsequently become fresh. Although a few lakes of glacial origin, such as the Laurentian Great Lakes and Great Slave Lake of Canada, have basins of great depth, few exceed a depth of 300 m. Most of the very deep lakes are found in

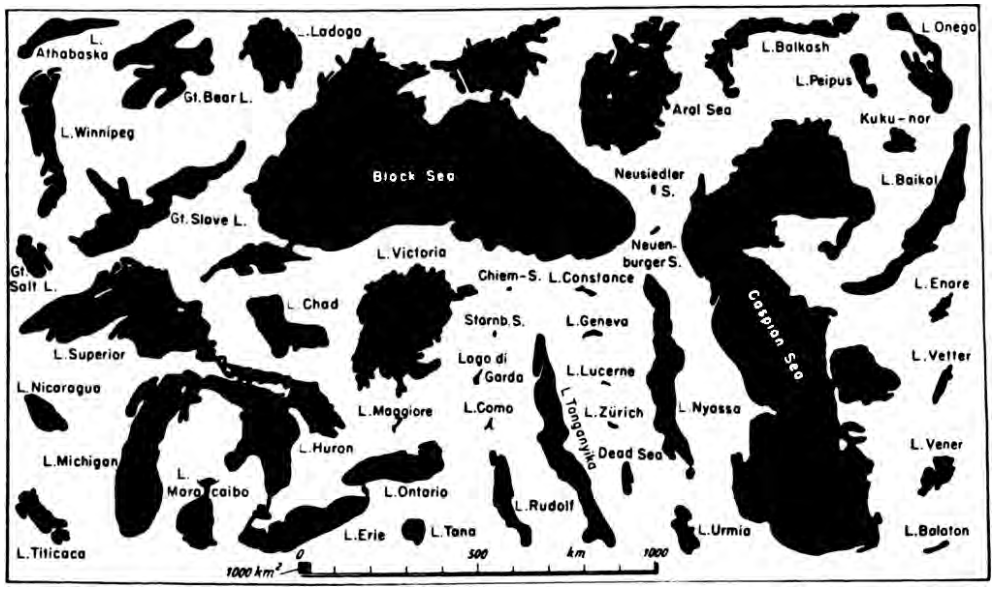

FIGURE 3-1 An approximate comparison of the surface areas of many of the larger inland waters of the world, all drawn to the same scale. The Aral Sea has experienced catastrophic reductions in area (less than half of that depicted here) because of diversions of water for agriculture. (After Ruttner, F.: *Fundamentals of Limnology.* Toronto, University of Toronto Press, 1963.)

mountainous regions along the western portions of North and South America, of Europe, and in the mountainous regions of central Africa and Asia. Lakes Baikal in Asia and Tanganyika in Africa are the only lakes known to have maximum depths in excess of 1000 m and mean depths over 500 m.

On an areal basis, only a few lakes are of very large surface area; most of these are compared in Figure 3-1. If we exclude the Black Sea, which is an inland water really connected to the ocean, the Caspian Sea, a large (436,400 km^2) salt lake, is the largest inland basin separated from the ocean. The Laurentian Great Lakes of North America—lakes Superior, Huron, Michigan, Ontario, and Erie—constitute the greatest continuous mass of fresh water on earth, with a collective area of 245,240 km^2 and a volume of 24,620 km^3. Lake Superior has the greatest area (83,300 km^2) of any purely freshwater lake. Some 253 lakes have a surface area greater than 500 km^2, and nearly half (48%) occur in North America, largely above 40°N latitude

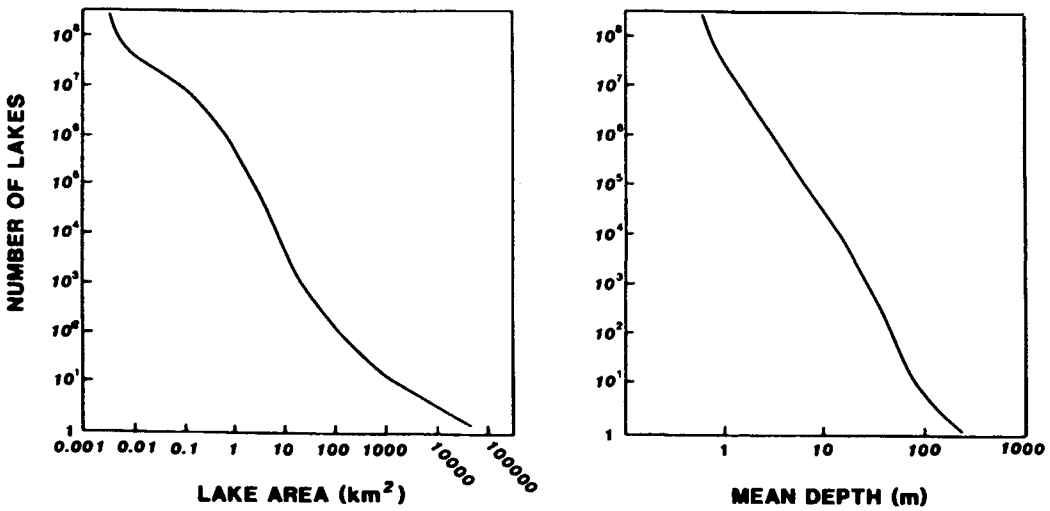

FIGURE 3-2 Number of lakes of the world in relation to lake area and approximate mean water depth. (From Wetzel, R. G.: *Verh. Internat. Verein. Limnol.* 24:6–24, 1990.)

(Herdendorf, 1984). About 75% of these large lakes contain fresh water. The estimated total of these large lakes (179,000 km^3) constitutes over 75% of the total inland surface water of the world.

Although these very large lakes constitute a major freshwater resource, most lakes are much smaller. Most lakes are of catastrophic origin, formed by glacial, volcanic, or tectonic processes. Consequently, many lakes are localized into lake districts in which large numbers of lake basins are concentrated. Glacial activity during the most recent period of major ice advance and retreat created literally millions of small depressions that subsequently were filled with water and modified. Thus large numbers of lakes are found in the Northern Hemisphere, where large land masses of North America and Europe–Asia interfaced with glacial movements. Consequently, numerous small, shallow basins are found throughout the arctic, subarctic, and northern temperate zones (Fig. 3-2).

More recently, humans have created large numbers of reservoirs and ponds (see Chaps. 20 and 26). Most of both natural and artificial lakes are small and relatively shallow, usually < 20 m in depth (Fig. 3-2). A vast number of lakes of the subarctic regions are very shallow, with mean depths of about a meter. Because of these morphometric characteristics, a large proportion of the lake volume is exposed to and interacts with the chemical and metabolic processes of soil and sediments. A great proportion of shallow lakes possess properties necessary for the development of sessile littoral flora, which generally results in markedly increased overall productivity.

II. RUNNING WATERS: LOTIC ECOSYSTEMS

Streams and rivers within their drainage basins are central to surface water ecosystems. A number of characteristics differentiate running water from lake ecosystems. Flowing freshwater environments are called ***lotic*** (*lotus,* from *lavo,* to wash) for obvious reasons of unidirectional water movement along a slope in response to gravity. Lotic ecosystems are contrasted to ***lentic*** (*lenis,* to make calm) or lake ecosystems. As already discussed (p. 4), most lakes are open and have distinct flows into, through, and out of their basins. Throughflows, termed the ***water renewal rates***, are often variable and very slow in lakes but are continuous. The distinction between lakes and running waters focuses on the relative residence times of the water. The importance of variable but continuous and rapid throughput of water and materials contained in it is evident in the biology of most organisms inhabiting running waters. When the energy of flowing water is dissipated, as in the transitional zone of reservoirs, the change to lentic characteristics is rapid.

The directional movement of water is a fundamental property of lotic ecosystems. Dissipation of energy from moving masses of water affects the morphology of streams, sedimentation patterns, water chemistry, and biology of organisms inhabiting them.

Rivers constitute an insignificant amount (0.001 or 0.1%) of the land surface. Only 0.0001% of the water of the Earth occurs in river channels. In spite of these low quantities, running waters are of enormous significance to humans. Erosion moves large amounts of dissolved and particulate matter from the land to the sea. Small streams and rivers often flow to lakes and eventually large river systems. Twenty or so major river systems exceed 2000 km in length and export a large percentage of the eroded materials from major continental land masses (Table 3-1).

TABLE 3-1 Catchment Size and Drainage from Selected Major River Basins[a]

Rivers by continent	*Drainage area* (10^3 km^2)	*Mean annual flow* (m^3 s^{-1})
North America	20,700	191,000
Colorado	629	580
Mississippi	3222	17,300

III. MORPHOLOGY AND FLOW IN RIVER ECOSYSTEMS

The continual downgradient movement of water, dissolved substances, and suspended particles in streams and rivers is derived primarily from the land area draining into a given stream channel. The hydrological, chemical, and biological characteristics of a stream or river reflect the climate, geology, and vegetational cover of the drainage basin (Hynes, 1970; Oglesby *et al.*, 1972; Beaumont, 1975; Whitton, 1975; Likens *et al.*, 1977, 1995).

A. Drainage Basin

The ***drainage basin***[1] is the area drained by tributary streams that coalesce into a main channel. Several methods have been used for ordering the tributary streams in a drainage network (reviewed by Gregory and Walling, 1973; Gordon *et al.*, 1992). The Horton-Strahler method (Horton, 1945; Strahler, 1952) is widely used. The smallest permanent stream is designated as the first order, and the confluence of two first-order streams (n) creates a second order ($n + 1$) (Fig. 3-3). The order of the trunk stream is not altered by the addition of a stream of lower order. Only when two tributaries of equal order are joined is the order increased. Deficiencies in this popular method of stream ordering, as well as alternatives, are reviewed by Gordon *et al.* (1992). Stream order is negatively correlated with the logarithm of the number of streams within a drainage basin and positively related to the logarithm of stream length (Table 3-2).

Many patterns of drainage networks are observed (Fig. 3-4). Usually surface features (topographic divides) are used to define drainage basins, although subsurface flows may have different boundaries (phreatic divides), particularly in areas underlain with relatively soluble or permeable rocks. Stream length (L_c, cf. Table 3-3) increases in a relatively constant way with drainage basin area (A) as:

$$L_c = jA^m$$

where j and m are derived from many measurements and average about 1.4 and 0.6, respectively. Thus, as drainage basins increase in size, they tend to elongate (Leopold *et al.*, 1964).

B. Water Influx and Movement

Water from all types of precipitation enters the drainage basins and either moves or is temporarily stored. Precipitation may be intercepted by vegetation

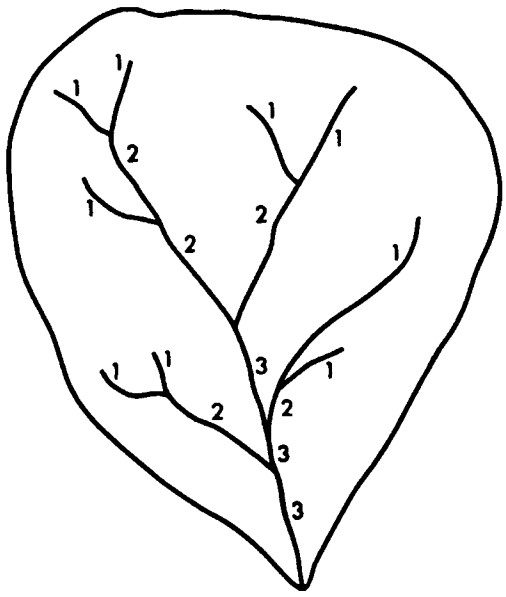

FIGURE 3-3 Stream ordering according to the Horton-Strahler methods. (From Wetzel and Likens, 1991.)

[1] In American usage, ***watershed*** is equivalent to ***drainage basin*** or the European term ***catchment***, all of which refer to the area of land drained by a river system.

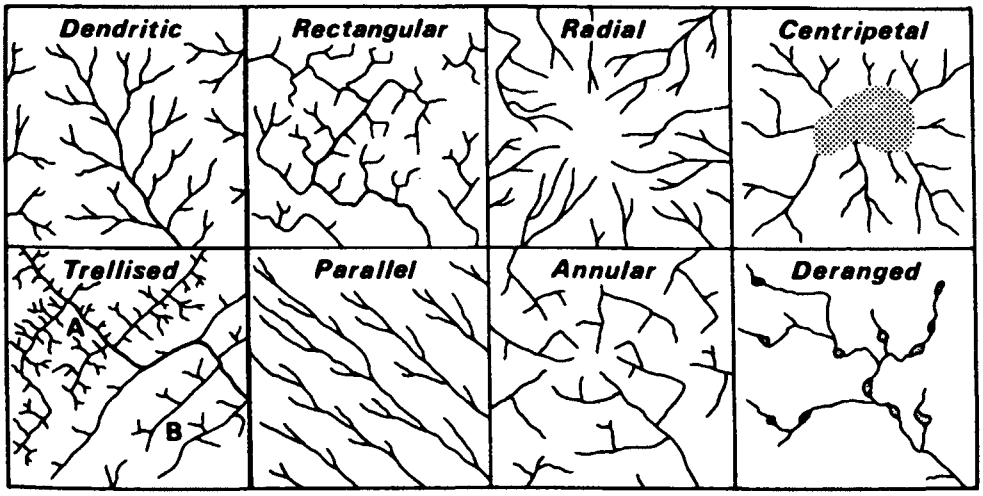

FIGURE 3-4 Common types of drainage networks. (From Gregory, K. J. and Walling, D. E.: *Drainage Basin Form and Process*. 1973. Edward Arnold Ltd., London, by permission.)

TABLE 3-3 Drainage Basin and Channel Characteristics[a]

	Definitions of topographic characteristics
Basin length (L_B)	Straight-line distance from outlet to the point on the basin divide used to determine the main channel length, L_C.
Basin width (W_B)	Average width of the basin determined by dividing the area, A, by the basin length, L_B: $W_B = A/L_B$
Basin perimeter (P_B)	The length of the line that defines the surface divide of the basin.
Basin land slope (S_B)	Average land slope calculated at points uniformly distributed throughout the basin. Slopes normal to topographic contours at each of 50- and preferably 100-grid intersections are averaged to obtain S_B. The difference in altitude for the two topographic contours nearest a grid intersection is determined, and the normal distance between these contours is measured.
Basin diameter (B_D)	The diameter of the smallest circle that will encompass the entire basin.
Basin shape (SH_B)	A measure of the shape of the basin computed as the ratio of the length of the basin to its average width: $SH_B = \frac{(L_B)^2}{A}$
Compactness ratio (CR_B)	The ratio of the perimeter of the basin to the circumference of a circle of equal area. Computed from A and P_b as follows: $CR_B = \frac{P_B}{2(\pi A)^{1/2}}$
Main channel length (L_C)	The length of the main channel from the mouth to the basin divide.
Main channel slope (S_C)	An index of the slope of the main channel computed from the difference in stream-bed altitude at point 10% (E_{10}) and 85% (E_{85}) of the distance along the main channel from the outlet to the basin divide. It can be computed by the equation $S_C = \frac{(E_{85} - E_{10})}{0.75L_C}$
Sinuosity ratio (P)	The ratio of the main channel length to the basin length: $P = \frac{L_C}{L_B}$

[a] Modified from Winter (1985).

and subsequently absorbed and transpired, or it evaporates from the plant surfaces. Some precipitation reaches the litter on the ground and soil surfaces by stem and leaf runoff or by direct soil interception. The rates of absorption of water and movement among soil particles by capillarity are variable with particle size and composition. When water from precipitation or snow/ice melt is added to the soil more rapidly than it can be absorbed, the ***infiltration capacity*** of the soil is exceeded. Excess water will then run downgradient by ***overland flow.***

Most water from precipitation infiltrates the soil. Soils possess variable capacities to store water depending on depth, bulk density, structure, composition, and other factors (Leopold *et al.,* 1964; Todd, 1980). This storage capacity must be exceeded before flow of excess to streams can occur. Water storage capacity is continually made available by losses from evaporation and plant evapotranspiration.

Waterflow through the soil is often channeled by soil structure and voids such as cracks, worm and other animal burrows, and old root channels. Dense or impermeable soil layers impede vertical movement of water and cause ***lateral flow*** of water at intermediate depths of the soil. The chemistry of the water is modified considerably by ionic exchange mechanisms as it passes through soils (Likens, 1984).

The ***surface*** (plane) of the saturated zone of permeable soil is termed the ***water table.*** Water held by capillarity in the soil above the water table is called ***vadose water*** and that saturated below the water table, ***ground water.*** Ground water flows laterally, intersects stream channels, and provides a moderately stable base flow input to streams. The ***overland flow,*** derived from precipitation influxes in excess of soil infiltration capacities, is supplemented by water that infiltrates soils and then flows laterally to the stream channel as ***subsurface storm flow*** to collectively provide the main loading during peak flows or floods (Chorley, 1978; Dunne, 1978).

Stream flow or discharge is the volume of water passing through the cross-sectional area of a stream channel per unit time.[2] Discharge can vary greatly from season to season or within and following a precipitation event. Following a rainstorm or rapid snowmelt period, stream discharge increases to a peak and then decreases (Fig. 3-5). The hydrograph indicates the response of stream discharge to storm events and is useful for comparisons among streams. The hydrograph varies with features of storm events and the drainage basin. The concave slopes of the rising limb reflect the infiltration and storage capacities of the drainage basin. The peak of the hydrograph represents the maximum runoff from the specific inflow precipitation event. The rate of change in the falling limb indicates soil characteristics of flow from storage after precipitation has ceased.

Discharges that exceed the "bankfull" capacities of the river channel are called ***floods.*** Floods are essentially random events. The mean annual flood

[2] $Q = Av$, where Q = discharge in $m^3 s^{-1}$, A = cross-sectional area in m^2, and v = mean velocity in $m s^{-1}$.

corresponds to the average value for the largest annual discharge over a series of years. The mean annual flood has a return period of 2.33 years (Leopold *et al.*, 1968). This recurrence interval[3] is the average time interval when the highest discharge of the year will equal or exceed the value of the mean annual flood. Mean bankfull stage recurrence intervals are about 1.5 years.

Stream flow and discharge are directly related to the drainage area. This relationship has been used to predict discharge, particularly for flood events (cf. Strahler, 1964). The relationships between mean annual flood event and size of drainage area are reasonably consistent within different hydrologic regions (Fig. 3-6). Differences reflect variations in elevational gradients and the tendency for drainage basins to elongate as they increase in size.

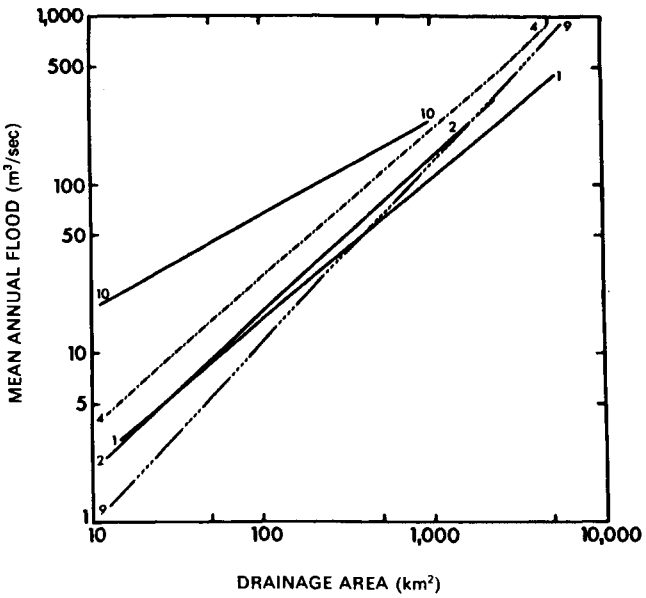

FIGURE 3-6 Relationships between mean annual flood discharge and size of drainage area for rivers in different hydrologic regions of the United States. (Redrawn from data of Tice, 1968.)

C. Channel Morphology

The basin or valley trough containing the flowing water is the stream or river ***channel.*** The channel is described physically in terms of length, width, depth, cross-sectional area, slope, aspect, and other parameters (Table 3-3; cf. Leopold *et al.*, 1964; Marisawa, 1968; Wetzel and Likens, 1991; Rosgen, 1996). The channel is usually bordered on one or both sides by a flat area called the ***flood plain.*** Much of the soil of the flood plain is connected hydrologically to the water of the channel. As is discussed later, many chemical changes occur in this water as it moves to the primary channel.

River channels can contain moderate discharges without overflowing the banks. A ***bankfull*** discharge is a flow that fills entirely the cross-sectional stream channel without overflow onto the flood plain. The bankfull stage (Bfs) will be equaled or exceeded on the average of once every 1.5 years (Leopold *et al.*, 1964). Usually, discharges are much smaller than bankfull stages.

River channels rarely flow over an even gradient and are never straight over an appreciable distance. As the energy of flowing water is expended against irregularities in channel morphology, with time there is a tendency to erode the channel to produce a more-even gradient and a more-uniform dissipation of potential energy per unit length of stream. The bending and meandering of the channel approach the theoretical equilibrium of an even energy gradient much more closely than do straight channels. Meandering channels also increase the total volume of the channel and its capacity to transport water over a given distance.

Stream and river channels gradually move laterally within the flood plain because of erosion and redeposition of sediment. Old, abandoned portions of river channels are common among most flood plains. The morphology of rivers has been classified and orga.ized on the basis of many criteria (cf. Kellerhals *et al.*, 1976; Kellerhals and Church, 1989). Distinctions can be based on many different criteria of fluvial morphology, such as drainage area, discharge, width–depth ratio, bed material size, channel slope, and others.

Most streams and rivers flow in valleys that exert some lateral and vertical control over the river. Reaches of lotic ecosystems are considered ***constrained*** when the valley floor is narrower than two active stream channel widths (Sedell *et al.*, 1990). Constrained river systems occur where natural geological or human-made features constrict the valley floor and limit lateral mobility and the development of adjacent plant communities. Rivers in valleys without genetic[4] flood plains are also called ***incised*** or ***entrenched.*** Canyons are an extreme case of river incision. Unconstrained river reaches have valley floors that are wider than two active channel widths and lack major lateral geological or artificial constraints (Gregory *et al.*, 1991). Most streams and rivers are of this type and are

[3] $Tr = \frac{N + 1}{M}$

where Tr = return period (y), N = number of years of record, and M = rank of an individual event in the set (Leopold *et al.*, 1968).

[4] A geological term referring to surfaces built or deposited by the present-day river in the course of lateral shifting or flooding (Kellerhals and Church, 1989).

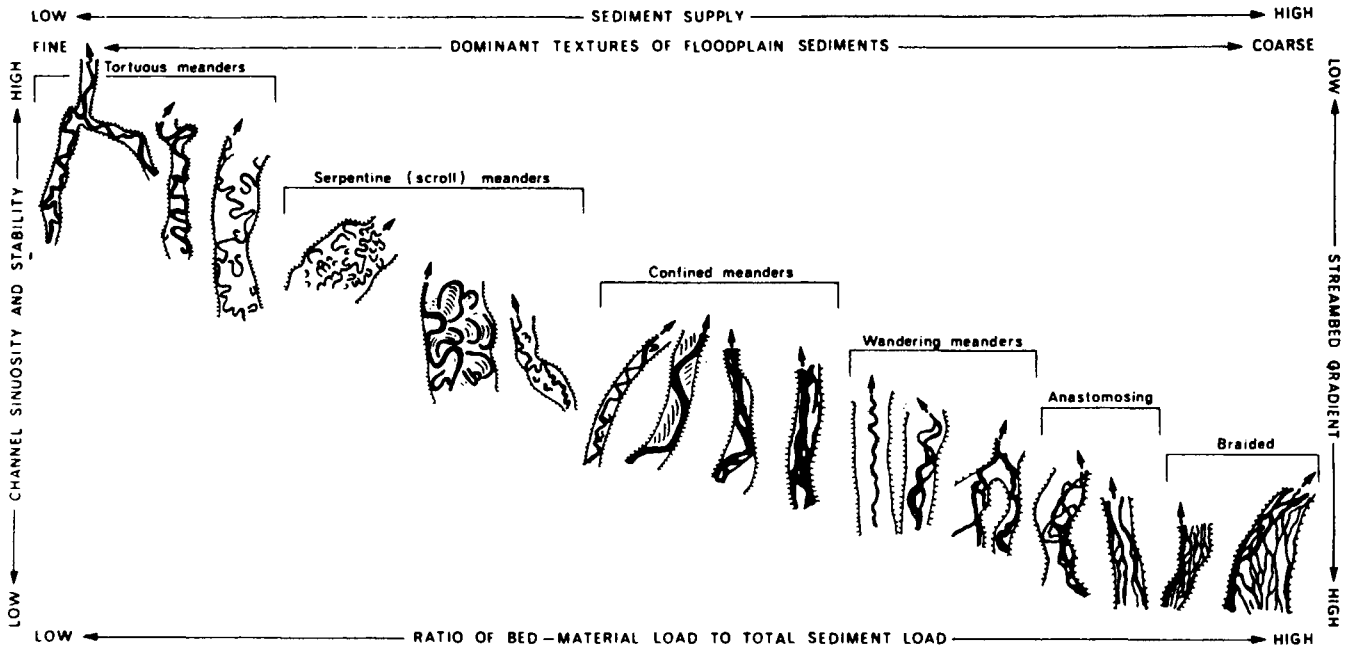

FIGURE 3-7 Form and gradient of alluvial stream channels and the type, supply, and dominant particle sizes of sediments. (Modified from Selby, 1985.)

characterized by active migrations of the channel that expand into extensive flood plains and often form braided channels (Kellerhals and Church, 1989; Pinay *et al.*, 1990; Wissmar and Swanson, 1990). The extent of lateral constraint is relative and quite variable from stream to stream as well as within the same river ecosystem.

The forms of river channels are very diverse (Fig. 3-7) and deviate from four general classes: (a) straight, (b) meandering, (c) braided, and (d) anastomosing. The examples of channel patterns and channel islands depict variations in the great networking of channels and extent of channel anastomosing around channel islands. Channel bars are accumulations of channel bed materials below the average water surface level that often move or are deformed by changing water velocities. Great variations in channel patterns are reviewed in Selby (1985), Kellerhals and Church (1989), Grant *et al.* (1990), Gordon *et al.* (1992), and Rosgen (1994, 1996). It should be rigorously emphasized, however, as correctly noted by Miller and Ritter (1996), that such classification systems function largely as communication tools. Such systems cannot be used effectively to assess stream parameters such as erosion potential, sediment supply, effects of vegetation, and sensitivity to geomorphic disturbances, particularly under different climatic and hydrological regimes.

Although most rivers flow in valleys, exceptions are common. These exceptions include rivers on deltas, fans, or broad plains (Kellerhals and Church, 1989). As discussed further later on (p. 30), deltas are river-deposited continuations of land built by sedimentation out into a body of water. Fans are alluvial, fan-shaped surfaces deposited where a narrow valley emerges onto a broad surface. Broad plains are usually alluvial, lacustrine beds of drained lakes or emergent coastal plains.

IV. GROUNDWATER FLUXES TO LAKES

The dominant inflows to and outflows from lakes occur in surface streams. The sediments of most lake basins have relatively low hydraulic conductivities and lose only small portions of their volume to ground water. Inputs of ground water require the ground water to be elevated above the lake to achieve head pressure, and the soil characteristics must have minimal permeability in connecting strata with the lake basin. Seepage inflow and outflow can fluctuate seasonally depending on the head pressures between the lake and the stagnation point, that is, the point of minimum head pressure along the local flow system boundary (Anderson and Munter, 1981). Groundwater inflows can occur through part of a lake basin, and outflow to recharge the groundwater system through other parts of the lake basin. Alterations in the levels of surrounding water tables or in the water level of the lake can alter the fluxes into or out of the basin. Groundwater inflow rates are more sensitive to seasonal variations in recharge than are outflow rates (Krabbenhoft *et al.*, 1990).

In seepage lakes where groundwater inflows are appreciable, most flow into a lake occurs in the littoral zone whether sediments are present or not (Winter, 1978). If losses of water occur to the groundwater system, in most cases the losses occur in the deeper parts of the lake basin. Water must move through the sediments, thereby considerably reducing the quantity of water lost from the lake compared to that entering the lake in the littoral zone, where sediments of high permeability usually are present. Losses of seepage water through the littoral zone to the ground water are only considerable where no water table mound occurs on the downslope side of the lake. Under these conditions, the water table slopes downward from the shore line, away from the lake. Among glacial terrains, in which most natural lakes occur, seepage from lakes is more common where the water table occurs in end morainal deposits of silty till (Winter, 1981). Much less seepage from lakes occurs in common areas of ground moraine, outwash plains, and flood plains.

A number of analyses have demonstrated the groundwater contributions to water and chemical fluxes of lakes to be negligible (Wetzel and Otsuki, 1974; Malueg *et al.*, 1975; Schindler *et al.*, 1976). In contrast, groundwater contributions to a seepage lake of Minnesota were the largest annual flux of water into (58–76%) and out of (73–83%) the lake during a 12-year study, during which the entire volume of the lake was replaced four times (3-year renewal time) (LaBaugh *et al.*, 1995). Ground water represented as much as half of the annual hydrological input of phosphorus and nitrogen to this lake; the remainder was supplied by atmospheric precipitation.

V. GEOMORPHOLOGY OF LAKE BASINS

The origins of lake basins and their morphometry are of much more than casual interest. The geomorphology of lakes is intimately reflected in physical, chemical, and biological events within the basins and plays a major role in the control of a lake's metabolism, within the climatological constraints of its location. The geomorphology of a lake controls the nature of its drainage, the inputs of nutrients to the lake, and the volume of influx in relation to flushing–renewal time. These patterns in turn govern the distribution of dissolved gases, nutrients, and organisms, so that the entire metabolism of freshwater systems is influenced to varying degrees by the geomorphology of the basin and how it has been modified throughout its subsequent history.

The shape of a lake basin often influences its productivity. Steep-sided U- or V-shaped basins, often formed by tectonic forces, are usually deep and relatively unproductive. In such lakes a proportionally smaller volume of water is contiguous with sediments. Shallow depressions with greater percentage contact of water with the sediments generally exhibit intermediate-to-high productivity.

The following brief résumé on the origin of lakes is based on Hutchinson's (1957) summary of the subject, which was drawn from an array of sources. Particularly seminal was the detailed geomorphologically based evaluation of the origins and classification of lake basins by Davis (1883), which served as a foundation for subsequent treatments. Hutchinson differentiated 76 types of lakes on the basis of geomorphological inception. This detailed classification has been variously modified or amended subsequently (e.g., Horie, 1962 and Timms, 1992, among others) but essentially stands intact. Discussion here is limited to nine distinct groups of lakes, each formed by different processes.

A. Tectonic Basins

Tectonic basins are depressions formed by movements of deeper portions of the earth's crust and are differentiated from lake basins that resulted from volcanic activity. The major type of tectonic basin forms as a result of ***faulting,*** in which depressions occur between the bases of a single fault displacement or in downfaulted troughs (Fig. 3-8). The latter type of basin is referred to as a ***graben,*** and is the mode of origin of many of the most spectacular relict lakes of the world. Foremost among these is Lake Baikal of eastern Siberia, the deepest lake in the world, which has a continuous lacustrine history from at least the early Tertiary period. Lake Baikal, and many other relict lakes, most of which lie in tectonic grabens, are of particular interest because they contain a large number of relict endemic species. For example, of 1200 animal species and at least half that number of plant species known from Lake Baikal, over 80% of those occurring in the open water are endemic to this lake (Kozhov, 1963; Kozhova and Izmest'eva, 1998). Lake Tanganyika of equatorial Africa is a similar deep graben lake (z_m = 1435 m) formed in rift valley displacements along crustal fractures and contains a large number of relict endemic species of plants and animals (Coulter, 1991). Pyramid Lake of Nevada and Lake Tahoe of California–Nevada are familiar examples of American graben lakes.

Tectonic movements causing moderate uplifting of the marine sea bed have isolated several very large lake basins. The relict marine basins of Eastern Europe, which include the Caspian Sea and the Sea of Aral, were separated by the formation of uplifted mountain ranges in the Miocene period. ***Upwarping*** of the earth's

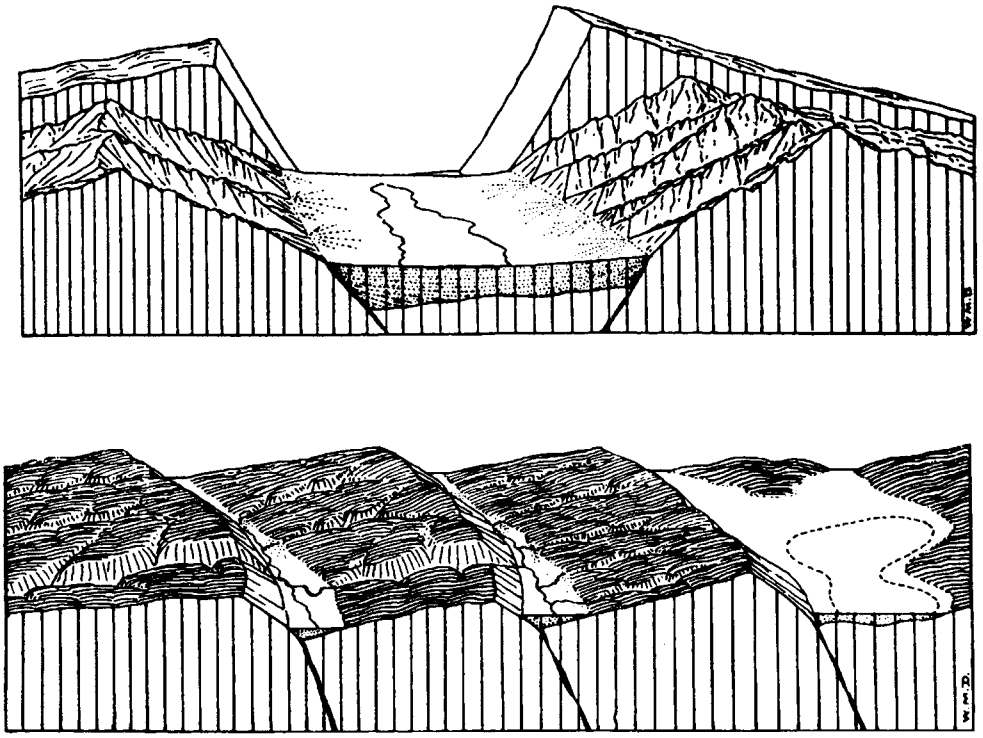

FIGURE 3-8 Tectonic lake basins. *Upper:* In the background, a depressed fault block between two upheaved fault blocks; in the foreground, the same after a considerable period of erosion and deposition. *Lower:* Diagram of the great fault blocks of the northern Sierra Nevada Mountains with the plain of Honey Lake to the east. (From Davis, W. M.: *Calif. J. Mines Geol.* 29:175, 1933.)

crust in lesser degrees also has resulted in the formation of many large lake systems. Lake Okeechobee in Florida resulted from minor depressions (z_m = ca. 4 m) in the sea floor as it uplifted in the Pliocene epoch to form the Floridian peninsula, and it forms one of the largest lakes (approximately 1880 km^2) completely within the United States, exceeded in area only by Lake Michigan. Similarly, Lake Victoria in central Africa resulted from upwarping of the margins of the plateau in which the lake basin lies. This uptilting also created a natural impoundment of the major river system that flowed into the valley. Drainage outlets of the Great Salt Lake basin of Utah were eliminated by uplifted deformations, and a closed lake basin was formed. Upwarping of the earth's crust also contributed, along with the primary glacial scouring activity, to the formation of the Great Lakes of America. As the massive glacial sheet receded, the release of pressure resulted in a significant crustal rebound.

Lake basins are occasionally formed in areas of localized subsidence that result from earthquake activity. Many of these depressions are dry or temporarily contain water, depending on the porosity of the basin material, while others become permanent lakes, usually open basins with outlet drainage.

B. Lakes Formed by Volcanic Activity

Catastrophic events associated with ***volcanic activity*** can generate lake basins in several different ways. As volcanic materials are ejected upward and create a void, or as released magma cools and is distorted in various ways, depressions and cavities are created. If these depressions are undrained, they may contain a lake (Fig. 3-9). Because of the basaltic nature of these lake basins and their drainage areas, which are often very restricted, many lakes associated with volcanic activity contain low concentrations of nutrients and are relatively unproductive.

Small crater lakes are occasionally found occupying cinder cones of quiescent volcanic peaks. However, crater lakes in depressions formed by the violent ejection of magma (Fig. 3-10), or by the collapse of overlying materials where underlying magma has been ejected to create a cavity, termed ***maars***, are generally small depressions with diameters less than 2 km and result from lava coming into contact with ground water or from degassing of magma. Maars are usually nearly circular in shape and can be extremely deep (> 100 m) in relation to their small surface area. Basins formed by the subsidence of the roof of a partially emptied magmatic

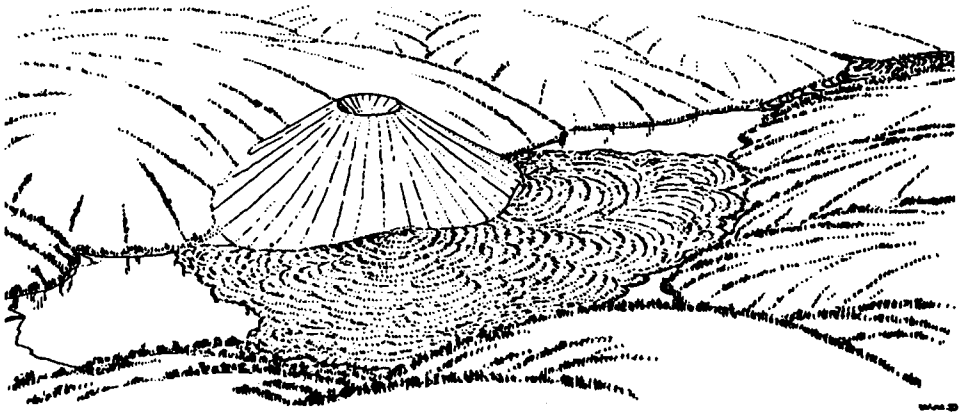

FIGURE 3-9 Volcanic lakes. A caldera lake within the volcanic cone and several lakes within the valleys dammed by lava flows. (From Davis, W. M.: *Calif. J. Mines Geol.* 29:175, 1933.)

chamber are termed ***calderas*** and can be somewhat larger than maars (minimum diameter about 5 km). Among the most spectacular of lakes formed by the collapse of the center of a volcanic cone is Crater Lake, Oregon, with an area of 64 km^2 and a depth of 608 m (seventh-deepest lake in the world). Caldera lakes can be modified in various ways by secondary peaks partially filling the original caldera depressions or by the occurrence of faulting over an emptied magma chamber.

Some volcanic lakes originated by a combination of large-scale volcanic and tectonic processes. In some situations, caldera collapse occurred on such a large scale that extensive portions of the surrounding land subsided in addition to the central portion of the volcano. Such subsidence usually takes place along preexisting fault fractures. Some of the largest lakes associated with volcanic activity were formed in this manner. Many examples of these lakes exist in equatorial Asia and New Zealand (cf. Bayly and Williams, 1973; Larson, 1989).

Lava flows from volcanic activity can form lakes in several ways. As lava streams flow, cool, and solidify, surface lava frequently collapses into voids created by the continued flow of the underlying molten lava. A lake basin may be formed in this manner when the unsupported overstory crust collapses and may be filled when the depression extends below groundwater level. Lava streams also commonly flow into a preexisting river valley and form a dam, behind which a lake can collect (Fig. 3-9). If the dam is of sufficient magnitude,

FIGURE 3-10 Lake Okama on Mt. Zao, northern Japan, a caldera lake. (Photo courtesy of I. Saijo.)

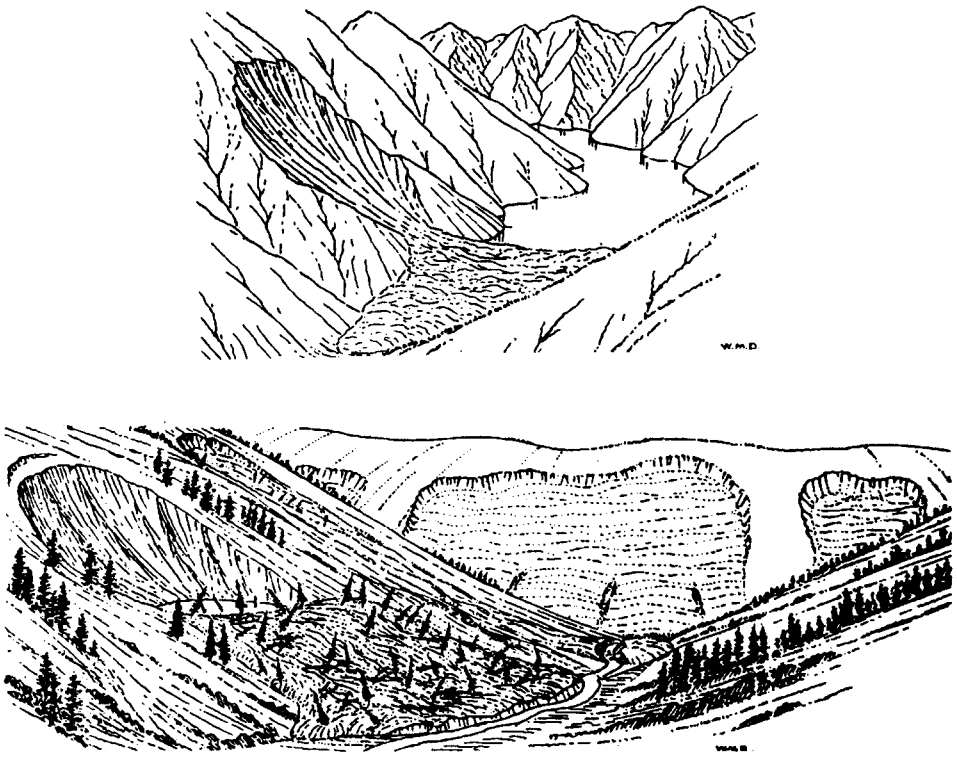

FIGURE 3-11 Lakes formed by a large landslide into a steep-sided stream-eroded canyon (*upper*) and in a hollow behind a recent slide with tilted trees (*lower*). Four mountain landslides are shown in the background. (From Davis, W. M.: *Calif. J. Mines Geol. 29*:175, 1933.)

the entire hydrology of the region can be changed by the resultant reversal of the river system. In some cases, the river flow is forced underground in order to pass the lava obstruction.

C. Lakes Formed by Landslides

Sudden movements of large quantities of unconsolidated material in the form of landslides into the floors of stream valleys can cause dams and create lakes, often of very large size (Fig. 3-11). Such landslide dams may result from rockfalls, mudflows, iceslides, and even flows of large amounts of peat, but they are usually found in glaciated mountains. The landslides usually are brought about by abnormal meteorological events, such as excessive rains acting on unstable slopes. More spectacular slides are occasionally initiated by earthquake activity. Lakes formed behind landslide dams are often transitory and exist only for a few weeks to several months. This short period is due to the fact that unless the slide is very massive, the unconsolidated dam is susceptible to rapid erosion by the effluent of the newly formed lake. Many disastrous floods have resulted from the rapid erosion of the dam material by the effluent, which, once started, can quickly empty the accumulated basin. As with damming by lava flows, if the landslide dam is sufficiently large, the lake can become permanent and reverse the direction of drainage flow from the river valley.

D. Lakes Formed by Glacial Activity

By far the most important agents in the formation of lakes are the gradual but nonetheless catastrophic erosional and depositional effects of glacial ice movements. Land surfaces that are now glaciated include Greenland and several smaller arctic islands, Antarctica, and numerous small areas in high mountains throughout the world. These contemporary glacial activities are small, however, in comparison to the massive Pleistocene glaciation that advanced and receded in four major episodes of activity in the Northern Hemisphere. With the retreat of the last Pleistocene glaciers, an immense number of small lakes were created. Lakes of glacial origin are far more numerous than lakes formed by other processes. The action of glaciers in mountainous regions of high relief usually produces lake basins that are quite different from those that result from the movements of large ice sheets on regions of more mature and gentle relief.

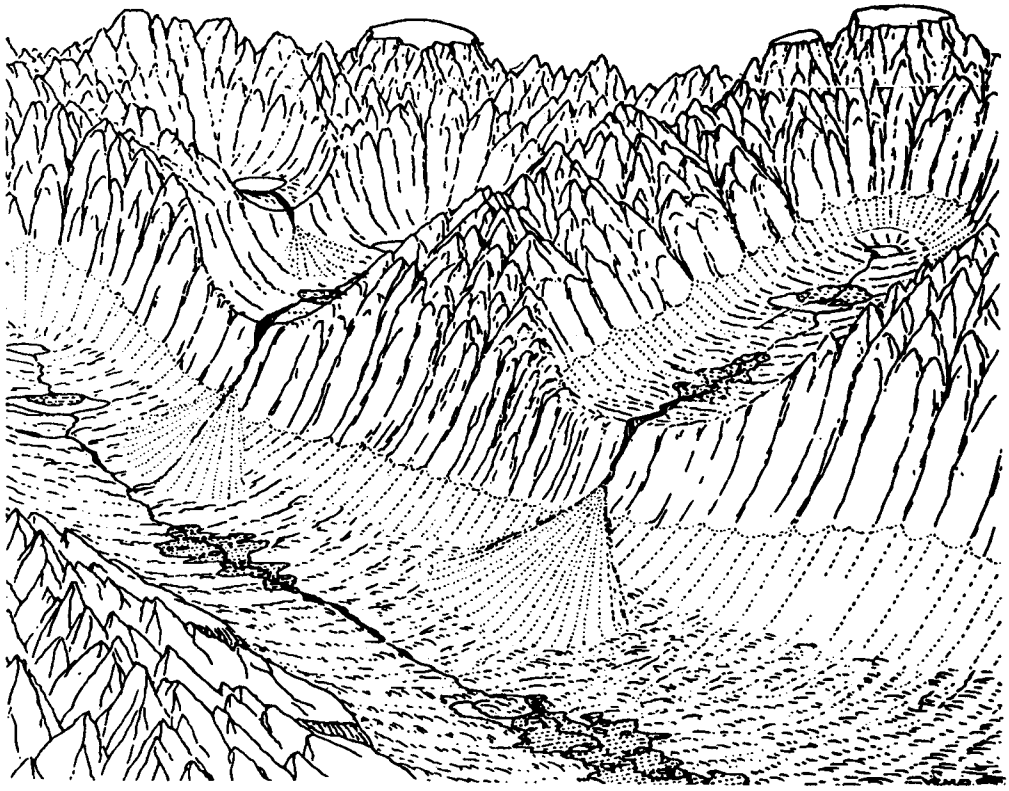

FIGURE 3-12 Several small cirque lakes within a mountain group from which several converging, cirque-headed branch troughs all join the same trunk trough. (From Davis, W. M.: *Calif. J. Mines Geol.* 29:175, 1933.)

A number of lakes, often temporary in nature, occur on the surfaces of, within, or beneath existing glacial ice masses in areas of transitory thaw. For example, numerous meltwater subice lakes several kilometers in diameter occur 3000–4000 m below the Antarctic ice sheet (Oswald and Robin, 1973). In high mountain regions, the fronts and lateral arms of glaciers, as well as terminal morainal deposits supported by the ice, often will function as effective dams in river valleys that originate almost totally from glacial meltwater.

Glacial ice-scour lakes are a vast number of small lakes formed by ice moving over relatively flat, mature rock surfaces that are jointed and contain fractures. The ice-scour lakes are particularly common in mountainous regions where glacial movements have removed loosened rock material along fractures. When the glaciers retreat, the rock basins thus formed fill with meltwater. Such glacial-scour lakes may be found on the upland peneplains of Scandinavia, in the United Kingdom, and in the great Canadian shield region.

A frequently occurring type of ice-scour lake forms in the upper portion of glaciated valleys of mountainous areas, where the valleys are shaped into structures resembling amphitheaters by freezing and thawing ice action (Fig. 3-12). The amphitheaterlike formation is referred to as a ***cirque,*** and lakes within such depressions are ***cirque lakes.***[5] Water is held in the cirque depression either by a rock lip above the depression or by morainal deposits. Cirque lakes, which are generally small and relatively shallow (< 50 m), are often found in tandem arrangement within a glaciated trough of a mountain valley, with the higher lake "hanging" above the lower succeeding lake in a stairwaylike fashion. True cirque lakes, which are common to all major mountainous regions, are formed at approximately the snow line in glaciated valleys. When the glaciers extend well below the snow line of constant freezing and thawing, the corrosive action of the ice can form rock basins within the glacial valley. When such valley rock basins form a chain of small lakes in a glaciated valley, resembling a string of beads, they are referred to as ***paternoster lakes.*** Where there are mountains adjacent to the sea, as in many areas of Norway and western Canada, ***fjord lakes*** can be formed within narrow, deep basins in glacially deepened valleys.

[5] Sometimes referred to as *tarns.*

The English Lake District, a small group of lakes in a roughly circular area of northwestern England, is worthy of special notice because of the long history of limnological investigations that have centered in this region (reviewed in detail by Macan, 1970). The geological formations of the Lake District consist of an elevated dome of Ordovician and Silurian slates and volcanic intrusions. Rock formations overlying the early uplifted region were later eroded into nine major valleys. In the process of widening and deepening the troughs, glacial erosive activity scoured piedmont basins in each of these valleys. The result was the formation of a series of valleys radiating from the dome, most of which contain one large lake depression and several smaller basins situated in deposits of morainal till.

Where continental ice sheets encountered weak areas in primary basal rock formations, glacial scouring of lake basins occurred on a massive scale in nonmountainous piedmont areas. Great Slave Lake and Great Bear Lake in the central Canadian subarctic region are examples of scouring of preexisting valleys to very great depths by the ice sheet movements. The most impressive example, however, of large rock basins produced by glacial continental ice erosion are the Great Lakes of the St. Lawrence drainage, which collectively form the largest continuous volume of liquid fresh water in the world.

The entire Great Lakes region was covered by continental ice during the glacial maxima. Three important events led to the formation of the contemporary Great Lakes during the retreat of the Wisconsin ice sheet (Fig. 3-13) approximately 15,000 years BP[6] (Hough, 1958). In the early phases of retreat, lakes formed in the Michigan and Huron–Erie basins against the retreating ice lobes and drained southwestward into the Mississippi valley. As the ice sheet repeatedly retreated and advanced over a period of nearly 8000 years, discharge channels from previous scouring were uncovered and altered which resulted in drainage changes to an easterly direction. Another factor that contributed to changes in drainage was the crustal rebound uplifting that took place as the weight of the overlying ice was removed. The flow patterns and configurations of the modern Great Lakes were fixed about 5000 years B.P., except for a lowering of lake levels and diversion of all discharge through the Erie–Ontario basins to the St. Lawrence drainage.

As continental glacial ice sheets retreated in the late Pleistocene, vast amounts of rock debris, moved and incorporated into the ice during former advances, were deposited in terminal moraines and laterally to the lobes of the retreating glacier. These deposits dammed up valleys and depressions in an irregular way and formed lake basins. Some depressions were below later groundwater levels; others were filled by meltwater and drainage from the surrounding topography. ***Morainal damming*** of preglacial valleys, usually at one end but occasionally at both ends, created many of the numerous lakes of the glaciated northern United States. Lake Mendota and many other Wisconsin lakes were formed in this way, and the Finger Lakes of New York underwent complex glacial modification in which morainic damming occurred at both ends of their deep, narrow valley basins (von Engeln, 1961; Bloomfield, 1978).

In regions glaciated by continental ice sheets, a very common process of formation of lakes was associated with the deposition of meltwater outwash left at the border of the retreating ice mass or with blocks of ice buried in this debris. The major features of basins formed in this manner, which accounts for the origin of thousands of small lakes of northern North America, are shown in Figure 3-14. Glacial drift material was deposited terminally and beneath the ice washed out into plains and often contained large segments of ice broken from the decaying glacier. Based on paleolimnological evidence, we know that these blocks of ice, deposited in glacial drift or in the outwash plain, often took several hundred years to melt completely (Florin and Wright, 1969) and resulted in the formation of ***kettle lakes.*** As the ice blocks melted, the morphometry of the resulting depressions was modified variously by the overburden of rock debris (Fig. 3-14c). The ensuing lake basins are highly irregular in shape, size, and slope, corresponding to the irregularities of the original ice blocks. Kettle lakes often exhibit variable underwater relief, with multiple depressions separated by irregular ridges and mounds. These lakes rarely exceed 50 m in depth; their shallow basin is related to the limiting depth of crevasse formation in the fracturing of the terminal glacier.

Most arctic lake basins result from glacial activity, as discussed earlier, or are ***cryogenic lakes*** formed from the effects of permafrost (Hobbie, 1973; Pielou, 1998). The most abundant type of water body found in the Arctic is the shallow pond formed inside of an ice-wedge polygon of raised soil banks that grow above the permafrost from water seepage through cracks in the surface of the ground. Eventually, polygonal networks of ridges are formed that often contain ponds from 10 to 50 m in diameter. Millions of these ponds exist in coastal northern Alaska, Canada, and flat regions of Siberia. The shallow ponds may coalesce into larger ponds, or large amounts of ice deeper in the permafrost may melt, especially if the plant cover is disturbed or destroyed, and thereby form a shallow ***thermokarst lake.***

[6] Before present.

(1) Cary substage; (2) Late Cary; (3) Cary-Valders interstadial, low water in eastern basins, marine transgression in Ontario Basin; (4) Valders maximum; (5) post-Mankato retreat; (6) postglacial thermal maximum; (7) Lake Nipissing with triple drainage; (8) modern lakes. (From Hutchinson, G. E.: *A Treatise on Limnology*. Vol. 1, New York, John Wiley & Sons, Inc., 1957, after various sources; see Hough, 1958, for details.)

Some lakes form in the thawed craters of pingos, small conical hills scattered over tundra plains, especially in the North American arctic regions. Water from previously insulated soils can rise by hydraulic pressure through cracks in the permafrost but is overlain with alluvium and tundra vegetation (Pielou, 1998). The water freezes and forms a mound, or pingo. The overburdern soil can rupture and the ice of the depression can thaw to form small ***pingo lakes*** (Likens and Johnson, 1966).

A very large number of arctic thaw lakes are elliptical, with the long axis oriented in a northeast–southwest direction across the prevailing winds. It is apparent, at least among the smaller elliptical lakes of this region of nearly constant wind, that the prevailing system of currents would tend to erode and thaw permafrost at the

ends of the long axis of the ellipse lying across the wind (Livingstone, 1954, 1963; Livingstone *et al.*, 1958; Pielou, 1998).

E. Solution Lakes

Lake depressions can be created in any area from deposits of soluble rock that are slowly dissolved by percolating water. Although many rock formations are readily soluble (salts such as sodium chloride [NaCl], calcium sulfate [$CaSO_4$], and ferric and aluminum hydroxides), most ***solution lakes*** are formed in depressions resulting from the solution of limestone (calcium carbonate, $CaCO_3$) by slightly acidic water containing carbon dioxide (CO_2). Solution lakes are very common in limestone regions of the world, notably the karst regions of the Adriatic, especially in the former Yugoslavia, the Balkan Peninsula, the Alps of Central Europe, and in Michigan, Indiana, Kentucky, Tennessee, and particularly Florida in North America.

Solution basins are usually very circular and conically shaped sinks, termed ***dolines,*** which develop from the solution and gradual erosion of the soluble rock stratum. Percolating surface or ground water dissolves limestone most readily at the joints and points of fault fracture through which it drains. Adjacent dolines may eventually fuse to form compound depressions that are more irregular in conformity. Alternatively, the dissolution of limestone frequently occurs in large subterranean caves. Continued erosion of the superstructure by ground water results in its weakening to the point where the roof collapses, which forms a reasonably regular conical doline.

The level of water in the solution basin is often highly variable. Usually, the depressions are sufficiently deep to extend well into the groundwater table and permanently contain water. Other basins that just reach the water table can undergo fluctuations in water level in response to seasonal and long-term variations in groundwater supply.

F. Lake Basins Formed by River Activity

The running waters of rivers possess considerable erosive power that may create lake basins along their courses from elevated land to large lakes or the sea. In

the upper reaches of rivers where gradients are steep, excavation by water can produce rock basins that may persist as lakes after the course of the river has been diverted. ***Plunge-pool lakes,*** excavated at the foot of waterfalls, provide a rare but spectacular example of such destructive fluvial action. Several large lakes of the Grand Coulee system of the state of Washington were surely plunge pools shaped by the former interglacial course of the Columbia River system.

A combination of destructive erosional and obstructive depositional processes occurs as rivers flow down more gentle slopes to form many lakes in the river flood plains. Many lakes were formed along large rivers when sediments of the main stream were deposited as levees across the mouths of tributary streams. In this way, the obstruction of the tributary flow continued until the side valley was flooded and a ***lateral lake*** was formed. Lateral lakes are frequently found in tributary valleys along major river systems in all continents, especially in the upper portion of the drainage. The reverse situation of fluviatile dams holding lakes in the main river channel occasionally occurs as a result of deposition by a lateral tributary. If more sediment than the main stream can remove is deposited, the resulting lake may be permanent.

The basins of ***floodplain lakes***[7] contain water throughout the year. When flooded, the flood plain of a river is usually covered continuously with water (Hamilton *et al.,* 1992). As the river level recedes, water drains from the flood plain. Lakes persist in depressions perched above the river or in deep depressions that remain connected with the river.

Three classes of floodplain lakes can be differentiated on the basis of their geomorphological origins. ***Blocked-valley lakes,*** common along the Amazon River, are shaped like drainage valleys and extend inland from the flood plain boundary. Lakes within the boundaries of the fringing flood plain are ***lateral levee lakes*** (Hutchinson, 1957). Two types of levee lakes are common (Hamilton and Lewis, 1990): ***Dish lakes*** are dish-shaped and have low rates of hydraulic throughflow during inundation; ***Channel lakes*** are more riverine, tend to have visible currents during inundation and are frequently in swales among concentric levees of course sediment (scroll bars). Channel lakes have a length-to-width ratio of >5; dish levee lakes have a ratio of <5 (Hamilton and Lewis, 1990).

[7] Floodplain lakes have many regional names. In Australia, such lakes can be termed ***billabongs,*** a word of aboriginal origins that refers to lentic waterbodies on a river flood plain formed by the geomorphic action of the mainstream (Hillman, 1986). In Brazil, *várzea* and *ria* floodplain lakes are differentiated on the basis of suspended particulate and dissolved organic matter loadings from different soil types (Irion and Förstner, 1975).

Where rivers enter the relatively quiescent waters of a lake or the sea, sedimentation results in the formation of deltas, often of very large size. Occasionally, a delta is sufficiently large when entering a long, narrow lake on one side to form a barrier that divides the original lake in half. Much more common, however, are lakes that are formed in the deltas of all major rivers of the world. As the river velocity becomes reduced and sediments are deposited, the water tends to flow around the sediments in a U-shaped pattern where the open end extends seaward. As alluvial deposition extends further seaward, the inward depressions eventually are isolated as shallow lakes, often of large size. Subject to the influence of tides and other water movements of the sea, these ***deltaic lakes*** often receive salt water and frequently are brackish.

As a river meanders within the irregularities of the topography, greater turbulence and erosion occur on the outer, concave side of the river bend, while deposition occurs on the inner, convex side where currents and turbulence are reduced. With time, continued erosion and concavity take place until the U-shaped meander of the river closes in upon itself (Fig. 3-15). The main course of the river cuts a channel through the initial portion of the meander, and levee deposits eventually isolate the loop, referred to as an ***oxbow lake,*** from the river channel. The outer, erosional side of oxbow lakes is usually deeper than the inner, concave side.

G. Wind-Formed Lake Basins

Wind action operates in arid regions to create lake basins by deflation or erosion of broken rock, or by redistribution of sand, and forms ***dune lakes.*** Such lake depressions may be solely or partially the result of wind action, and the water they contain is often temporary and dependent upon fluctuations in climate.

Bayly and Williams (1973) and Timms (1986) differentiate several types of dune lakes based on those found in Australia and New Zealand, although they occur in many other parts of the world as well. Dune barrage lakes form behind sand dunes that are moving inland and blocking a river valley draining toward a coast. These lakes are typically triangular in shape, with the deepest part close to the sand dune, and are found inland in desert regions as well as in coastal areas. If a large amount of deflation occurs so that little or no sand is left on the floor between the trailing arms of parabolic dunes and an impervious rock floor is exposed, a lake may develop. Organic additions from vegetation assist in creating impervious, organically bonded sand–rock in dune depressions. Deflation depressions that are permeable to water can form lakes when they extend below an extensive water table.

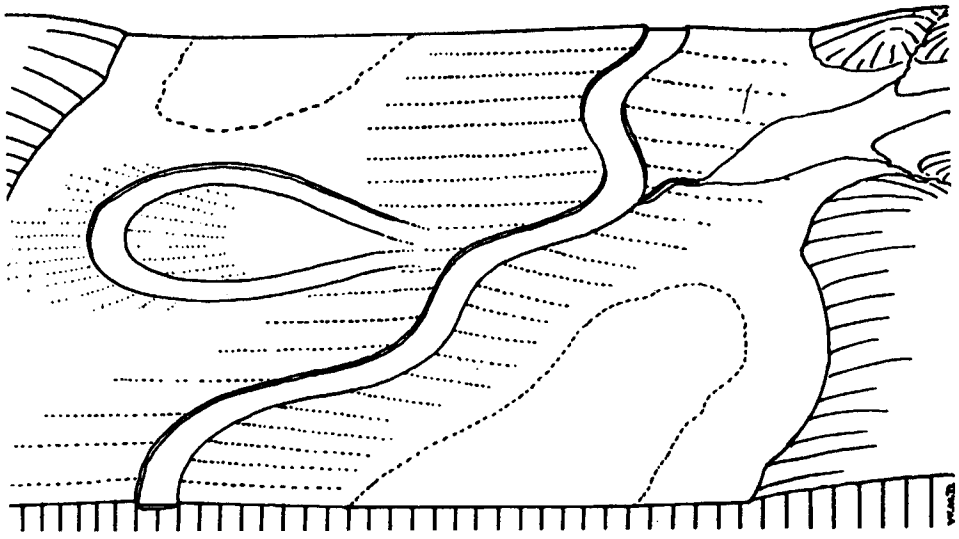

FIGURE 3-15 Diagram of lakes, including an isolated oxbow lake, and sloughs resulting from river activity. (From Davis, W. M.: *Calif. J. Mines Geol.* 29:175, 1933.)

Numerous small, shallow lakes of this type occur along the eastern shore of Lake Michigan among wind-blown depressions of the sand dunes (e.g., Barko *et al.*, 1977). All of these lakes are extremely transitory.

Deflation basins are also common where material is moved and eroded from horizontal strata of rock or clay. The wind-eroded material may be deposited in crescent-shaped mounds downwind or removed completely from the area, which permits the formation of large pans on nearly level areas, often called ***playas.***[8] Deflation basins commonly fill with water during rainy seasons or wet periods and become increasingly saline with evaporation and dry during opposing seasons or dry periods. These ephemeral lakes are common in large portions of Australia, south Africa, endorheic (see p. 46) regions of Asia and South America, and the plains and arid regions of the United States.

H. Basins Formed by Shoreline Activity

When the coast line of a large body of water, such as the sea or a large lake, possesses some irregularity or indentation, the potential exists for the formation of a bar across the depressions to form a ***coastal lake.*** A longshore current flowing along the shore line and carrying sediment will, on encountering a bay, deposit the material in the form of a bar or spit across the mouth of the indentation (Fig. 3-16). Often the spit can eventually separate the bay from the sea or large lake to form a coastal lake.

Marine coastal lakes commonly result from bar formation across the mouths of old estuaries that have been inundated by rising water levels or slight subsidence of the land. Often, river discharge and tidal currents are sufficient to prevent complete separation of the lake from the sea. The result is an alternation between fresh and brackish water in the lake, and the salinity depends upon the ratio of freshwater inputs and saltwater intrusions. Other coastal lakes are completely separated from the sea.

Numerous coastal lakes are found inland, adjacent to large lakes. The formation of these water bodies occurs in analogous fashion, by the deposition of bars across bays and river valleys. Spits are known to have formed on two sides of a lake as a result of current patterns in relation to specific morphometry. The spits may then join in the middle, dividing the lake into two.

I. Lakes of Organic Origin

The array of lakes created by the damming action of plant growth and associated detritus is incompletely known. It is clear that plant growth can be sufficiently profuse to dam the outlet of shallow depressions and alter the drainage pattern of lakes. Such alterations of drainage by plant growth are common in dystrophic lakes (cf. Chap. 25). The drainage patterns of many lakes, particularly in flood plains of tropical river systems, can be extensively altered by the massive growths of emergent and floating aquatic plants (cf. Beadle, 1974). The effectiveness of this method of water

[8] *Playa* is a geological term for flat and generally barren lower portions of arid basins that periodically flood (*a playa lake*) and accumulate sediment. Most basins of playas have multiple origins (see detailed review of Neal, 1975).

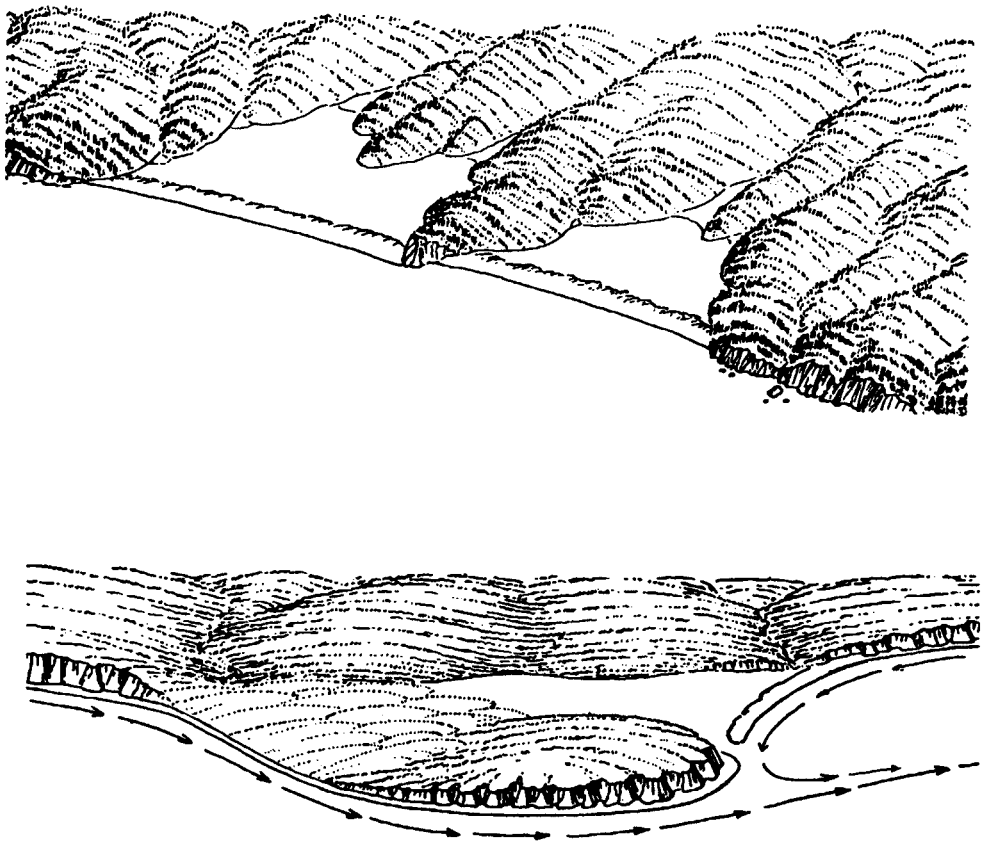

FIGURE 3-16 *Upper:* Coastal lakes formed by enclosure of lagoons by wave and current-built bars on a shore line embayed by slight subsidence. *Lower:* A land-bound island with a bay behind it, closed by a sand-reef beach formed by reverse eddy currents. (After Davis, W. M.: *Calif. J. Mines Geol.* 29:175, 1933.)

retention in flat regions, such as the arctic tundra, is unknown. The photosynthetic activities of attached cyanobacteria and algae as well as other plants can induce massive precipitation of $CaCO_3$ from calcareous waters. In time, these deposits can form barriers and isolate small bodies of water from stream systems (cf. Golubić, 1975).

1. Reservoirs

Two mammals, the beaver and humans, are particularly effective in constructing dams across river valleys to impound water into lakes. The American beaver created numerous large, long-lived lakes, many of which became permanent by means of sediment deposited against the dams. Humans have created artificial lakes by damming streams for at least 4000 years. Only in the last two centuries, however, has this activity become highly significant for the purposes of flood control and the provision of power and water supplies for urban populations.

Reservoirs are being constructed on an unprecedented scale in response to the exponential demophoric demands of humans. Plans for the construction of enormous reservoirs, approaching the area of some of the Laurentian Great Lakes, are underway in Canada and the Soviet Union. Such massive alterations of large drainage systems will result in major modifications in topography and regional climate that are not yet fully recognized or even partially understood. A great need exists for careful planning in the construction of reservoirs because deleterious effects commonly exceed expected benefits (cf. Dussart *et al.*, 1972).

Small, shallow reservoirs, in the form of farm ponds and moderate-sized inundations, have created literally millions of small lakes (see Chap. 20). Particularly characteristic of the morphometry of these lakes is that they are generally shallow and possess large areas where macrophytic vegetation can grow. Such plant life radically alters the productivity of the lake system (Chaps. 18 and 20). Moreover, small reservoirs

generally receive high nutrient inputs in relation to their volume, which further increases their productive capacity. Most reservoirs are relatively short-lived because of the extensive sediment load delivered by the influents.

VI. MORPHOLOGY OF LAKE BASINS

The shape and size of a lake basin affect nearly all physical, chemical, and biological parameters of lakes. The forms of lake basins are extremely varied and reflect their modes of origin, how water movements have subsequently modified the basin, and the extent of loading of materials from the surrounding drainage basin.

The morphometry of a lake is best described by a bathymetric map, which is required for the determination of all major morphometric parameters. Such a map is prepared by a survey of the shoreline by standard surveying methods, often in combination with aerial photography. From the map of the shore line a detailed bathymetric map of depth contours must be constructed from a series of accurate depth soundings along intersecting transects. Methods commonly employed for both lake and stream mapping are discussed by Welch (1948), Håkanson (1981), and Wetzel and Likens (2000). Accurate sonar transects, which permit acquisition of much greater detail than was previously possible by manual sounding methods, are now used almost exclusively.

A. Morphometric Parameters

The many morphometric parameters that can be determined from a detailed bathymetric map are discussed at length by Hutchinson (1957). The most commonly used parameters are defined here.

Maximum Length (l). The distance on the lake surface between the two most distant points on the lake shore. This length is the maximum effective length or fetch for wind to interact on the lake without land interruption.

Maximum Width or Breadth (b). The maximum distance on the lake surface at a right angle to the line of maximum length between the shores. The mean width ($\bar{b}$) is equal to the area divided by the maximum length: $\bar{b} = A/1$.

Area (A). The area of the surface and each contour at depth z is best determined by digital integration or planimetry (cf. Welch, 1948; Wetzel and Likens, 2000) or, less precisely, by a grid enumeration analysis (Olson, 1960).

Volume (V). The volume of the basin is the integral of the areas of each stratum at successive depths from the surface to the point of maximum depth. The volume is closely approximated by plotting the areas of contours, as closely spaced as possible, against depth. The integrated area of this curve corresponds to basin volume. Alternatively, the volume can be estimated by summation of the frusta of a series of truncated cones of the strata:

$$V = \frac{h}{3}(A_1 + A_2 + \sqrt{A_1 A_2})$$

where h is the vertical depth of the stratum, A_1 the area of the upper surface, and A_2 the area of the lower surface of the stratum whose volume is to be determined.

Maximum Depth (z_m). The greatest depth of the lake.

Mean Depth ($\bar{z}$). The volume divided by its surface area: $\bar{z} = V/A$.

Relative Depth (z_r). The ratio of the maximum depth as a percentage of the mean diameter of the lake at the surface, expressed as a percentage.

$$z_r = \frac{50 z_m \sqrt{\pi}}{\sqrt{A_0}}$$

Most lakes have a z_r of less than 2%, whereas deep lakes with a small surface area usually have $z_r > 4\%$.

Shore Line (L).[9] The intersection of the land with permanent water is nearly constant in most natural lakes. The shore line, however, can fluctuate widely in ephemeral lakes and especially in reservoirs in response to variations in precipitation and discharge. The length of the shore line can be determined directly or from maps with a map measurer (chartometer or rotometer; cf. Welch, 1948; Wetzel and Likens, 2000).

Shoreline Development (D_L). The ratio of the length of the shore line (L) to the circumference of a circle of area equal to that of the lake:

$$D_L = \frac{L}{2\sqrt{\pi A_0}}$$

Very circular lakes, such as crater lakes and some kettle lakes, approach the minimum shoreline development value of unity. The conformation of most lakes, however, deviates strongly from the circular. Many are subcircular or elliptical in form, with D_L values of about 2. A more elongated morphometry increases the value of D_L markedly, as for example is found in the dendritic outlines of lakes occupying flooded river valleys. Shoreline development is of considerable interest

[9] Two words (*shore line*) as a noun; one (*shoreline*) as an adjective.

because it reflects the potential for greater development of littoral communities in proportion to the volume of the lake.

B. Hypsographic and Volume Curves

The shape of a lake basin can influence biological productivity. In comparative analyses of productivity among lakes, quantitative morphometric analyses of the relationships of lake surface area to the area of sediments exposed to specific volumes of water at different depths permit insights into potential parameters that influence productivity.

The ***hypsographic curve*** (depth–area curve) is a graphical representation of the relationship of the surface area of a lake to its depth (Fig. 3-17). The hypsographic curve represents the relative proportion of the bottom area of the lake that is included between the strata under consideration. The hypsographic curve is, however, only an approximation of the area of the exposed lake bottom because areal measurements are related to the horizontal plane of the lake surface, whereas the actual sediments are slightly sloped and greater in area. The area of the bottom below a square meter of lake surface is larger if the slope of the bottom is appreciable. For example, if the slope of the bottom were 15° from the horizontal, the area of bottom below 1 m^2 at the surface would be 1.04 times greater (Loeb *et al.*, 1983). If the bottom slope were 35°, the benthic area would be 1.22 times greater than the area at the water surface. The hypsographic curve may be expressed in absolute terms (m^2, hectares, or km^2) or as a percentage of the lake area overlying a given depth contour (Fig. 3-17).

The ***depth–volume curve*** is closely related to the hypsographic curve and represents the relationship of

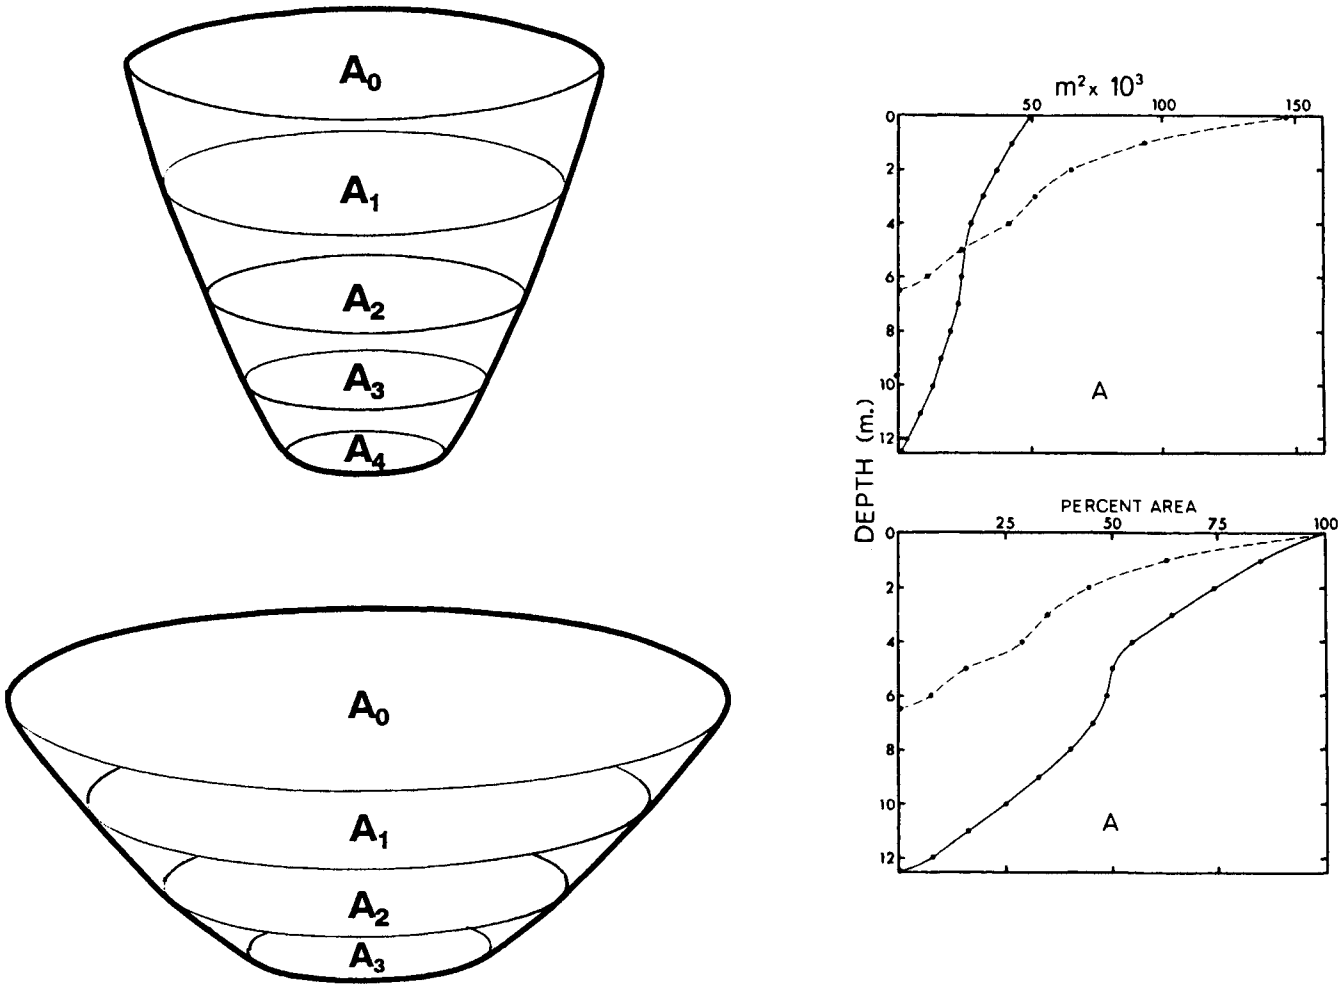

FIGURE 3-17 Hypsographic (depth–area) curves of oligotrophic Lawrence Lake (——) and eutrophic Wintergreen Lake (----), southwestern Michigan. (From Wetzel, R. G., unpublished data.)

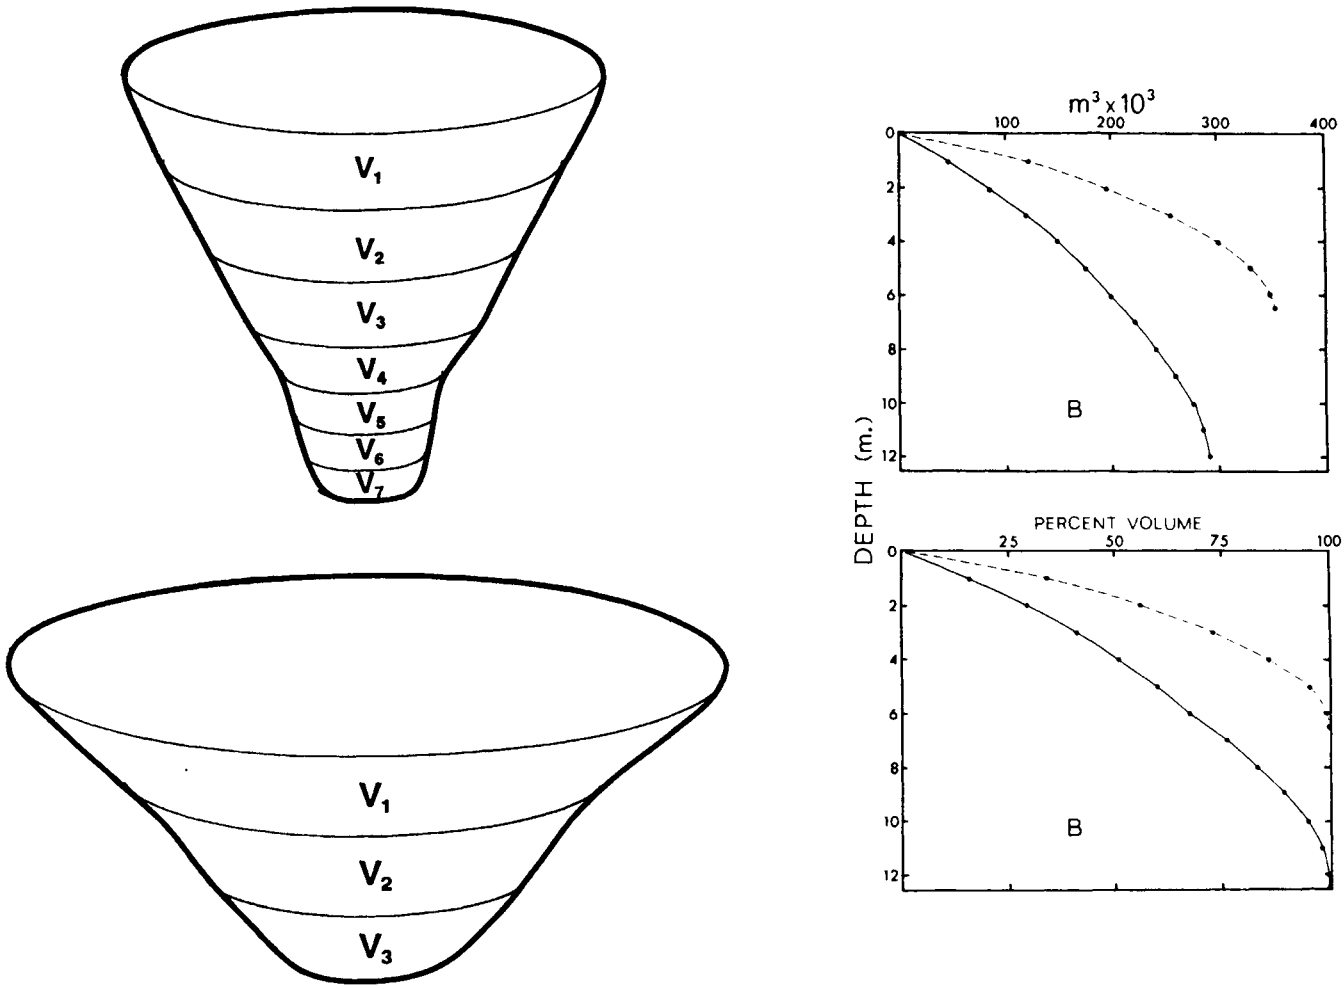

FIGURE 3-18 Depth–volume curves of oligotrophic Lawrence Lake (——) and eutrophic Wintergreen Lake (----), southwestern Michigan. (From Wetzel, R. G., unpublished data.)

lake volume to depth (Fig. 3-18). Similarly, the depth–volume curve can be expressed in actual volume units (m^3 or km^3) or in percentage of total lake volume above a specific depth. The depth–volume curve can be used to estimate readily the approximate mean depth of a body of water, that is, that depth above which 50% of the lake volume occurs.

Among lakes with otherwise comparable conditions, biological productivity is generally greater in those with more sediments in contact with water that receives sufficient light to support photosynthesis (Thienemann, 1927; Strøm, 1933; Rawson, 1955, 1956). The extent of shallow water in a lake is a determining factor in the interrelationships of these zones of photosynthetic production and of decomposition (cf. Ch. 6) and determines the area available for the growth of rooted aquatic plants and associated littoral communities (cf. Chaps. 18 and 19).

The ratio of mean to maximum depth ($z{:}z_m$) is an expression similar to the ratio of the volume of the lake to that of a cone of basal area A and height z_m [$A\bar{z}/\frac{1}{3}z_mA = 3\bar{z}/z_m$]. The ratio $\bar{z}{:}z_m$ thus gives a comparative value of the form of the basin in terms of volume development. For most lakes, the value $\bar{z}{:}z_m$ is >0.33, which is the value that would be given by a perfect conical depression. The ratio exceeds 0.5 in many caldera, graben, and fjord lakes, whereas most lakes in easily eroded rock usually have ratios between 0.33 and 0.5. Very low values of $\bar{z}{:}z_m$ occur only in lakes with deep holes, such as solution or kettle lakes.

Examination of the morphometry of a large number of lakes has shown that the average shape of lake basins approximates an elliptic sinusoid (Neumann, 1959; Fig. 3-19). The elliptic sinusoid is a geometric body whose base is an ellipse, so that planes perpendicular to the base of an ellipse passing through the center

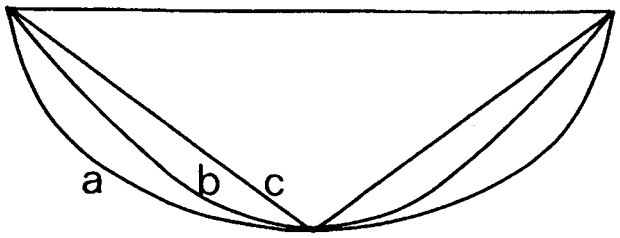

FIGURE 3-19 Vertical cross sections through three forms of lake basins: (a) half an ellipsoid of revolution; (b) elliptic sinusoid; and (c) right elliptic cone. (Modified from Neumann, 1959.)

of the ellipse intersect the surface of the body along troughs of sine curves. The volume of such an elliptic sinusoid is:

$$V = 4\left(1 - \frac{2}{\pi}\right)abz_m = 1.456abz_m$$

where a and b are the half-axes of the lake surface ellipse. Since the area of the lake surface ellipse concerned is πab, $\bar{z} = V/A = 0.464z_m$, the ratio $\bar{z}{:}z_m = 0.464$. This value is very close to the average value (0.467) of the ratio for over 100 lakes that have been evaluated (cf. also Hayes, 1957; Anderson, 1961; Koshinsky, 1970). Therefore, the elliptic sinusoid serves as a good model for an average lake in which irregularities and submerged depression individuality are not severe. The mean depth of an average lake is slightly less than one-half (0.46) of its maximum depth.

Since the pioneering work of Thienemann, much attention has been focused on the importance of lake morphometry, especially mean depth, to lake productivity in relation to the effects of climatic and edaphic factors (Hutchinson, 1938; Rawson, 1952, 1955, 1956; Edmondson, 1961; Patalas, 1961; Hayes and Anthony, 1964). Mean depth was regarded as the best single index of morphometric conditions, and mean depth exhibits a general inverse correlation to productivity at many trophic levels among large lakes.

A ***morphoedaphic index*** (MEI) was set forth initially to couple empirical log-log relationships of fish productivity (mass/area/time) with abiotic parameters of lake–basin morphometry, expressed as mean depth, volume, and area (Ryder, 1965, 1982). The MEI was a simple ratio, $N/\bar{z}$, where N is a nutrient value or related parameter, and $\bar{z}$ was the mean depth or another appropriate morphometric surrogate. Originally, total dissolved solids and mean depth were used and correlated to some empirical measure of fish yield or of productivity. The ratio was modified extensively with many different parameters for the nutrient component, and the concept was extended to many other biotic measurements among the plankton and benthic organisms. Often, the resulting ratios were misapplied, particularly with self-correlations, and severely criticized for statistical misuse of ratio variables in linear regression modeling (Jackson *et al.*, 1990). These models can be modified to overcome some of the shortcomings to allow certain morphometric parameters of surface area and lake volume to weakly predict, on the basis of total dissolved solids, annual fish yield for moderately deep lakes (Rempel and Colby, 1991). The MEI, however, does not account for the age structure of the fish populations or the recruitment differences within the populations. The production values used are the harvested portion of the older age structures of the populations, taken for commercial or sport purposes, which are not necessarily indicative, and likely marked underestimates, of real production.

The morphoedaphic relationship deteriorates among small lakes and indicates, as will become apparent in later discussions, that regulation of the dynamics of metabolism and productivity in aquatic ecosystems is multifaceted. For example, in shallow lakes various mineral substances of bottom sediments can be resuspended by water movements and cause high turbidity. The suspended materials often include clays brought into lakes and reservoirs from eroding soils, glacial flours, and calcite precipitates in hard waters. Turbidity can persist for long periods of time, reduce light availability, and markedly suppress the productivity of phytoplankton and littoral plants as well as higher trophic levels, regardless of nutrient loading (e.g., Cuker *et al.*, 1990). Thus, the morphometry of the lake basins is only one, although an important, interacting parameter regulating overall productivity but is of very limited value alone for the prediction of ecosystem productivity.

VII. RESERVOIRS

Much of our limnological understanding originates from natural lake ecosystems. Hundreds of thousands of reservoirs, however, have been created by human activities. These artificial water bodies have been created for specific purposes of water management. Examples include water storage, flood control, generation of electrical energy, and recreation.

Reservoirs differ in significant ways from natural lake ecosystems. Study of reservoir ecosystems, however, indicates many functional similarities between artificial and natural lakes. In order to effectively manage and utilize reservoirs, it is important to understand the structural differences between these human-made ecosystems and natural lakes while simultaneously appreciating their functional similarities. Understanding of these structural differences is mandatory for effective

management and use of impounded water resources. Failure to recognize basic similarities in metabolic functioning and community interrelationships of the biota will only result in redundancies in reservoir research that can be basically understood from our existing knowledge of processes in natural lakes.

A. Reservoir Characteristics

Reservoirs are most frequently constructed by damming a river valley, within which water accumulates behind the dam. Water released downstream is regulated according to water inputs from the drainage basin as well as uses of the water. As a result of the common linear morphology in a river valley, several distinct physical and biological patterns develop longitudinally along the length of reservoirs. Small reservoirs and artificial ponds are constructed also in valley depressions to which inflows occur by surface flows and/or seepage. In some cases, excavations of soil for construction or mining purposes result in reservoirs or artificial lakes as the excavations cut into water table aquifers (e.g., strip mining lakes, "barrow pit" lakes adjacent to major highways). Among many excavated reservoirs outflows may occur only by subaqueous seepage or evaporation during much of the year. The dam or levees may be breached only occasionally during and following major precipitation events.

Large reservoirs also bring about complex hydrodynamic characteristics with physical and chemical changes that influence aquatic biota in many ways and can be deleterious to the environment and human welfare (e.g., Morgan, 1971; Baxter, 1985). Large impoundments often modify the regions in their vicinities or for large distances below the dam. The reservoir serves as a source or sink for heat, sediments, and solutes that can cause severe effects far downstream from the dam, sometimes for hundreds of kilometers. Diurnal and annual flooding patterns are altered (see Chap. 26), and movements of anadromous fishes are impeded or inhibited.

Because many reservoirs function to reduce river flows, they serve as collectors of riverine sediment loads. As a result, the longevity of reservoirs is often very short, generally less than 100 years. The short-term gains in flood control, hydropower, and other assets must be carefully evaluated against disadvantages. Reservoirs may contribute to the spread of certain diseases that contain waterborne vectors and may reduce the incidence of others. Sometimes serious dislocations of traditional human societies occur.

B. Zonation in Reservoirs

Three distinct zones occur along the longitudinal gradient: a *riverine* zone, a zone of *transition*, and a *lacustrine* zone (Fig. 3-20). Each zone possesses unique and dynamic physical, chemical, and biological characteristics. The riverine zone is often relatively narrow as a result of river geomorphology. Water is usually well mixed. Although water velocities decrease as the water enters the reservoir, advective transport by currents is sufficient to move significant quantities of fine suspended particulates (silts, clays, and organic particulate matter) (Thornton, 1990). High particulate turbidity commonly reduces light penetration and limits primary production within the water of this zone. Loading of organic matter from allochthonous sources is high in proportion to water volume in the riverine zone. High decompositional rates often result with high consumption of dissolved

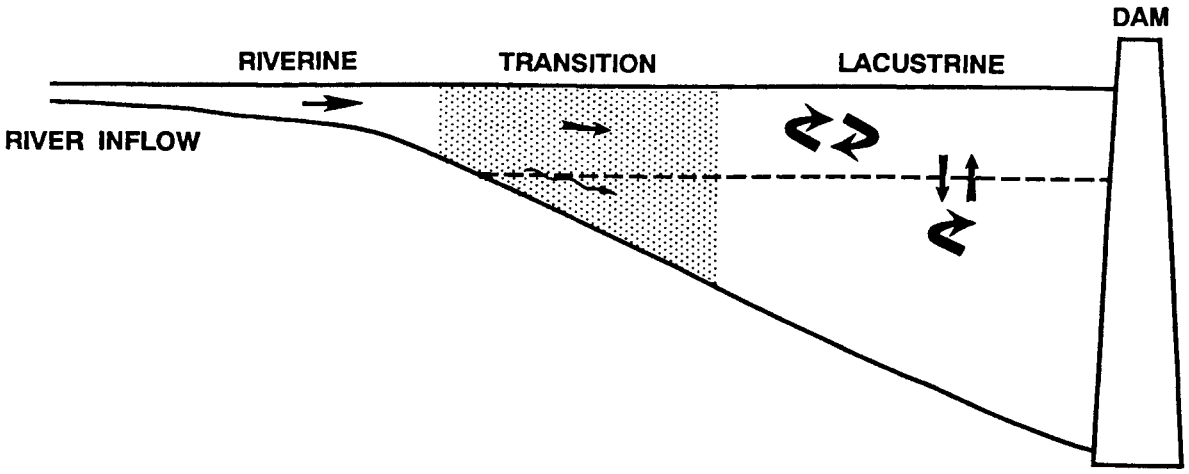

FIGURE 3-20 Generalized zones along longitudinal gradients in reservoirs.

oxygen, but aerobic conditions generally prevail in the shallow, well-mixed riverine zone.

Riverine water velocities decrease as energy is dispersed over larger areas in the transitional zone (Fig. 3-20). An appreciable portion of the turbidity load settles out of the upper water strata as a result. Decreased turbidity results in enhanced depth of light penetration and increased rates of photosynthetic productivity by phytoplankton. Gradually, a shift occurs to an increasing percentage of total organic matter loading from phytoplankton and, in some shallow reservoirs, from rooted vascular plants.

Within the lacustrine zone, characteristics become more similar to lake ecosystems (Fig. 3-20). This portion of the reservoir often stratifies thermally and assumes many of the properties of natural lakes in regard to planktonic production, limitations by nutrients, sedimentation of organic matter, and decomposition in the hypolimnion. Stratification and water movements can be modified or complicated, both spatially and in time, by hypolimnetic or bottom withdrawal of water from the reservoir at the dam, as is commonly the case.

VIII. COMPARATIVE GEOMORPHOLOGICAL CHARACTERISTICS

Comparative analyses of the structural differences in geomorphological characteristics and properties among rivers, reservoirs, and natural lakes can be instructive to point out functional similarities among these different but integrated ecosystems. A comparative summary of relative morphological attributes is presented in Table 3-4.

Rivers are erosional where moderate to rapid flow prevails and are depositional of silt and organic particles in sections of slow current. River channel characteristics are constantly changing in relation to variables of discharge, width, depth, substrata resistance, and transport of sediment.

TABLE 3-4 Comparative Geomorphological Characteristics and Properties among River, Reservoir, and Natural Lake Ecosystems[a]

Property	*Rivers*	*Reservoirs*	*Natural lakes*
Drainage basins	Many small tributaries coalesce into trunk stream; drainage area high in relation to surface area	Usually narrow, elongated lake basin in base or drainage area; area large in comparison to lake area (ca. 100:1 to 300:1)	Circular, lake basin usually central; drainage area usually small in comparison to lake area (ca. 10:1)
Shape	Long, meandering, linear rivers elongate as drainage basins increase in size	Variable, ovoid to triangular	Circular to elliptical predominate
Mean depth	Shallow in headwaters, increases to mouth	Shallow in riverine portions, increasing in lacustrine zones	Moderate to high; average less than 10 m
Depth gradient	Increases from headwaters to mouth	Increases from riverine through transitional to lacustrine zones	Deepest usually remote from shore line
Shoreline erosion and substrata distribution	Extensive, induced by water currents, gravity driven	Extensive in riverine areas by water currents; less from wind-induced currents in lacustrine zones	Localized, induced by wind-generated waves and currents
Shoreline development	Great, astatic	Great, astatic	Relatively low; stable
Sediment loading	High with large drainage basin area	Large with large drainage basin area; flood plains large; deltas large, channelized, gradation rapid	Low to very low; deltas small, broad, gradation slow
Deposition of sediments	Determined by water currents; highly variable with precipitation events	High in riverine zone, decreasing exponentially down reservoir; greatest in old riverbed valley; highly variable seasonally	Low, limited dispersal; relatively constant rates seasonally
Sediment suspended in water (turbidity)	High, variable	High, variable; high percentage of clay and silt particles; turbidity high	Low to very low; turbidity low

[a] Assembled from data of many sources particularly of the syntheses on rivers by Ryder and Pesendorfer (1989) and on reservoirs and lakes by Wetzel (1990b) and many references cited therein.

TABLE 3-5 Comparative Hydrodynamic Characteristics among River, Reservoir, and Natural Lake Ecosystems[a]

	Rivers	*Reservoirs*	*Natural lakes*
Water level fluctuations	Large, rapid, irregular; flooding common	Large, irregular	Small, stable
Inflow	Overland and groundwater runoff; highly irregular and seasonal, less so with large groundwater inflows	Most runoff to reservoir via river tributaries (high stream orders); penetration into stratified strata complex (over-, inter-, and underflows); often flow is directed along old riverbed valley	Runoff to lake via tributaries (often low stream orders) and diffuse sources; penetration into stratified waters small and dispersive
Outflow (withdrawal)	Discharge highly irregular with inflows and precipitation event frequency	Highly irregular with water use; withdrawals from surface layers or from hypolimnion	Relatively stable; usually largely surface water via surface outflow or shallow ground water
Flushing rates	Rapid, unidirectional, horizontal	Short, variable (days to several weeks); increase with surface withdrawal, disruption of stratification with hypolimnetic withdrawal; three dimensional	Long, relatively constant (one to many years); three-dimensional

[a] Assembled from many sources and the syntheses on rivers of Ryder and Pesendorfer (1980) and on reservoirs and lakes by Wetzel (1990b).

Reservoirs are created predominantly in regions where large natural lakes are sparse or unsuitable (e.g., too saline) for human exploitation. In these regions, the climate tends to be warmer than is the case in regions with many natural lakes, resulting in somewhat higher average water temperatures, longer growing seasons, and precipitation inputs that are closely balanced to, or less than, evaporative losses (Wetzel, 1990b). The drainage basins of reservoirs are consistently much larger in relation to the reservoir surface area than is the case among most natural lakes. Because reservoirs are almost always formed in river valleys and in the base of the drainage basins, the morphometry of reservoir basins is usually dendritic, narrow, and elongated (Table 3-5). These physical characteristics affect biological processes in many complex ways, the most important of which are light and nutrient availability. Reservoirs receive runoff water mainly via high-order streams, which results in higher energy for erosion, large sediment-load carrying capacities, and extensive penetration of dissolved and particulate loads into the recipient lake water. Since reservoir inflows are primarily channelized and often not intercepted by energy-dispersive and biologically active wetlands and littoral interface regions, runoff inputs are larger, more directly coupled to precipitation events, and extend much farther into the reservoir lake per se than is the case in most natural lakes (Table 3-5). All of these properties result in high, but irregularly pulsed, nutrient and sediment loading to the recipient reservoir.

Extreme and irregular water level fluctuations commonly occur in reservoirs as a result of flood inflow characteristics, land-use practices not conducive to water retention, channelization of primary influents, flood control, and large, irregular water withdrawals for hydropower generation operations (Table 3-5). Multiplicative effects on loadings result. Large areas of sediments are alternately inundated and exposed; these manipulations usually prevent the establishment of productive, stabilizing wetland and littoral flora. Erosion and resuspension of floodplain sediments augment high loadings from the large drainage basin sources. Surficial sediments are alternately shifted between aerobic and anaerobic conditions, which enhances nutrient release. The reduction or elimination of wetland and littoral communities around many reservoirs minimizes the extensive nutrient and physical sieving capacities that function effectively in most natural lake ecosystems (Wetzel, 1979, 1990a, 1990b). Consequently, shoreline erosion in natural lakes is small and localized to wind-generated currents. As a result, compared to reservoirs the basin morphology of natural lakes is relatively stable.

IX. SUMMARY

1. Some 40% of the total volume of fresh water is contained in the great lakes basins. Most lakes and reservoirs are much smaller, however, and are concentrated in the subarctic and temperate regions of the Northern Hemisphere. Most of the millions of

lakes are small and relatively shallow, usually <10 m in depth.

2. Rivers account for only an extremely small amount (0.0001%) of the water of the Earth but are major transporters of dissolved and particulate matter from the land to the sea.
   a. Water from precipitation enters drainage basins and either moves or is temporarily stored, particularly in soils.
   b. Stream flow and discharge are directly related to the drainage area. Differences are the result of variations in elevational gradients and soil characteristics.
   c. Stream and river channels move laterally within the flood plain because of erosion and redeposition of sediment.
   d. Forms of river channels deviate from four general classes: straight, meandering, braided, and anastomosing. River morphology varies widely with geology, drainage area, discharge, width–depth ratios, river bed material size, and channel slope.
3. Most natural lakes were formed by catastrophic events.
   a. *Tectonic* lake basins are depressions formed by displacements of the Earth's crust. Many of the deepest relict lakes of the world, such as *graben lake* basins, were formed by faulting movements. Uplifting of the earth has created a number of lake basins; these basins were often modified by glacial scouring activity.
   b. Lakes can result from ***volcanic*** activity. Small, deep *maar* lakes can form in volcanic cones; the collapse of the roof of partially emptied magmatic chambers can result in large, deep *caldera* lakes within a volcano. Lava flows often dam preexisting river valleys and create isolated lakes.
   c. Temporary or permanent lakes can result from ***landslides*** into stream valleys. Lakes can also form in depressions created behind the landslide material.
   d. The erosional and depositional activity of ***glaciers*** was the most important agent of lake formation. Many lakes were formed from the outwash morainal deposits at the retreating edges of continental glaciers or from melted blocks of ice buried in this morainal debris (*kettle lakes*). In mountainous regions, terminal and lateral morainal deposits can effectively dam river valleys and form lakes. Glaciers often scour lake basins in glaciated valleys of mountainous areas and form amphitheater-shaped depressions termed *cirque lakes*. Several cirque lakes can form in the trough of a mountain valley in a series of connected lakes of successively lower elevation (*paternoster lakes*). Many arctic and subarctic lakes also formed from glacial activity. Some arctic lakes (*cryogenic lakes*) are very shallow and form by water seepage into the permafrost, which, on freezing, forms a polygonic network of ridges that contains subsequent meltwater.
4. Other natural lakes form by gradual events.
   a. ***Solution lakes*** result from sinks, termed *dolines*, formed by the gradual dissolution of rock, such as limestone, along fissures and fractures. Eventually the superstructure is weakened to the point of collapse into the depression.
   b. The erosional and depositional action of ***river water*** can isolate depressions to form lakes (e.g., *plunge-pool lakes* below former waterfalls, *oxbow lakes* of former river channels).
   c. ***Wind erosion*** can form shallow depressions that often contain water temporarily or seasonally (e.g., *dune lakes* in sandy areas and *playa lakes* of flat, arid or semiarid regions).
   d. ***Coastal lakes*** often form along irregularities in the shore line of the sea or large lakes. Longshore currents deposit sediments in bars or spits that eventually isolate a fresh or brackish-water lake.
   e. ***Reservoirs*** are impoundments created largely by humans by the damming of river valleys. Because of high rates of sedimentation, reservoirs, smaller inundation lakes, and farm ponds are very short-lived.
5. Variation in basin morphology is great; most lake basins approximate an elliptic sinusoid shape. The mean depth of lakes is about half (0.46) of the maximum depth.
6. The morphology of a lake basin has profound effects on nearly all physical, chemical, and biological properties of the lake. Morphometry of lake basins and geological substrates of the drainage basin influence sediment–water interactions and lake productivity, especially extremely productive littoral communities. The greater productivity of small, shallow lakes is usually correlated with the higher water–sediment interface area per water volume (i.e., lower mean depth).
7. Reservoirs, formed by the damming of river valleys, possess three distinct zones along the longitudinal gradient:
   a. A narrow ***riverine zone*** has high advective water transport and high particulate turbidity.
   b. A ***zone of transition*** has decreased water velocities as energy is dispersed over larger areas.

Turbidity general decreases and sedimentation increases.

c. The ***lacustrine zone*** in the region above the dam has characteristics more similar to natural lakes in relation to stratification and morphological interactions.

8. Comparison of geomorphological characteristics among river, reservoir, and natural lake ecosystems focuses upon effects of water movements on erosion and movement of soil, rock, and sediments. Rivers are shallow and shift between erosional and depositional changes in water discharge. Natural lakes are morphologically much more stable than rivers and reservoirs in regard to depth, shoreline development, sediment loading, turbidity, and deposition of sediments.

4 WATER ECONOMY

I. Hydrological Cycle
  A. Evaporation and Precipitation
  B. Runoff Flow Processes
II. Global Water Balance
  A. Water Balance in Lake Basin
III. Summary

The water in lakes and rivers is balanced in the basic hydrological relationship in which change in water storage is governed by inputs from all sources less water losses. Water income from precipitation, surface influents, and groundwater sources is balanced by outflows from surface effluents, seepage to ground water, and evapotranspiration. Each of these incomes and losses varies seasonally and geographically and is governed by the characteristics of particular lake basins, their groundwater and river geomorphology, drainage basins, and the climate.

The distribution of water over continental land masses depends on the global hydrological cycle, in which excessive oceanic evaporation is counterbalanced by greater precipitation over land. The hydrological cycle, which can be altered extensively by human-induced changes of surface water systems, determines the distribution of lakes and rivers regionally in relation to the distribution of suitable catchment lake basins.

I. HYDROLOGICAL CYCLE

The hydrological cycle of the earth evaluates the cyclical budgetary processes of water movement. These processes include movement from the atmosphere, inflow, and temporary storage on land, and outflow to the primary reservoir, the oceans. The cycle consists of three principal phases: ***precipitation, evaporation,*** and ***surface and groundwater runoff.*** Each phase involves transport, temporary storage, and a change in the physical state of the water.

A. Evaporation and Precipitation

Evaporation of water into the atmosphere occurs from land, the oceans, and other water surfaces. Primary sites of evaporation include evaporation from precipitation; from precipitation intercepted by vegetation; from the oceans, lakes, and streams; from soils; and from transpiration of plants. Evaporation rates from each of these and other sources of water are determined by an array of dynamic environmental parameters (cf. Meinzer, 1942; Grey, 1970; Gates, 1980; Berner and Berner, 1987; Jones 1992). The mass of atmospheric water vapor, although small in relation to the amount of total global water, is stored as vapor for the least amount of time (average renewal time of 8.9 days) before returning to the earth as rain, snow, sleet, hail, or condensates (dew and frost), either on land or on the oceans.

Precipitated water may be intercepted or transpired by plants, may run off over the land surface to streams (surface runoff), or may infiltrate the ground (Fig. 4-1). Much of the intercepted water and surface runoff (up to 80%) is returned to the atmosphere by evaporation. Infiltrated water may be stored temporarily (average renewal time approximately 280 days) as soil moisture prior to being evapotranspired. Some of the water percolates to deeper zones to be stored as ground water (average renewal time of 300 years). Ground water

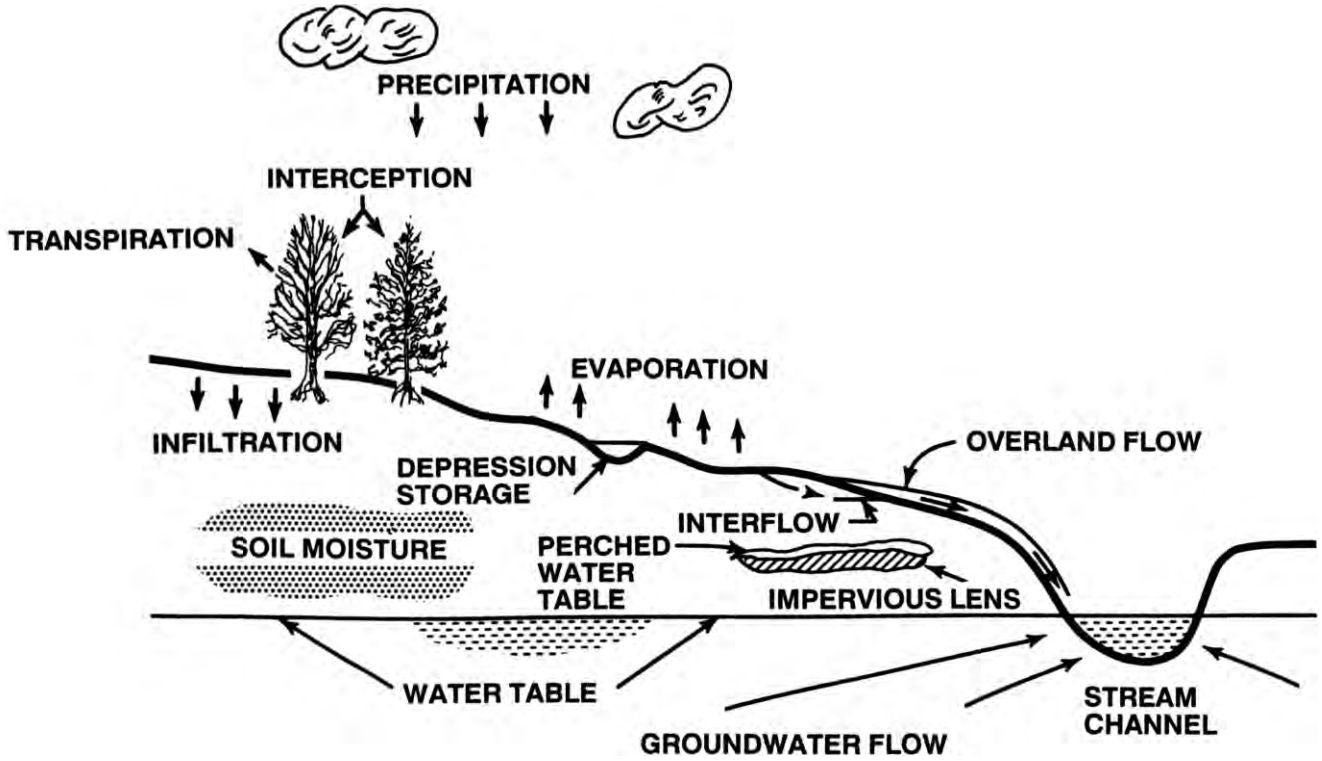

FIGURE 4-1 Major pathways of precipitation and the runoff phase of the hydrologic cycle. (From Wetzel and Likens, 1991.)

moves along flow paths of varying lengths from areas of recharge (precipitation on land, from lake, wetland, or river reservoirs) to areas of discharge. Ground water is actively exchanged and may be used by plants, flow out as springs, or seep to streams as runoff. The runoff phase is exceedingly complex and variable because of the extensive involvement with plants, the extreme heterogeneity of soil structure and composition, and variations in climate.

B. Runoff Flow Processes

The soil and rock of river and lake drainage basins determine pathways and regulate the rates of hillslope runoff of water received as rain and meltwater (cf. review of Dunne, 1978). These pathways of runoff influence many characteristics of the landscape, the uses to which land can be put, and the requirements for effective land management.

When the rate of rainfall or snow meltwater influx exceeds the absorptive capacity of the soil (i.e., the infiltration capacity is exceeded), the excess water flows over the surface as ***overland flow.*** Overland flow is most common in arid and semiarid regions; it also occurs in humid areas where the original vegetation and soil structure have been disturbed or in areas where normally porous soil contains a thin layer of frost and consequently cannot absorb meltwater (Dunne and Black, 1970a, 1970b, 1971).

The storage capacity of the soil is made continually available by evaporation and plant transpiration. Normally, most of the water from precipitation infiltrates the soil. When precipitation is first absorbed by the soil, the water may be stored or it may move by gravity along several pathways within the soil structure and along voids (cracks, worm or other animal burrows, old root channels) toward stream channels. If the soil or rock is deep and of relatively uniform permeability, the ***subsurface water*** moves vertically to the zone of saturation and then follows a generally curving path to the nearest stream drainage channel. This simple pattern of ***groundwater flow*** often is disrupted by irregularities of the base geological structure (Leopold *et al.,* 1964; Davis and DeWiest, 1966; Stephens, 1996; Winter *et al.,* 1998). Water progression can encounter impermeable layers that impede the vertical movement and cause lateral flow. The surface of the saturated zone of permeable soil is called the ***water table.*** Water in the soil above the water table is termed ***vadose water*** and that below the water table,

the ***ground water.*** Rates of groundwater flow are generally low and the pathways long; hence much of this ground water contributes to the relatively stable baseflow (see Fig. 3-5) of streams between periods of precipitation. Drainage of water from storms is added to this more uniform groundwater discharge. Although the long route of groundwater flow generally dominates the baseflow of streams, the rate of flow can increase in very permeable rock formations such as limestones and jointed basalts and add significantly to runoff from stormflows to recipient drainage streams.

The sediments of lake basins are generally quite impermeable to rapid inflows from ground water or to seepage outflows. Such connectivity with ground water is usually through shallow sediments near the land–water interface regions, often located in shallow wave-impacted sediments. Lakes, however, and particularly wetlands, can receive groundwater inflows throughout their sediments and have seepage outflows from many different, or nearly the entire, sediment areas. Hydraulic movement through dense organic-rich sediments, particularly of wetlands, is often low but can be accelerated by the uptake, conductance, and evapotranspiration of water by floating-leaved and emergent aquatic plants (Wetzel, 1999a).

When shallow surface soil and weathered rock is permeable and underlaid with relatively impermeable soil horizons, percolating water will be diverted horizontally as ***subsurface stormflow.*** The shallow subsurface pathway of drainage to a stream channel or lake basin is much shorter than the pathway of groundwater flow and generally occurs in soils of high permeability. Therefore, subsurface stormflow can be volumetrically greater than runoff, particularly along steep gradients in narrow drainage valleys.

As subsurface water flows down the gradient of a hillslope, vertical and horizontal ***percolation*** can saturate the soil. Shallow subsurface flow encountering these saturated areas emerges from the soil surface as ***return flow*** and continues to the recipient channel or basin as overland flow. Similarly, direct precipitation onto saturated areas flows over the surface of the soil. These processes assume greater significance in gently sloping, wide valleys with thin soils.

Each of these processes of rainfall or meltwater runoff responds differently to variations in topography, soil, and characteristics of the precipitation events themselves and indirectly to variations in climate, vegetation, and land use. Therefore, runoff flow processes control the volume, periodicity, and chemical characteristics of water entering streams and lake basins. Water that infiltrates the soil and then flows laterally as subsurface stormflows added to overland flow is the main component of peak flows or ***floods*** (cf. Dunne, 1978; Chorley, 1978).

II. GLOBAL WATER BALANCE

More water evaporates from the oceans than is returned via precipitation, whereas on land more water is received via precipitation than is lost by evaporation (Fig. 4-2). Most continental water income originates from evaporation of the oceans. The water of land masses is not uniformly distributed over the major

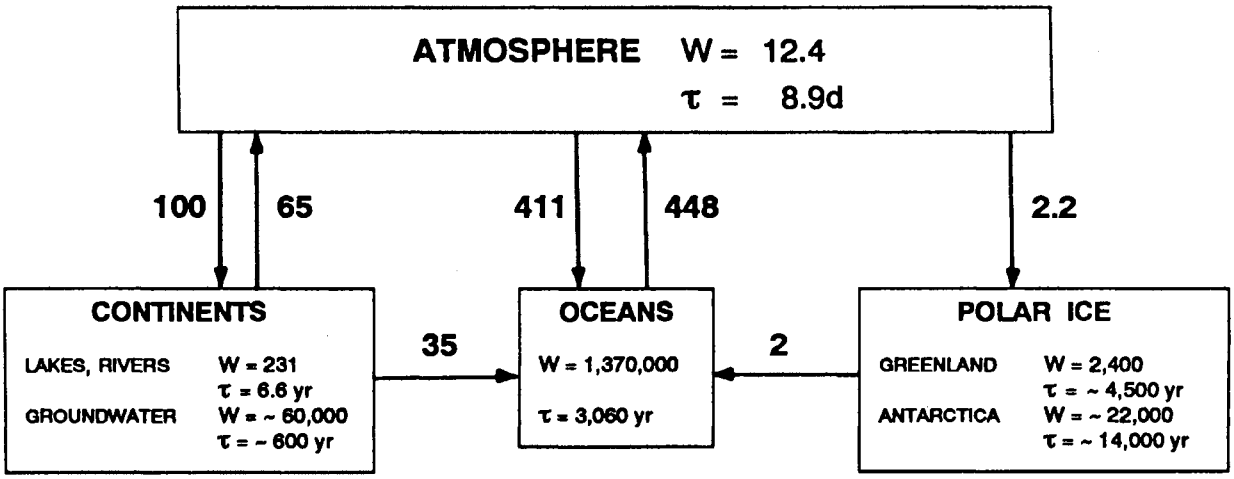

FIGURE 4-2 Global water balance. W = water content in 10^3 km^3, values on arrows = transport in 10^3 km^3 yr^{-1}, and τ = retention time. Estimate of ground water is to a depth of 5 km in the Earth's crust; much of this water is not actively exchanged. (Modified from Flohn, 1973, after L'vovich.)

TABLE 4-1 Water Resources and Annual Water Balance of the Continents of the World[a]

	Europe[b]	*Asia*	*Africa*	*N. America*[c]	*S. America*	*Australia*[d]	*Total*
Area (10^6 km^2)	9.8	45.0	30.3	20.7	17.8	8.7	132.3
Precipitation (km^3)	7165	32,690	20,780	13,910	29,355	6405	110,305
River runoff (km^3)							
Total	3110	13,190	4225	5960	10,380	1965	38,830
Underground	1065	3410	1465	1740	3740	465	11,885
Surface	2045	9780	2760	4220	6640	1500	26,945
Total soil moistening (infiltration and renewal of soil moisture)	5120	22,910	18,020	9690	22,715	4905	83,360
Evaporation	4055	19,500	16,555	7950	18,975	4440	71,475
Underground runoff (% of total)	34	26	35	32	36	24	31

[c] Includes Central America but not the Canadian archipelago.
[d] Includes New Zealand, Tasmania, and Papua New Guinea.

continents (Table 4-1). The total and groundwater runoff are greatest in South America, nearly twice that per area of the other continents.

Until recent times, the global water balance fluctuated very little. Humans have introduced regional fluctuations by extensive environmental modifications for irrigation, industrial, and domestic uses, such as land clearing to obtain more arable land, changes in drainage patterns, and exploitation of groundwater reserves (Flohn, 1973). Water demand for agricultural and industrial purposes is projected to increase the human-induced fraction of continental evaporation from its present nearly 3%–10% soon after the year 2000, and to 50% well before the end of the twenty-first century. The result is an accelerated rate of continental freshwater turnover. Because freshwater supplies are inadequate where demand is greatest, continued expansions at sites of high demand will be curtailed. Large-scale desalinization of sea water, at great energy expense, is a practical contemporary alternative for expansions of freshwater exploitation. The energy costs for redistribution of water, however, restrict desalinization of sea water to coastal regions. Manipulations of surface waters on a massive scale will inevitably lead to irreversible modifications of climate. Modifications of regional climatic conditions have already occurred as a result of extensive alterations of large river systems in which surface waters and evaporation are increased greatly. These modifications are further confounded by those associated with global climate changes induced by human-induced alterations in the gaseous composition of the atmosphere.

Three hydrological regions are recognized among the continental land masses (Hutchinson, 1957). The distribution of lakes is related partly to distribution of lake basins and partly to that of water. ***Exorheic regions,*** within which rivers originate and from which they flow to the sea, contain the major lake districts of the world and most of the lakes. ***Endorheic regions,*** within which rivers arise but never reach the sea, occur between subtropical deserts and the tropical and temperate humid regions. ***Arheic regions,*** within which no rivers arise, are desert areas that occur in the latitudes of the trade winds, between which lies the zone of equatorial rains. Endorheic regions, transitional in nature between the other two, can shift to exorheic or arheic characteristics with relatively small changes in climate.

A. Water Balance in Lake Basins

The water balance of a lake is evaluated by the basic hydrological equation in which the change in storage of the volume of water in or on the given area per unit time is equal to the rate of inflow from all sources less the rate of water loss. Water income to a lake includes several sources.

(a) *Precipitation Directly on the Lake Surface.* Although most lakes, largely in exorheic regions, receive a relatively small proportion of their total water income from direct precipitation, this percentage varies greatly and increases in very large lakes. Extreme examples include equatorial Lake Victoria of Africa, which receives most (>84%) of its water from precipitation on its surface (Kilham and Kilham, 1990; Yin and Nicholson, 1998), and the endorheic Dead Sea, which receives practically no water from direct precipitation.

(b) *Water from Surface Influents of the Drainage Basin.*[1] The amount of the total water income to a lake from surface influents is highly variable. Lakes of endorheic regions receive nearly all their water from surface runoff. The rate of runoff from the drainage basin and corresponding changes in lake level are influenced strongly by the nature of the soil and vegetation cover of the drainage basin. One of the best examples of this effect resulted from the experimental forest cutting and use of herbicides to prevent vegetation regrowth in the Hubbard Brook drainage in New Hampshire (Likens *et al.*, 1967, 1970, 1977; Bormann and Likens, 1979; Likens and Bormann, 1995). Annual streamflow increased 39% the first year and 28% the second year above the values prior to selective deforestation.

(c) *Groundwater Seepage below the Surface of the Lake.* Seepage of ground water is commonly a major source of water for lakes in rock basins and lake basins in glacial tills that extend well below the water table. Sublacustrine groundwater seepage forms the major source of water flow into, and out of, karst and doline lakes of limestone substrata.

(d) *Ground Water Entering Lakes as Discrete Springs.* Sublacustrine springs from ground water occur frequently in hardwater lakes of calcareous drift regions, where the basin is effectively sealed from groundwater seepage by deposits within the basin. For example, ground water largely from springs contributed nearly 40% of the annual water income to calcareous Lawrence Lake, Michigan, in comparison to 10% from precipitation and the remainder from surface runoff in two streams (Table 4-2). Groundwater inputs were closely related to rates of precipitation and evapotranspiration each month.

In ***drainage lakes,*** loss of water occurs by ***flow from an outlet*** (Birge and Juday, 1934), and in ***seepage lakes*** losses occur by ***seepage into the ground water*** through the basin walls. Deposition of clays and silts commonly forms a very effective seal in drainage lakes, from which most or all of the outflow leaves by a surface outlet (e.g., Table 4-2). In seepage lakes the sediments over much of the deeper portions of the basin also often form an effective seal; losses to ground water usually occur from the upper portions of the basin in these lakes. For example, in Mirror Lake most of the large seepage losses occurred within the upper 5 m of sediments (Table 4-2).

[1] The *drainage basin* or *catchment area* (*Einzugsgebiet; bassin versant*) is, in American usage, equivalent to *watershed*, the region or area drained by a river. *Watershed*, as used in the United Kingdom, refers to the ridge or crest line dividing two drainage areas and is defined similarly in German (*Wasserscheide*) and French (*ligne de partage des eaux*).

Further losses of water occur directly by ***evaporation*** or by ***evapotranspiration*** from emergent and floating-leaved aquatic macrophytes. The extent and rates of evaporative losses are highly variable according to season and latitude and are greatest in endorheic regions. Lakes of semiarid regions commonly have no outflow and lose water only by evaporation. Such lakes are termed ***closed,*** in contrast to ***open lakes*** that have outflow by an outlet or seepage.

Evaporative losses are modified greatly by the transpiration of emergent and floating-leaved aquatic plants (cf. reviews of Gessner, 1959, and Wetzel, 1999). Rates of transpiration and evaporative losses to the atmosphere vary greatly with an array of physical (e.g., wind velocity, humidity, temperature) and metabolic parameters and structural characteristics of different plant species (Brezney *et al.*, 1973; Bernatowicz *et al.*, 1976; Boyd, 1987; Jones, 1992). Plant growth and evapotranspiration are predominantly seasonal in lake and river wetlands of exorheic regions. In tropical and subtemperate lakes, many of the large perennial hydrophytes grow more or less continually. In most

TABLE 4-2 Annual Water Budget for Lawrence Lake, Michigan, and Mirror Lake, New Hampshire

Source/loss	10^3 m^3	*Percentage of total*
Lawrence Lake:[a]		
Inputs		
Inlet 1	146.6	32.1

situations, transport of water from the lake or river to the air is increased greatly by a dense stand of actively growing littoral vegetation, as compared to evaporation rates from open water (Table 4-3 and Wetzel, 1999b). Because most lakes are small and often possess a well-developed littoral flora, these communities contribute significantly to the water balance of many surface waters.

Analytical techniques for a detailed evaluation of the water balance of a lake and its drainage basin are complex and require much work and effort (Sokolov and Chapman, 1974; Winter, 1981, 1995; Wetzel and Likens, 2000). Because of numerous local fluctuations in climate from year to year, analyses should extend over several years. Methodology varies greatly in relation to objectives and is beyond the scope of this work. Many detailed reviews are available on specific hydrological and isotopic methods (see Chow, 1964; Stout, 1967; Gray, 1970; Rodda *et al.*, 1976; Kirkby, 1978; Gordon *et al.*, 1992; Sen, 1995).

III. SUMMARY

1. The hydrological cycle consists of the global processes affecting the distribution and movement of water.
   a. Greater evaporation from the oceans is counterbalanced by greater precipitation onto land masses.
   b. Although the amount of water in the atmosphere is small, its retention time is low, and it cycles on the average every nine days.
   c. Once moved from sites of evaporation, water is returned by precipitation. Much of this water is returned to the atmosphere by evaporation and plant transpiration.
   d. On land, water is absorbed by soil, stored within ground water, and moves by gravity to stream channels and lake depressions. Retention times within groundwater reservoirs are variable and depend on the composition of the soil and rock, slope gradients, vegetation cover, and climate. Groundwater flow rates are generally slow and the pathways long.
   e. Retention times in lakes are generally short (6–7 years on the average).
   f. Human modification of the environment can result in major alterations in the global water balance and the climate.
2. Changes in water storage and retention in lakes result from alterations in the balance between input rates from all sources and rates of water losses.
   a. Water income results from:
      i. Precipitation directly on the lake surface.
      ii. Water from surface influents of the drainage basin.
      iii. Groundwater seepage below the surface of the lake through the sediments or as discrete subsurface springs.
   b. Losses of water from lakes occur by:
      i. Flow from an outlet in the most common ***drainage lakes*** or by seepage through the basin walls into the ground water in ***seepage lakes.***
      ii. Direct evaporation from the lake surface.
      iii. Evapotranspiration from emergent and floating-leaved aquatic plants.

VIII. Utilization and Effects of Solar Radiation
IX. Summary

Solar radiation is of fundamental importance to the dynamics of aquatic ecosystems. Nearly all energy that controls the metabolism of lakes and streams is derived directly from the solar energy utilized in photosynthesis. That energy stored in photosynthetically formed organic matter is either synthesized within the lake or stream (***autochthonous***) or within the drainage basin and brought to the lake or stream in various forms (***allochthonous***). Utilization of this energy received within the water or imported from the drainage basin and factors that influence the efficiency of conversion of solar energy to potential chemical energy are fundamental to lake productivity.

In addition to these effects, absorption of solar energy and its dissipation as heat have profound effects on the thermal structure, stratification of water masses, and circulation patterns of lakes. Nutrient cycling, distribution of dissolved gases and biota, and behavioral adaptations of organisms are all markedly influenced by the thermal structure and stratification patterns. Therefore, the optical properties of lakes and reservoirs are important regulatory parameters in the physiology and behavior of aquatic organisms. They deserve detailed scrutiny.

I. LIGHT AS AN ENTITY

The term ***light*** is often confusing, in part because of different usages in absolute physical terms, reactions of visual receptors of animals to light, and responses of plants to light energy. For purposes of this discussion, it is essential that light be treated physically, as part of the radiant energy of the electromagnetic spectrum. Light is energy, that is, something that is capable of doing work and of being transformed from one form into another, but can neither be created nor destroyed. Radiant energy is transformed into potential energy by biochemical reactions, such as photosynthesis, or into heat. Energy transformations are far from 100% efficient in a system such as a lake, and most of the radiant energy is lost as heat.

A. Electromagnetic Spectrum

The electromagnetic spectrum is expressed as units of frequency (cycles per time) and wavelength. At one extreme are cosmic rays of very high frequency (10^{24} cycles per second (cps)) and short wavelength (10^{-14} cm), and at the other are radio and power transmission waves of low

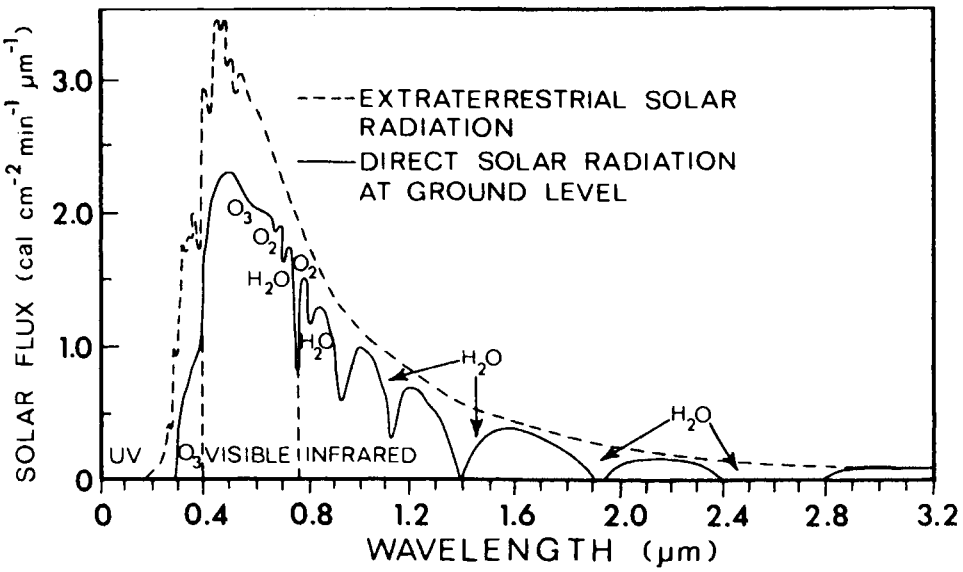

FIGURE 5-1 Extraterrestrial solar flux and that at the surface of the Earth, showing major absorption bands from atmospheric O_2, O_3, and water vapor. (Modified from Gates, 1962.)

frequency (1 cps) and long wavelength (to 10^{10} cm). For all practical purposes, solar radiation constitutes all of the significant energy input to aquatic systems. This solar flux of energy consists of wavelengths of 100 to >3000 nm, from the ultraviolet (UV) to infrared radiation, as it is received extraterrestrially (Fig. 5-1). As solar radiation penetrates and diffuses in the atmosphere of the earth, the energy of certain wavelengths is absorbed strongly and attenuated by scattering. The visible portion of the spectrum, with maximum energy flux in the blue and green portions (480 nm) of the visible range, is only a small amount of the total energy radiated by the Sun (Fig. 5-1). Ultraviolet energy is absorbed largely by ozone and oxygen, and infrared wavelengths are absorbed by water vapor, ozone, and carbon dioxide.

As one evaluates the mechanisms by which life receives light energy, it is important to view light as the radiation of packets of energy termed ***quanta*** or ***photons.*** A photon is a pulse of electromagnetic energy; as this energy propagates it has an electric (*E*) and magnetic (*H*) field, with respect to direction of flux and wave characteristics of wavelengths (*l*) and amplitude (*A*) (Fig. 5-2). Hence, light is effectively a transverse wave of energy that behaves as a movement of particles with defined mass. The photon carries energy in a wave conformation.

B. Absorption of Light

Absorption of light energy by atoms and molecules can occur when the electrons of the atoms and molecules resonate at frequencies that correspond to an energy state of a photon. In the collision of an electron and a photon, the electron gains the quantum of energy lost by the photon. It is important to keep this basic photochemical relationship in mind, because the quantum energy imparted by the photon functions in relation to frequency, and each molecular or atomic species has a unique set of absorption characteristics or bands. *Life responds to quantum energy of photons at specific frequencies.*

If the energy distribution of solar flux is plotted against wavelength, as was done in Figure 5-1, the maximum monochromatic intensity of sunlight appears to occur in the blue-green portion of the visible spectrum, an illusion caused by the manner of presenting the data. It is more meaningful to express energy against frequency, where the area under any portion of the curve

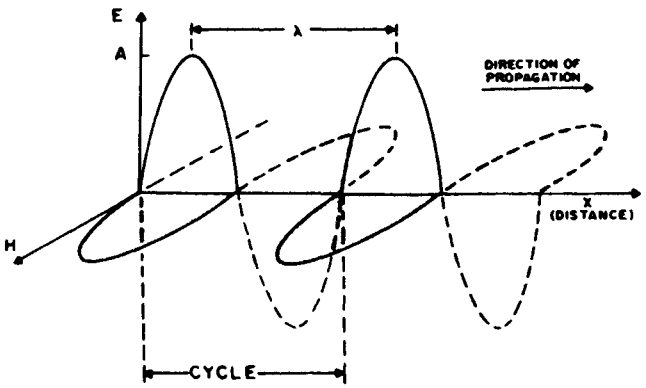

FIGURE 5-2 Instantaneous electric (*E*) and magnetic (*H*) field strength vectors of a light wave as a function of position along the axis of propagation (*x*), showing the amplitude (*A*), wavelength (*l*), cycle, and direction of propagation. (From Bickford, E. D., and Dunn, S.: *Lighting for Plant Growth.* Kent, Ohio, Kent State University Press, 1972.)

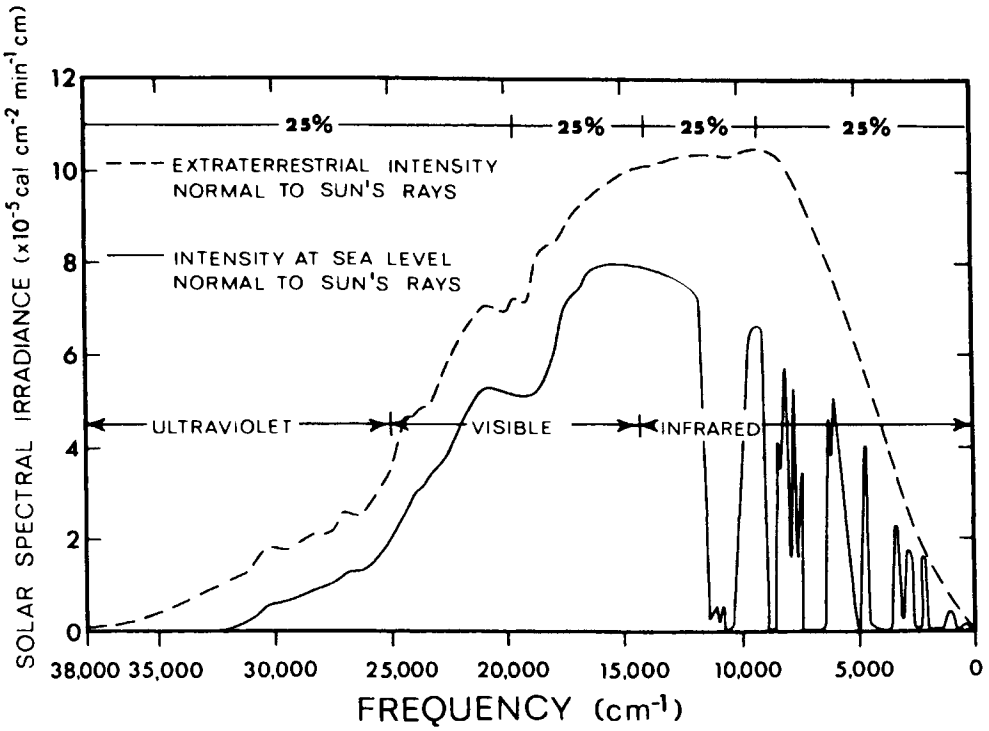

FIGURE 5-3 Solar spectrum at the mean solar distance from the earth as received outside of the earth's atmosphere and at sea level on a surface perpendicular to the solar rays (solar constant of 2.00 cal cm^{-2} min^{-1}). (Modified from Gates, 1962.) Frequency (cm^{-1}) of the abscissa refers to the wavenumber (ν^1), or number of wavelengths per cm, and is therefore equal to the reciprocal of the wavelength.

is directly proportional to energy (Fig. 5-3). The energy of the photon in the electromagnetic spectrum is proportional to frequency and inversely proportional to wavelength in accordance with Planck's law:

$$e = h\nu$$

where:

e = energy of the photon, ergs
h = Planck's constant, 6.63×10^{-27} ergs
ν = frequency of the radiation in cps.

When energy is expressed against frequency (Fig. 5-3), the true maximum energy of solar irradiance is found in the infrared at wavelengths somewhat greater than 1000 nm, or 1 mm. The median value of irradiance occurs in the near infrared at a frequency of 14,085 cm^{-1} (= a wavelength of 710 nm), slightly above the visible range. A major portion (29%) of the incoming radiation occurs at wavelengths greater than 1000 nm (frequency $< 10{,}000$ cm^{-1}) and 50% beyond the red portion of the visible range. This distribution of energy shifts somewhat as the solar radiation passes through the Earth's atmosphere (Fig. 5-3). The point to be made, however, is that *a large portion of irradiance impinging on the surface of water is in the infrared portion of the solar spectrum and has major thermal effects on the aquatic system.*

Wavelength (l) is a quantitative parameter of any periodic wave motion, not only of light but also of water movements, as will be discussed later on. It is defined simply as the linear distance between adjacent crests of waves and is equal in cm to the speed of light ($c = 2.998\ 10^{10}$ cm s^{-1}) divided by the frequency (ν) in cycles per second (cps):

$$l = c/\nu$$

Wavelength is also often expressed as the wave number (ν^1, or k), which is the number of wavelengths per cm, or the reciprocal of the wavelength:

$$\nu^1 = 1/l$$

The speed of light is reduced in a roughly linear fashion as it passes through transparent materials of increasing density (Table 5-1). (A conversion table for

TABLE 5-1 Speed of Light (589 nm, sodium D-lines)

Medium	*Speed (cm s^{-1})*
Vacuum	2.9979×10^{10}
Air (760 mm, 0°C)	2.9972×10^{10}
Water	2.2492×10^{10}
Glass	1.9822×10^{10}

commonly used units of length and irradiance is given in the appendix.)

II. LIGHT IMPINGING ON WATER

The amount of solar energy that reaches the surface of a lake or other water body is dependent upon an array of dynamic factors. The amount of direct solar energy per unit of time from the Sun, incident upon a surface outside the atmosphere perpendicular (normal) to the rays of the Sun at an average distance of the Earth from the Sun, is referred to as the ***solar constant.***[1] The amount of energy received is a function of the angular height of the Sun incident to the earth and is greatly influenced by latitude and season (Fig. 5-4). The angle of light rays impinging on the water has a marked effect upon the productivity within the water, as will be illustrated repeatedly in subsequent chapters. In equatorial regions, sunlight impinges vertically and leads to relatively constant energy inputs. In temperate and polar areas, however, the sun's angle changes with the sequence of the seasons (Fig. 5-4). Time of day is another factor that influences strongly the solar flux reaching the surface of water bodies, for time of day influences the position of the Sun and the distance that the path of light must travel through the absorbing atmosphere. In polar extremes, for example, direct solar energy decreases to zero for over one-third of the year, and polar waters then receive thermal radiation only from indirect sources.

The absorptive capacities of the atmosphere for solar radiation are governed largely by oxygen, ozone, carbon dioxide, and water vapor, as discussed previously. Moreover, atmospheric transparency can be modified extensively in some regions by both industrial- and urban-derived contaminants. Scattering and absorption also increase in moist air, which is more common on the downwind side of large water bodies. The elevation of a lake and the angular height of the sun both determine the quantity of atmosphere through which the radiation must travel. In summary, the amount and spectral composition of ***direct solar radiation*** reaching the surface of a water body vary markedly with latitude, season, time of day, altitude, and meteorological conditions.

Indirect solar radiation from the sky is largely the result of the scattering of light as it passes through the atmosphere. The extent of scattering is a function of the fourth power of the frequency, and therefore the UV and shorter wavelength radiation of high frequencies is reduced by about one-fourth as a result of scattering. The result is the blue sky we see directly overhead on clear days. The factors influencing direct solar radiation also influence scattering, but of particular importance are solar height and the atmospheric distance through which the light must pass. The percentage of indirect radiation increases significantly as deviations of the rays from the perpendicular increase, for example, 20–40% at a Sun elevation from the horizontal of 10° in contrast to 8 to 20% at a Sun elevation of 40°.

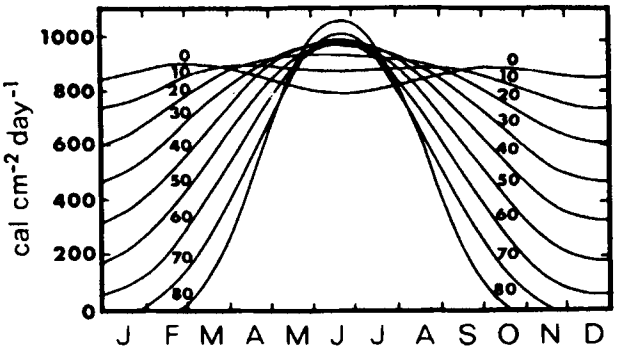

FIGURE 5-4 Daily totals of the undepleted solar radiation received on a horizontal surface for different geographical latitudes as a function of the time of year (solar constant 1.94 cal cm^{-2} min^{-1}). (After Gates, 1962.)

A. Ultraviolet Radiation and Its Absorption

Reduction of the ozone in the stratosphere from reactions with chemical pollutants has resulted in increases in global ultraviolet radiation (e.g., Kerr and McElroy, 1993; Madronich, 1994). Appreciable increases in the ultraviolet radiation in the past several decades have impacted aquatic ecosystems by enhancing injury to organisms, altering the energy devoted to production of protective pigments, and altering rates of biogeochemical cycling of organic compounds.

Of the ultraviolet radiation (UV) band (100–400 nm), nearly all of UV-C (< 280 nm) is absorbed by the stratospheric gases and by the water of aquatic ecosystems. Although relatively little UV-B (280–320 nm) passes through the stratosphere, UV-B is highly energetic and an important photoactivating agent in waters. UV-A (320–400 nm) is less energetic than UV-B but is absorbed less readily in water and penetrates more deeply. Recent measurements *in situ* have demonstrated great variability in the penetration of UV-B and UV-A but much greater penetration than was believed previously (see discussion below).

[1] The solar constant is difficult to measure but recent evidence from satellite instrumentation indicates a value of 1.94 cal cm^{-2} min^{-1} (Drummond, 1971; Gates, D. M., personal communication). Hickey *et al.* (1980), found 1.97 cal cm^{-2} min^{-1} (1376.0 W m^{-2}).

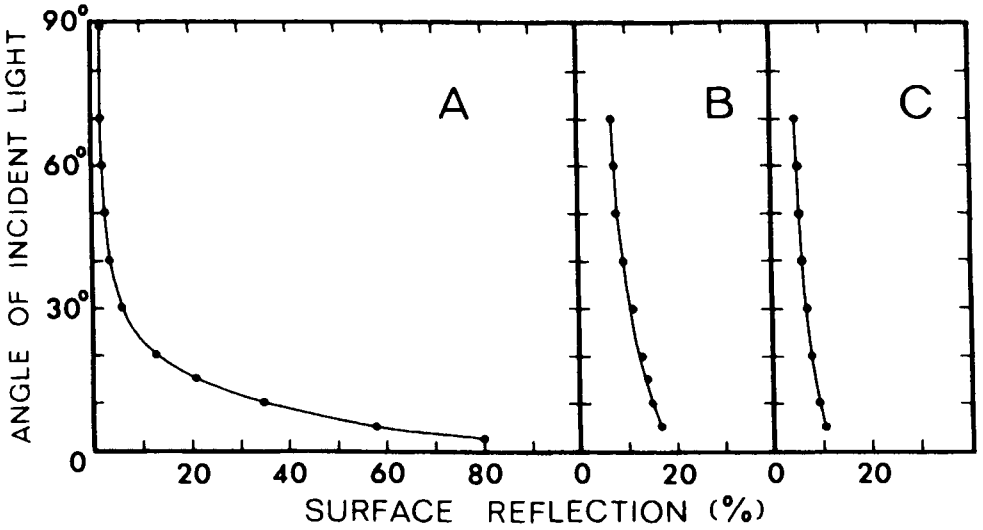

FIGURE 5-5 Surface reflection and backscattering as a percentage of total solar radiation at angles of incidence varying from the horizontal. (A) Clear, cloudless conditions; (B) reflection of diffuse light under moderate cloud cover; (C) heavily overcast conditions. (Generated from data in Steleanu, 1961, and Sauberer, 1962.)

B. Distribution of Radiation Impinging on Water

All of the solar radiation that impinges upon the surface of an inland water body does not penetrate the water. A significant portion is ***reflected*** from the surface and is lost from the system unless it returns to the water after being backscattered from the atmosphere or surrounding topography.

The extent of reflectivity of solar radiation varies greatly with the angle of incidence, the surface characteristics of the water, the surrounding topography, and the meteorological conditions. The ***reflection*** (R) of unpolarized direct sunlight as a fraction of the incident light is a function of Fresnel's law:

$$R = \frac{1}{2}\left[\frac{\sin^2(i-r)}{\sin^2(i+r)} + \frac{\tan^2(i-r)}{\tan^2(i+r)}\right]$$

where i = angle of incidence, and r = angle of refraction. This function states simply that the reflectivity is dependent upon the solar height from the zenith (Fig. 5-5A), that is, the greater the departure of the angle of the Sun from the perpendicular, the greater the reflection will be. Indirect radiation from the sky is also reflected from a water surface but is less affected by solar height (Fig. 5-5B). Under an overcast sky the amount of indirect light that is reflected decreases (Fig. 5-5C). An average reflectance loss value of 6.5% is common, although reflective losses can be reduced further if surrounding topography—mountains, for example—moderates low-angle radiation (Sauberer, 1962).

When the surface of water is disturbed by wave action, reflection increases by about 20% at low angles of incident light (ca. 5°) to approximately a 10% increase at higher angles (5–15°). The difference is small at angles of incidence greater than 15° from the horizontal. Reflection may decrease slightly when the waves are very large and light is exposed to the water surfaces at angles more closely approaching the perpendicular. Ice and particularly snow cover affect markedly the reflectivity of light from the surfaces of lakes. Although data are meager, clear, smooth ice has reflection characteristics similar to those of undisturbed liquid water. Changes in the texture of the ice generally increase reflectivity. Reflection increases markedly with the greatly increased angles and quantity of surface planes of granular ice in the form of snow cover. On the average, about 75% of incident light striking snow is reflected, and under some conditions, as much as 95% can be reflected.[2]

Of the total incident light impinging upon the surface of water, a reasonable average amount that is reflected on a clear, summer day is 5–6%. This mean value increases to about 10% during winter. Qualitatively, light in the red portion of the spectrum is reflected to a slightly greater extent than light of higher frequencies, particularly at low angles of incidence. About half of the total quantity of light leaving the lake is by reflection and half by scattering of light.

[2] The ***albedo,*** the ratio of reflected to incident irradiance, is influenced by many factors, such as internal reflections, bubble and particle inclusions, and crystal orientations within the ice and snow, zenith angle, upwelling of scattered light, and other factors (Sauberer, 1962; Adams, 1978; Stewart and Brockett, 1984). Moreover, the distribution of winter ice and snow thickness and condition is often nonuniform over the surface of lakes (Adams, 1978, 1981).

C. Scattering of Light

Scattering of light from the water results in the loss of large amounts of light energy from the lake. This phenomenon is apparent to anyone who has looked down into relatively clear waters where the surface reflection is eliminated. Of the total light energy entering water, portions are absorbed by the water and particles suspended in it, as will be discussed in detail further on, and a significant portion is scattered. ***Scattering of light*** is the result of deflection of quanta by the molecular components of the water and its solutes but also, to a large extent, by particulate materials suspended in the water.

The scattering of light energy can be viewed in a simple way as a composite of reflection at a massive array of angles internally within the water (cf. Mobley, 1994). The energy scattered in all directions within a volume of water varies greatly with the quantity of suspended particulate matter and its optical properties. Volcanic siliceous materials, for example, scatter light much less than suspended particulate matter of lower transparency.

The scattering of light can change significantly with depth, season, and location in a lake and in response to variations in the distribution of particulate matter. When particulate matter is concentrated in the middle zone of great density change (metalimnion) of a thermally stratified lake, either as a result of reduced sinking as the particles encounter increased water densities or as a result of the development of large populations of plankton in certain strata, the scattering of light can increase. Scattering can also increase markedly in areas of the lake where wind-induced currents and wave action agitate and temporarily suspend littoral and shore deposits of particulate matter (Tyler, 1961b). When dimictic or amictic lakes (see Chap. 6) undergo complete circulation, a significant portion of the recent sediments of the lake basin are brought into resuspension (Wetzel *et al.*, 1972; Davis, 1973; White and Wetzel, 1975) and can affect the scattering properties of the lake for an extensive period (weeks). Similarly, the variable influxes of suspended inorganic and organic matter from stream inflows to reservoirs can radically increase the scattering of light nonuniformly within the lake basin. For example, cold, silt-laden, glacial meltwaters can move as subsurface density currents along the metalimnion far out into a lake or reservoir.[3] These alterations in optical properties can be short- or long-lived depending upon the composition and density of the material and the density characteristics of the recipient water at that particular time.

[3]This common phenomenon is called *la bataillere* in the Lake of Geneva, Switzerland.

A significant amount of light can be reflected and scattered from the sediments both in the littoral zone and in shallow areas, as well as from the bottom of moderately deep, clear lakes (Fig. 5-6). The amount of light returned to the water is dependent upon the composition of the sediments; sand sediments or those sediments rich in calcium carbonate (marl; $CaCO_3$) reflect considerably more light than dark-colored sediments of high organic content.

Differential scattering of light also depends on scattering coefficients for different wavelengths, as well as on absorption characteristics for different wavelengths. In very clear water, scattering occurs predominantly in the blue portion of the visible spectrum. As the quantity and size of suspensoids increase, radiation of longer wavelengths is scattered preferentially and greater absorption of the light of high frequencies occurs. Hardwater lakes with large amounts of suspended $CaCO_3$ particles characteristically backscatter light that is predominantly blue-green; lakes rich in suspended organic materials appear more green or yellow.

Diffuse light from scattering and reflecting sources is of obvious importance to organisms that utilize it directly in photosynthesis or indirectly in behavioral responses. In lake ecosystems where light enters the environment unidirectionally from above, diffuse scattered light can form a major supplementary source of energy. The amount of light scattering can easily be one-fourth of the light absorbed by the water. The true values are likely even higher, because most of the existing data on scattering were acquired with unidirectional (2π—flat,

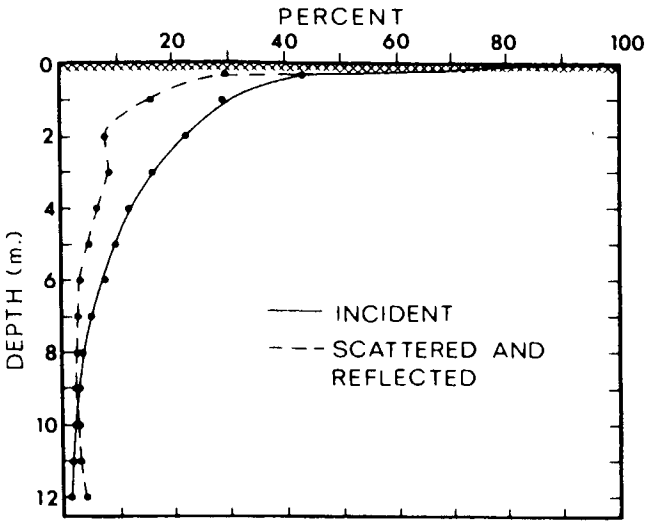

FIGURE 5-6 Comparison of incident light penetration (percentage of total surface light) with depth to that backscattered from concentrations of plankton, especially at 3 m, and from calcareous sediments. Lawrence Lake, Michigan; 17 March 1972; 23 cm cloudy ice.

cosine) instruments. When scattering values obtained with this type of sensor are compared with those obtained with instruments approaching 4π (spherical, scalar) geometry (e.g., Rich and Wetzel, 1969; Smith and Wilson, 1972; Kirk, 1994), higher values are commonly found. Comparisons between cosine and scalar measuring instruments among a range of depths and weather conditions in Loch Neigh, Northern Ireland, for example, showed that cosine values were between 64 and 80% of scalar values (Jewson, 1984). A portion of the scattered light is returned to the surface of the water, and much (80–90%) of that which returns to the surface is lost to the atmosphere. Because of differences in lightwave refraction properties at different frequencies, somewhat less of the red scattered light reaches the surface than the blue.

Several terms are in common usage in relation to light radiation used by photosynthetic organisms. ***Photosynthetically active radiation*** (PAR) is defined as radiation in the 400–700-nm waveband. The photosynthetically active range may extend below 400 nm to wavelengths as low as 290 nm (Halldal, 1967; Klein, 1978), but the amount of subsurface irradiance available at the shortest wavelengths is very small, especially if the water contains significant amounts of dissolved organic compounds (as most inland waters do; see the following discussion). PAR is a general radiation term that is applicable to both energy terms and the preferred photon (quantum) term.

Photosynthetic irradiance is the radiant energy (400–700 nm) incident per unit time on a unit surface (i.e., radiant energy flux density of PAR in units such as W m^{-2}). ***Photosynthetic photon flux density*** is the number of *photons* (quanta) in the 400–700-nm waveband incident per unit time on a unit surface (i.e., photon flux density of PAR in units μmol m^{-2} s^{-1}, formerly μeinsteins m^{-2} s^{-1}).[4]

The total underwater light received by a receptor system, such as that received by an algal cell from all angles, is the optimum measure of radiant energy available for photosynthesis. This realistic value is the ***photosynthetic photon flux fluence rate*** or PPFFR (i.e., photon scalar irradiance or scalar quantum irradiance, Smith and Wilson, 1972), which is defined as the integral of photon flux radiance at a point over all directions about the point. In other words, PPFFR is a measure of the total number of photons of PAR per unit time and area arriving at a point from all directions about the point when all directions are weighted evenly (Smith and Wilson, 1972). Such spherical, 4π quantum sensors are now available commercially and respond equally to all photons in the 400–700 nm range (units in μmol m^{-2} s^{-1}).

Photosynthetic and phototropic responses of organisms are related to the number of quanta of light of specific frequencies (wavelengths) impinging upon biochemical receptor systems. The attenuation of illuminance under water between a spectral range of 350 to 700 nm is not exactly the same for energy units as it is for quanta (Steemann, Nielsen, and Willemoës, 1971; Lewis, 1975). The rate of attenuation of quanta is approximately equal to that of energy in moderately clear water bodies containing intermediate concentrations of dissolved organic carbon (approximately 5 mg $liter^{-1}$). In more transparent waters, energy is absorbed at a slower rate than quanta; the opposite is true in more deeply stained waters containing greater amounts of dissolved organic matter. The divergence in penetration of quanta and energy can increase in certain specific portions of the spectral range and thus affect the utilization by the action spectra of organisms. For example, small differences in the utilization of illuminance during photosynthesis between diatoms, green algae, and cyanobacteria with differing action spectra of photosynthetic pigments occur when the rate of illumination is measured in energy units. The ratio of total quanta to total irradiance energy within the spectral region of photosynthetic activity, however, varies by no more than $\pm 10\%$ and is $2.5 \pm 0.25 \times 10^{18}$ quanta s^{-1} W^{-1} within a number of waters differing in optical characteristics (Morel and Smith, 1974). The ratio can be used to determine accurately the total quanta available for photosynthesis from measurements of total energy; the converse is also true.

III. THERMAL RADIATION IN LAKE WATER

Lake water behaves like a blackbody[5] to radiation of low frequency (wavenumber 14,000 cm^{-1}) and long wavelengths (750–12,500 nm). Because of surface reflection, only about 97% of thermal radiation is emitted into the atmosphere. The atmosphere does not function as a blackbody, but thermal radiation from it is influenced by water vapor pressure and the extent of cloud cover. At night, the net emission of thermal radiation from the surface of a lake, in cal cm^{-2} day^{-1}, approximates [11 × (°K of water − °K of air)] or simply [11 × (temperature of the water − that of the air)] (cf. discussion in Hutchinson, 1957).

[4] The einstein has been used to represent both the quantity of energy in Avogadro's number of photons and also Avogadro's number of photons (Incoll *et al.*, 1977). When used as the quantity of photons, 1 einstein (E) = 1 mole = 6.02×10^{23} photons. The E has now been replaced in the international system (SI) by moles.

[5] A blackbody absorbs all of the radiant energy incident upon it. The thermal radiation (Q) from a blackbody is proportional to the fourth power of the absolute temperature (K): $Q = 8.26 \times 10^{-9}$ $(K)^4$.

A. Net Radiation

The net amount of solar radiation affecting a lake can be referred to as the ***net radiation surplus*** (Q_B):

$$Q_B = Q_S + Q_H + Q_A - Q_R - Q_U - Q_W$$

where

Q_S = direct solar radiation
Q_H = indirect scattered and reflected radiation from sky and clouds
Q_A = long-wave thermal radiation from the atmosphere and from surrounding topography (the latter is usually insignificant)
Q_R = radiation reflected from the lake
Q_U = radiation scattered upward and lost
Q_W = emission of long-wave radiation.

At night, most components are negligible, and the net radiation surplus becomes equal to the long-wave thermal radiation of the atmosphere minus that emitted from the water:

$$Q_B = Q_A - Q_W$$

or, approximately, $Q_B = -11$(temperature of the water − the temperature of the air) in cal cm^{-2} day^{-1}. We will return to these relationships when discussing heat budgets in the following chapter. It should be emphasized, however, that even though the mean value of Q_B may be positive, the lake can be losing heat through evaporation and convective heating of the air (Hutchinson, 1957).

The collective value for the inputs ($Q_S + Q_H + Q_A$) can be measured directly by sensitive Moll thermopile pyranometers. The subject of radiation measurement is treated excellently by Latimer (1972), Bickford and Dunn (1972), Šesták *et al.* (1971), and Coulsen (1975).

IV. TRANSMISSION AND ABSORPTION OF LIGHT BY WATER

The quantity of light energy penetrating the water is dispersed by the mechanisms just discussed and absorbed. The diminution of radiant energy with depth, by both scattering and absorption mechanisms, is referred to as ***light attenuation,*** whereas ***absorption*** is defined as diminution of light energy with depth by transformation to heat (cf. Westlake, 1965). It is important to understand the selective absorptive properties of water, first in pure water and then in waters of differing optical characteristics.

The transmission and absorption of light in water can be approached in several ways. Perhaps the most direct way is to look first at the percentage of transmission or absorption of monochromatic light through given depths of pure water. This ***percentile absorption,*** or Birgean percentile absorption (after E. A. Birge, who used the relationship extensively), is based on the expression

$$\frac{100(I_0 - I_z)}{I_0}$$

where

I_0 = irradiance at the lake surface
I_z = irradiance at depth z, in this case taken as 1 m

In distilled water, the percentile absorption is very high in the infrared region of the spectrum, decreases rapidly in the lower wavelengths to a minimum absorption in the blue, and then increases again in the violet and especially UV wavelengths (Table 5-2). These absorption relationships usually are expressed graphically in linear or, even better, in logarithmic form (Fig. 5-7). Generally about 53% of the total light energy is transformed into heat in the first meter.

The light intensity or irradiance, I_z, at depth z is a function of intensity at the surface (I_0) and the log of the negative extinction coefficient (η) times the depth distance, z, in meters:

$$I_z = I_0 e^{-\eta z}$$

or

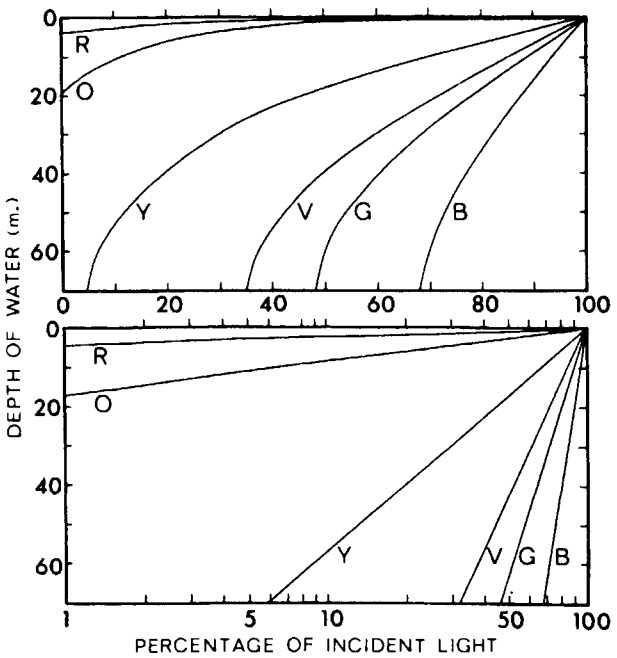

FIGURE 5-7 Transmission of light by distilled water at six wavelengths (R–720, O–620, Y–560, G–510, B–460, V–390 nm). Percentage of incident light that would remain after passing through the indicated depths of water expressed on a linear (*upper*) and a logarithmic (*lower*) scale. (After Clark, 1939.)

TABLE 5-2 Absorption Coefficients (Percentile Absorption) and Extinction Coefficients of Monochromatic Light of Liquid Water at 21.5°C by Laser Optoacoustic Spectroscopy[a]

Wavelength (nm)	*Wave number (ν^1) (cm^{-1})*	*Absorption coefficient (10^{-4} cm^{-1}) ("percentile absorption")*	*Extinction coefficient (η m^{-1})*

$$\ln I_0 - \ln I_z = \eta z$$

The extinction coefficient (η) is a constant for a given wavelength; approximate values for pure water are given in Table 5-2. This relationship is imperfect in nature because sunlight is not monochromatic, but is instead a composite of many wavelengths.

Direct sunlight rarely enters the water at right angles to the surface, and indirect irradiance is not perpendicular to the surface at any time. Moreover, the natural total extinction coefficient (η_t) is influenced not only by that of the water itself (η_w), but also by absorption of particles suspended in the water (η_p), and particularly by dissolved, colored compounds (η_c). Thus the *in situ* extinction coefficient (η_t) is a composite of these components (Åberg and Rodhe, 1942):

$$\eta_t = \eta_w + \eta_p + \eta_c$$

At low concentrations, the particulate suspensoids have relatively little effect on absorption. With high turbidity, however, the effect is quite significant, particularly at lower wavelengths of the visible spectrum. In detailed analyses of the absorption of lake water and its dissolved components, the particulate fraction is commonly removed by filtration or centrifugation.

A. Effects of Dissolved Organic Compounds

The effects of dissolved organic compounds on the absorption of light energy are very marked and are best introduced by examples taken from the extensive work of James with Birge (1938). In comparison to distilled water, lake water with increasing concentrations of dissolved organic compounds, particularly humic acids, not only reduces drastically the transmission of light but shifts absorption selectively (Table 5-3). Common to all waters is a very high absorption of infrared and red wavelengths, which results in significant heating effects in the first meter of water. At the other extreme, although distilled water absorbs relatively little UV light, even very low concentrations of dissolved organic compounds increase UV absorption greatly. In lakes highly stained with humic compounds, such as Helmet Lake, absorption of UV, blue, and green wavelengths is essentially complete in much less than a depth of 1 m. This relationship of intense absorption of UV light by dissolved organic compounds has been used extensively as a relative assay of their concentrations, as will be discussed in a subsequent chapter on organic matter.

UV-B attenuation depths (z_a = 1% of surface irradiance) ranged from a few centimeters to >10 m

among a number of lakes (Kirk, 1994; Scully and Lean, 1994; Morris *et al.*, 1995; Williamson *et al.*, 1996; Sommaruga and Psenner, 1997). Much (>90%) of the among-lake variation in diffuse attenuation coefficients (K_d) could be explained by differences in dissolved organic carbon (DOC) concentrations, which directly influenced dissolved absorbance. Throughout the solar UV-B and UV-A range, K_d was well estimated with a univariate power model based on DOC concentration, particularly in waters of low to moderate productivity. The z_a is strongly dependent on DOC concentrations when below 2 mg liter^{-1} and very sensitive to small changes in DOC (Fig. 5-8). In eutrophic lakes, densities of phytoplankton can assume greater importance in UV attenuation (Hodoki and Watanabe, 1998).

UV radiation penetrates more deeply in saline waterbodies than in freshwater ecosystems containing similar concentrations of dissolved organic matter (DOC) (Arts *et al.*, 2000). Over a large number of water bodies in central Saskatchewan, Canada, that ranged widely in DOC concentration (4–156 mg C liter^{-1}) and electrical conductivity (270–74,300 μS cm^{-1}), attenuation of UV-B (280–320 nm) was much greater in fresh waters than in saline waters (Fig. 5-9, *upper*). Attenuation of UV-A (320–400 nm) was also greater in fresh waters than in saline environments (Fig. 5-9, *lower*), although the differences were less pronounced than the situation with UV-B attenuation. The reasons for the differences are not clear, but in shallow saline environments, chromophoric humic substances are very low; most of the DOC is associated with non-

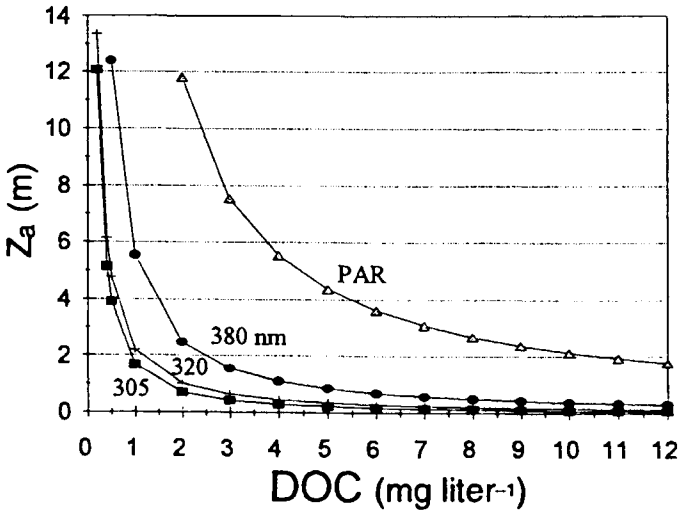

FIGURE 5-8 Relationship between the 1% attenuation depth (z_a = 1% of surface irradiance) and dissolved organic carbon concentration (DOC) based on a survey of 65 glacial lakes in North and South America. Model curves for 305, 320, and 380 nm and photosynthetically active radiation (PAR, 400–700 nm). (After data of Morris *et al.*, 1995, and Williamson *et al.*, 1996.)

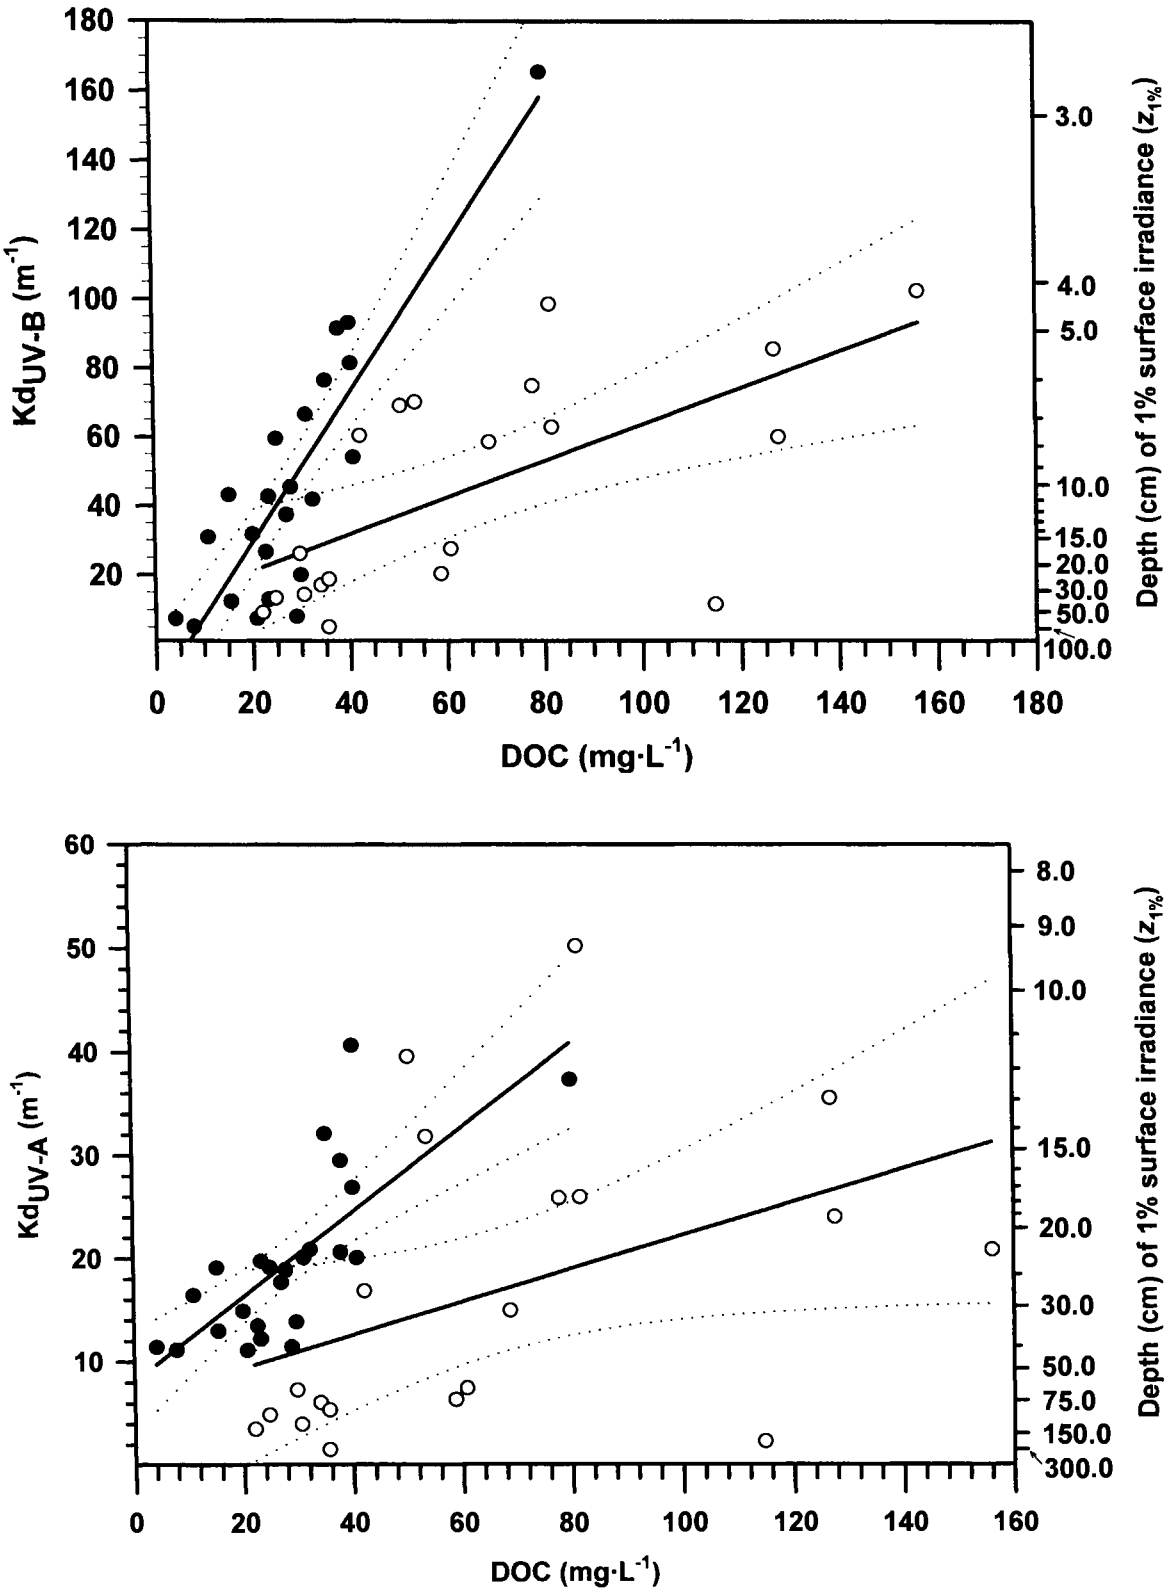

FIGURE 5-9 Vertical attenuation coefficients (K_d, in m^{-1}) and depths ($z_{1\%}$ in cm) at which 1% of the surface irradiance remained as a function of dissolved organic carbon (DOC) concentration for (*upper*) UV-B radiation (280–320 nm) and (*lower*) UV-A radiation (320–400 nm). chromophoric dissolved organic substances that are quite recalcitrant to microbial degradation. The chromophoric colored substances generally absorb UV radiations that results in partial photolysis to smaller biodegradable compounds or complete photolysis to CO_2 (cf. Chap. 23). Some UV-insensitive non-chromophoric compounds tend to be more stable and can accumulate.

The major effects of dissolved organic matter and particulate suspensoids on absorption of light at varying wavelengths are illustrated graphically in Figure 5-10. The total absorption characteristics in the spectrum (T) are compared to the percentile absorption values through 1 m of distilled water (W), absorption attributable to particulate suspensoids (P), and absorption by lake water that has been filtered to remove particles > 1 mm (C), termed *color absorption.* Absorption by dissolved organic compounds ("dissolved color") is selective and greatest in the UV, blue, and green wavelengths. The absorption by dissolved color at the red end of the spectrum is less selective and is probably unrelated to the organic compounds absorbing at lower wavelengths. The extinction coefficients of dissolved color (η_c) increase directly with the color units of the water, which are measured by the relative visual comparisons of the color of the filtered lake water under standard conditions to the color of a specific mixture of platinum–cobalt compounds in serial dilution (discussed further on; cf. also Wetzel and Likens, 1991). In the examples given in Figure 5-10, the water of Crystal Lake indicated zero platinum (Pt) units, Lake George, 24, Rudolf Lake, 50, and that of Helmet Lake, 236 Pt units, which is about the color of weak tea.

Also apparent from this classic work is the relationship that absorption resulting from particulate suspensoids (P) is relatively unselective at different wavelengths, particularly at lower concentrations. The η_p functions essentially independently of the η_c but, along with the absorption of water (η_w), η_p values are additive for a particular lake at depth at a given time of year (cf. Åberg and Rodhe, 1942).

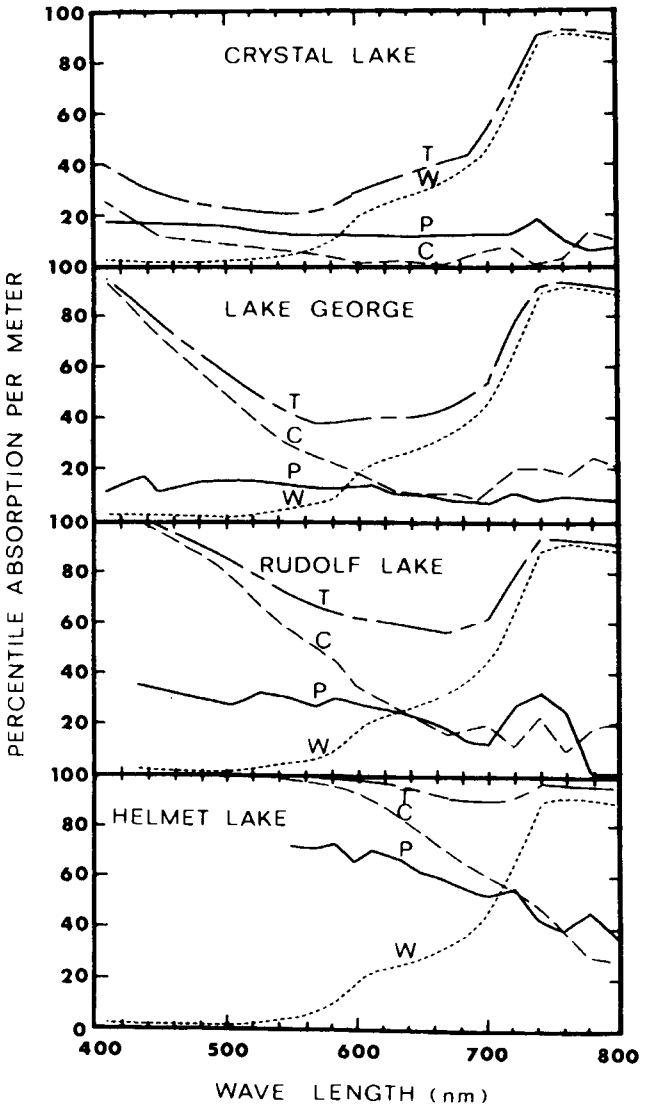

FIGURE 5-10 Percentile absorption of light at different wavelengths passing through 1 m of water of four lakes of northern Wisconsin of increasing concentrations of dissolved organic matter. T = total absorption; C = absorption by dissolved organic color; P = absorption by suspended particulate matter; and W = absorption by pure water. (Modified from James with Birge, 1938.)

B. Analysis of Light Transmission

The transmission or absorption within a lake of the total white light from direct insolation and indirectly from the sky has been analyzed in many ways. The vertical extinction coefficient is most commonly determined from the percentile absorption of surface light through depth (Fig. 5-11). The isopleths[6] of these examples of depth–time distribution of light indicate some of the marked fluctuations that are found in natural waters, seasonally and vertically. The composite mean η_t of all depths in Lawrence Lake, an unproductive hardwater lake with rather high concentrations of particulate and colloidal $CaCO_3$ suspensoids, was 0.39 m^{-1} (n = 1746 measured profiles), within an annual range of 0.05 to 1.02. The same value for extremely productive Wintergreen Lake was 1.00 m^{-1} (range, 0.46–1.68). In the former case, the η_t is largely

[6] An isopleth is a line on a graph of a specified constant value showing the occurrence of a parameter as a function of two variables (depth and time in this case). See Wetzel and Likens (2000:26) for details of preparation of these diagrams.

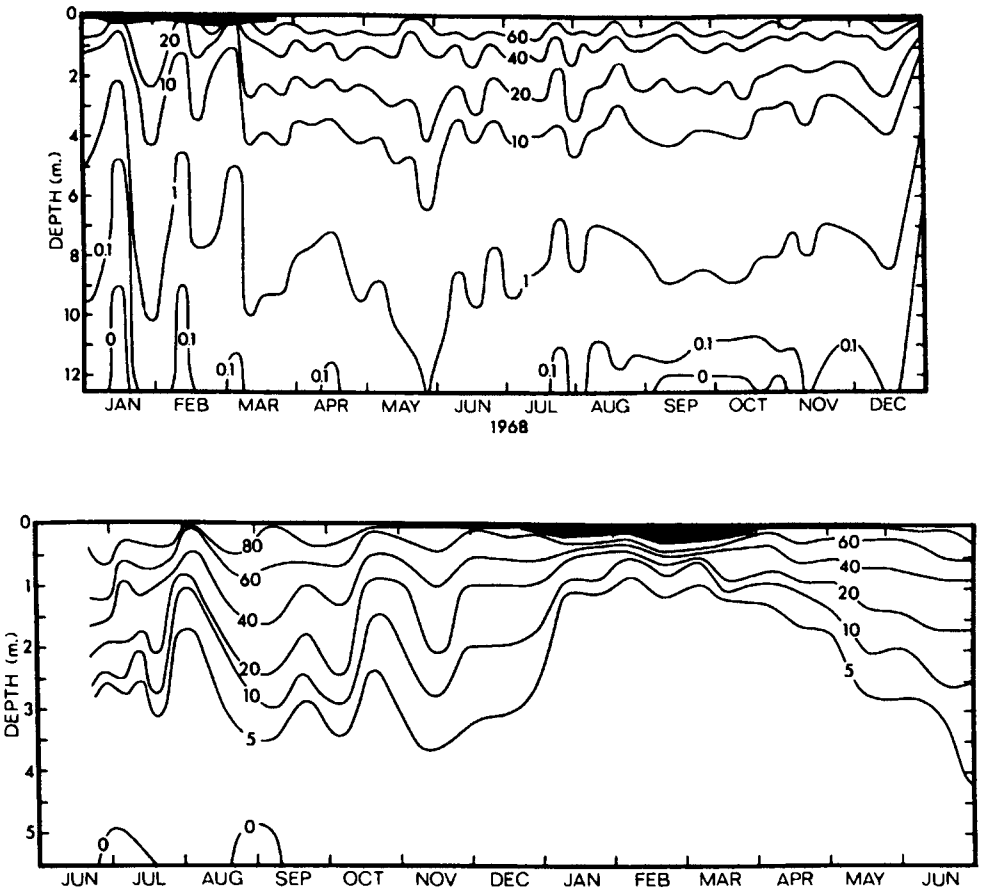

FIGURE 5-11 Isopleths of the percentage transmission of light at the surface with depth and time in unproductive Lawrence Lake (*upper*) and extremely productive Wintergreen Lake (*lower*), southwestern Michigan. (From Wetzel, unpublished observations.)

constant over an annual period, whereas in the latter situation the marked fluctuations in particulate suspensoids of algae are reflected in the mean η_t m^{-1} and mean percentage transmission m^{-1} of the water column (Fig. 5-12).

Calculations of the vertical extinction coefficient are not very reliable in the first meter below the surface because of surface agitation. Average calculations often exclude this region. Direct calculations are made using the formula given earlier, or changed to

$$\eta z = \ln I_0 - \ln I_z$$

The values cited for the vertical extinction coefficient (η_t) obviously represent a composite for all of the wavelengths, each of which is variously influenced by the absorption characteristics of water, particulate

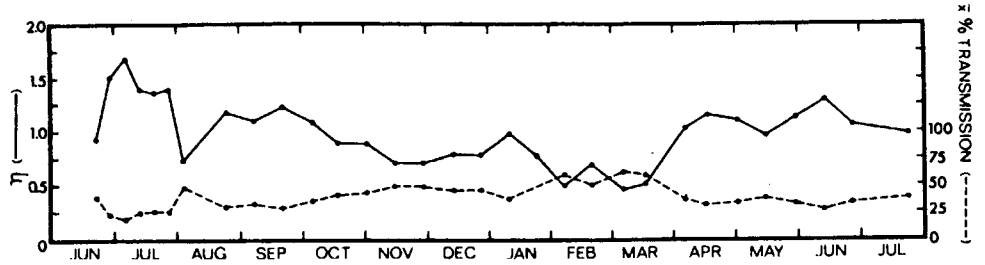

FIGURE 5-12 Average extinction coefficient (η_t) per meter and percentage transmission of light per meter of the water column, Wintergreen Lake, Michigan, 1971–72. (From Wetzel, unpublished data.)

matter, and dissolved organic matter. The η_t values for natural lake waters vary from approximately 0.2 per meter (about 80% transmission m^{-1}) in very clear lakes, such as Crystal Lake, Wisconsin, Lake Tahoe, California, and Crater Lake, Oregon, to about 4.0 m^{-1} in highly stained lake waters or lakes with very high biogenic turbidity. Where turbidity is extremely high, such as in reservoirs near major river inflows under flood conditions (e.g., Roemer and Hoagland, 1979) or in lakes receiving fine materials, such as volcanic ash, that remain in colloidal suspension, extinction coefficients in excess of 10 m^{-1} are not unusual.

As the composite distribution of light transmission with depth is dissected, the spectral selectivity of light reaching deep water should be apparent from the foregoing discussion. It is rather common for the green portion of the spectrum to penetrate most deeply (Fig. 5-13). In very clear waters, the deepest penetration of light is in the blue portion of the spectrum; in Crater Lake, maximum penetration occurred at approximately 469 nm, and in Lake Tahoe at approximately 475 nm (Tyler and Smith, 1970; Smith *et al.*, 1973). In lakes that are darkly stained with dissolved organic matter, practically no light of wavelengths below 600 nm penetrates below 1 m.

The rapid attenuation of light by dense populations of algae or bacteria at certain depths in stratified lakes is common, particularly in the lower depths where certain microorganisms are adapted to low light intensities (Fig. 5-14). Similarly, abiogenic suspensoids

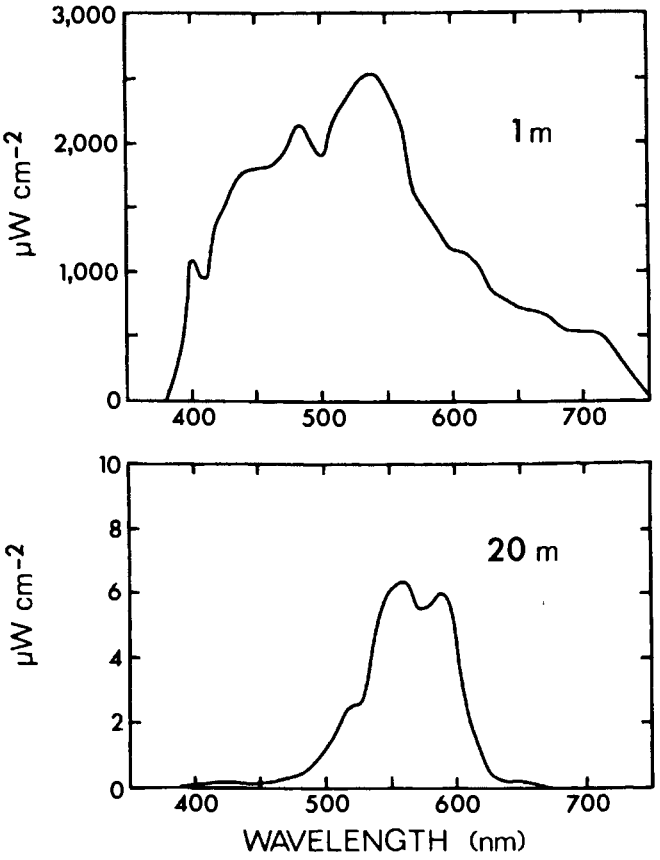

FIGURE 5-13 Comparison of the spectral distributions of energy using a scanning spectroradiometer, Gull Lake, Kalamazoo-Barry counties, Michigan, 16 November 1975 at 1 m (*upper*) and 20 m (*lower*). (From Wetzel and Likens, 1991.)

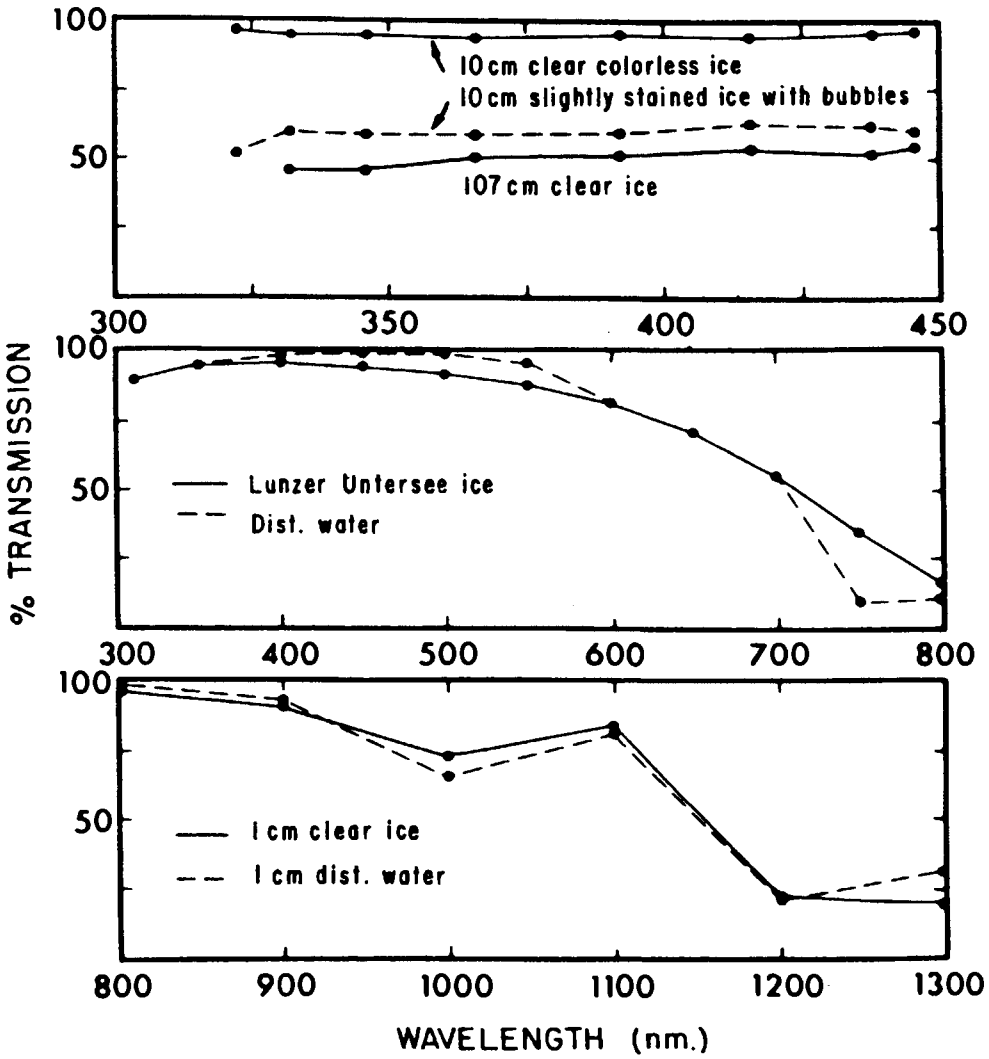

FIGURE 5-15 Percentage spectral transmission of light through ice in comparison to water. (From data of various sources cited in Sauberer, 1950; see also data of Adams, 1978.)

may be brought into a water basin through an inlet at temperatures colder than the surface strata. When this occurs, the suspensoid-laden water will penetrate to deep strata of comparable densities, and the stratified particles can markedly influence the vertical extinction of light.

The characteristics and amount of light penetrating the littoral zone of lakes are greatly altered by the type and extent of development of floating-leaved and emergent higher aquatic plants, as well as by reflection and scattering from the substratum. Since the structure of the littoral macroflora changes seasonally, dense vegetative stands commonly reduce incident light by 50 to over 90% (Gessner, 1955; Szumiec, 1961; Ondok, 1973a, 1973b, 1978; Grimshaw *et al.*, 1997).

V. TRANSMISSION THROUGH ICE AND SNOW

The percentage of light transmission through clear, colorless ice[7] is not greatly different from that through liquid water (Fig. 5-15). Attenuation of light increases greatly, however, if the ice is stained with dissolved organic matter or is cloudy, that is, contains air bubbles or forms irregular crystals upon freezing (Adams, 1978, 1981). Absorption is greatest in the red portion of the photosynthetic spectrum (Adams *et al.*, 1984; Roulet and Adams, 1986; Bolsenga *et al.*, 1991). White

[7] ***Black ice*** is clear and virtually free of gas bubbles; being transparent, it appears very dark over deep water. ***White ice,*** often formed when water saturates lower snow layers, is much less transparent because of internal reflectance and scattering of light.

TABLE 5-4 Light Penetration through Ice and Snow Cover of Lakes under Different Conditions[a]

Ice–snow conditions	*Thickness (cm)*	*Percentage transmission of surface insolation*
Clear ice	43	72
Clear ice	154	23.2
Clear ice with vestige snow	39	53
Clear ice with sediment floc	149	14.8
Milky ice with bubbles	29	54
Wet ice with bubbles	39	41
Translucent ice ("snow ice")	25	11–18
Ice with irregular surface	29	58
Clear ice with 3 cm snow	149 (ice) + 3 (snow)	0.57
New snow	0.5	34
	5.0	20
	10.0	9
	17–20	8.8–6.7
Compacted old snow	17–20	5–1

[a] Selected data from Albrecht (1964) and Bolsenga *et al.* (1991, 1996).

ice exhibits greater red absorption than does snow. Light transmission through black ice is very similar to that through water.

The addition of snow over ice reduces light transmission greatly (Table 5-4). It is common for light to be attenuated to essentially zero at a depth of as little as a meter below the underside of ice and wet, heavy snow. Prolonged periods of heavy snow and ice cover, with attendant severe reduction or elimination of light from the water and from photosynthetic organisms, can have profound effects on the entire metabolism of the lake. In very productive lakes, consumption of dissolved oxygen by catabolic process can exceed production by photosynthesis, which leads to severe reductions in dissolved oxygen or even to total anoxia. Oxygen reduction or anoxia resulting from excessive snow or ice cover occurs commonly in shallow, productive lakes and ponds in temperate latitudes (see Chap. 9) and often leads to the death of many organisms. When fish die under these conditions, this phenomenon is termed ***winterkill.***

Ice and particularly snow are not uniformly distributed over lake surfaces (Adams, 1978; Adams and Lasenby, 1978; Adams and Prowse, 1978; Adams and Roulet, 1982). The thickness of ice and snow can vary as much as a factor of 2 within short distances (< 25 m) and lead to considerable patchiness in both reflectance of light and attenuation of light through ice cover. This patchiness in light distribution beneath ice–snow cover can, in turn, influence horizontal distribution of algal photosynthesis and behavioral responses of planktonic animals.

VI. COLOR OF NATURAL WATERS

The observed color of natural water is the result of light being scattered upward from the water after it has passed through the water to various depths and undergone selective absorption en route. Because molecular scattering of light in the water is a function of the fourth power of the frequency, observed light and therefore color is greater for shorter than for longer wavelengths, and blue dominates in the visible portion of the spectrum. Scattering of light from particulate suspensoids, however, is increasingly less selective with increasing particle size (Hutchinson, 1957). Colloidal $CaCO_3$, common to hardwater lakes and certain glacially fed streams, scatters light in the greens and blues and gives these waters a very characteristic blue-green color. Most of the color of lake waters results from dissolved organic matter and its rapid, selective absorption of the shorter wavelengths of the visible spectrum. As a result, emitted scattered light dominates in the green portion of the spectrum and, with increasing concentrations of organic matter, especially humic compounds, increases in the yellows and reds.

A. Sestonic Color and Turbidity

When the density of particulate matter suspended in the water becomes great, a ***seston***[8] color can be imparted to the water in spite of the relatively nonselective scattering properties of the particles. Suspension of large amounts of inorganic materials, such as clays or volcanic ash, can yield a yellow to brownish-red coloration. Seston color, however, is usually associated with large concentrations of suspended algae or, less frequently, with pigmented bacteria or microcrustaceans. Where cyanobacteria or diatoms occur in great profusion and often accumulate in the surface waters, they may produce blue-green or yellowish-brown colors, respectively. Blood-red color occurs commonly in lakes where conditions are temporarily ideal for massive development of populations of certain dinoflagellate algae, such as *Glenodinium.* At low concentrations of suspended algae, as in the open ocean, the chlorophyll bands of algal pigments have no appreciable influence on water color (Yentsch, 1960). Most of the absorption of light is by the water and dissolved organic compounds. Much absorption and scattering of light by particles is caused by nonchlorophyllous suspensoids (over 65% in a subalpine, oligotrophic lake; Priscu, 1983).

[8] ***Seston*** is a collective term for all particulate material present in the free water. Seston includes both ***bioseston*** (plankton and nekton; see Chap. 8) and ***abioseston*** or ***tripton*** (nonliving particulate material).

Turbidity is also a visual property of water and implies a reduction or lack of clarity that results from the presence of suspended particles or suspensoids. Turbidity usually consists of inorganic particles and originates by erosion of soil of the catchment basin and from resuspension of the bottom sediments (e.g., Nolen *et al.*, 1985). Inorganic turbidity tends to be higher in reservoirs than in natural lakes, in part often associated with larger fetch distances and shallower depths for much of the basin. These inorganic particles often range in size from 0.2 to 2 μm and consist of silicate minerals (mica, illite, montmorillonite, vermiculite, kaolinite) and aluminum and iron oxides (Kirk, 1994).

Suspended particles absorb as well as scatter photons. Although suspensoids usually absorb light substantially only in certain waters, the particles contribute almost entirely to the scattering of solar radiation in natural waters. Light incident upon inorganic particles is reflected externally, can enter the particle to be reflected internally and refracted upon exiting, or be transmitted through the particle and refracted upon leaving. Most of the scattered light will be in a forward direction, within a small angle of the direction of the incident light (Kirk, 1994). The increased scattering of light by turbidity causes enhanced reflection and scattering of light out of the water into the atmosphere.

A particularly common suspensoid in hardwater lakes is associated with colloidal and particulate $CaCO_3$, almost entirely as calcite crystals (cf. detailed discussion in Chap. 11). These suspensions of carbonate become particularly abundant and visually conspicuous as "whitings" in temperate lakes during spring and early summer. During this period, supersaturated conditions are often exceeded because of increasing temperatures and photosynthetic utilization of CO_2 and production of hydroxyl ions, which result in precipitation of particles in the range of 1–20 μm. As these particles settle, turbidity increases markedly, with large increases in backscattering of light, particularly in the blue-green portion of the spectrum (e.g., Weidemann *et al.*, 1985; Effler *et al.*, 1987; Hanson *et al.*, 1990). In certain lakes, such as appropriately named Blind Lake in southeastern Michigan (Schelske *et al.*, 1962), the suspension is so fine and production so intense from supersaturated groundwater sources, that the colloidal suspension renders the water nearly opaque continuously. Light is backscattered with a brilliant blue-green opalescence.

B. Color Scales

Any color (shade or tint) always has two decisive characteristics: color intensity (brightness) and light intensity (lightness) (Albers, 1963). This duality in color intervals results in an extremely subjective ability to discriminate colors. Moreover, visual memory is very poor in comparison with auditory memory. Therefore, the psychophysical nature of reactions of visual organs to light and color has led to several attempts to standardize observations by means of various color scales.

Several color scales have been devised to empirically compare the true color of lake water, after filtration to remove suspensoids, to various combinations of inorganic compounds in serial dilutions. Platinum units[9] is the most widely used comparative scale in the United States. Very clear lake water would yield a value of 0 Pt units, and heavily stained bog water about 300 (cf. Table 5-3). In Europe, the Forel-Ule color scale, involving comparisons to alkaline solutions of cupric sulfate ($CuSO_4$), potassium chromate (K_2CrO_4), and cobaltus sulfate ($CoSO_4$), is commonly used. A strong correlation exists between the brown organic color, which is derived chiefly from decomposing plant detritus, and the amount of dissolved organic carbon in the surface waters (Juday and Birge, 1933). Frequently, color units increase with depth in strongly stratified lakes; this is most likely related to increased concentrations of dissolved organic matter and ferric compounds near the sediments. The subjectivity of color evaluations can be reduced greatly by rather elaborate optical analyses and comparisons with standardized chromaticity coordinates (see Smith *et al.*, 1973).

VII. TRANSPARENCY OF WATER TO LIGHT

Evaluation of the vertical extinction and spectral characteristics of light in natural waters is commonly accomplished *in situ* with modern underwater quantum sensors. An approximate evaluation of the transparency of water to light was devised by an Italian scientist, Secchi (pronounced "sekki"), who observed the point at which a white disk lowered into the water was no longer visible. This method continues to be used widely owing to its simplicity. The Secchi disk transparency is the mean depth of the point where a weighted white disk, 20 cm in diameter, disappears when viewed from the shaded side of a vessel and that point where it reappears upon raising it after it has been lowered beyond visibility (cf. Wetzel and Likens, 1991).

The Secchi disk transparency is essentially a function of the reflection of light from its surface and

[9] 1000 Pt units = the color from 2.492 g potassium hexachloroplatinate (K_2PtCl_6), 2 g cobaltic chloride hexahydrate ($CoCl_2 \cdot 6H_2O$), 200 ml concentrated hydrochloric acid (HCl), and 800 ml water. The color units of filtered water are best examined spectrophotometrically at 410 nm, calibrated against Pt-Co reference solutions (Hongve and Åkesson, 1996).

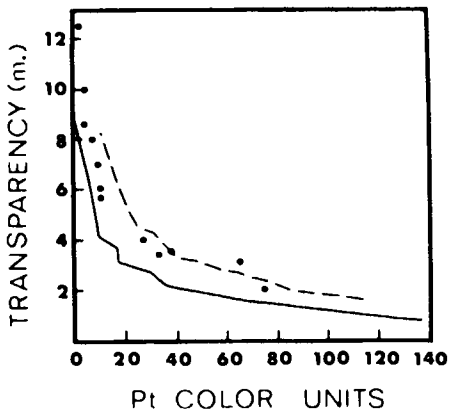

FIGURE 5-16 Relationship between Secchi disk transparency and dissolved color from Swedish lakes (points and dashed line) and 470 Wisconsin lakes (solid line). (From data of Åberg and Rodhe, 1942.)

is therefore influenced by the absorption characteristics both of the water and of its dissolved and particulate matter. Within limits, a parabolic relationship exists between dissolved organic matter and Secchi disk transparency (Fig. 5-16). However, both theoretical analyses and a large number of empirical observations have shown that the reduction in light transmission in relation to Secchi transparency measurements is associated to a greater extent with increased scattering by particulate suspensoids (Štěpánek, 1959; Szczepański, 1968). This correlation is particularly true in very productive lakes and in a very generalized way has been used to estimate the approximate density of phytoplankton populations. Where even moderate amounts of nonalgal turbidity are present, attempts to estimate algal biomass for trophic state classification from Secchi depth data are inappropriate (Lind, 1986). Although the transparency depth is independent of surface light intensity to a significant extent, results become erratic near dawn and dusk (Åberg and Rodhe, 1942), and the Secchi disk should be used preferably at midday.

Observed Secchi disk transparencies range from a few centimeters in turbid reservoirs to over 40 m in a few rare clear lakes. The Secchi disk transparency correlates closely with percentage transmission of light. At the extremes, Secchi disk transparency depths can represent from 1 to 15% transmission (Beeton, 1958; Štěpánek, 1959; Tyler, 1968; and others). The variation is related to differences in the sensitivity of underwater photometers and to the size of suspensoids. In general, the Secchi disk transparency depth corresponds to the depth of approximately 10% of surface light. The relationship between Secchi disk transparency and the extinction coefficient is very good during ice-free periods. The relationship, based on empirical data, of $\eta\ m^{-1} = 1.7/z_{sd}$, where z_{sd} is the Secchi disk transparency depth in meters (Poole and Atkins, 1929), has been shown to be approximately correct in a variety of inland waters (Idso and Gilbert, 1974), although Walker (1980) indicates that $\eta\ m^{-1} = 1.45/z_{sd}$ is more in agreement with results for the sea. Seasonal variations, such as are depicted in Figure 5-17, are common for lakes of the

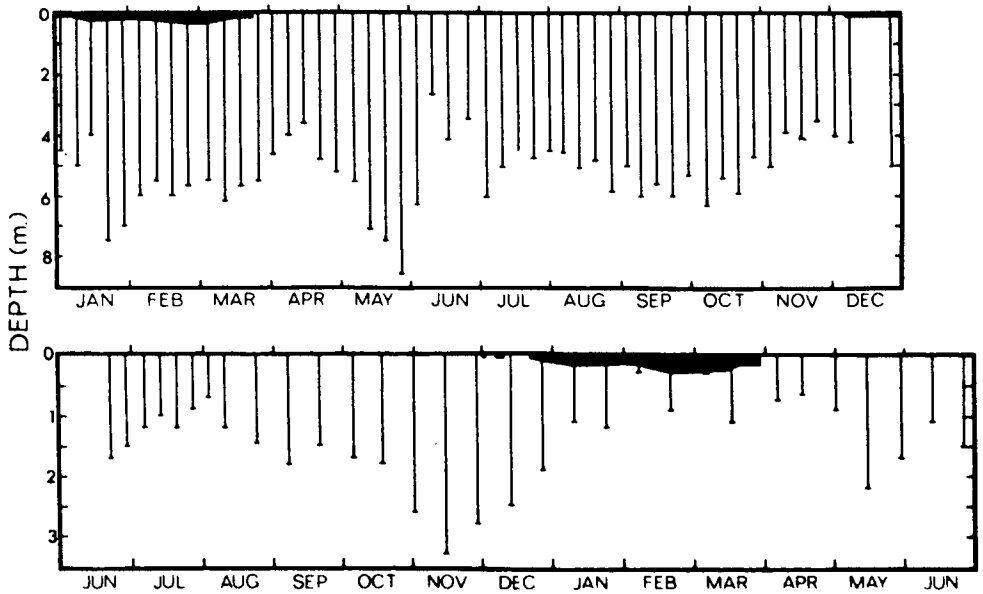

FIGURE 5-17 Annual variations in the Secchi disk transparencies of hardwater Lawrence Lake, 1968 (*upper*), and very productive Wintergreen Lake, 1971–1972 (*lower*), southwestern Michigan. (From Wetzel, unpublished data.)

temperate zone. The examples cited include an unproductive hardwater lake and a highly productive lake with dense algal populations throughout much of the year, particularly in the period of late winter through early summer. Even in the clearest lakes, such as alpine lakes, similar seasonal trends occur.

Colored Secchi disks have been employed in estimations of the spectral distribution of light with depth (Štěpánek, 1959; Elster and Štěpánek, 1967). Within general limits, comparisons of transparencies with a series of colored disks to that of white provides an approximate evaluation of the spectral characteristics of lake waters.

VIII. UTILIZATION AND EFFECTS OF SOLAR RADIATION

Solar radiation is the major energy source driving the productivity of aquatic ecosystems, whether it is incorporated into potential energy by biochemical conversions within the lake directly by its flora or by terrestrial components within the watershed and imported as organic matter to the lake. Algae and macrophytes use between 4 and 9 quanta of light energy per molecule of CO_2 reduced. The photosynthetic receptor is the chloroplast, which consists of a lamellar structure from 1 to 10 μm in diameter and approximately 0.25 μm in thickness. Absorption of light energy is specific for different chlorophyllous pigments: the absorption peaks of the primary pigment chlorophyll *a* are at 640 nm and 405 nm, and those of chlorophyll *b* at 620 nm and 440 nm. Certain plants, such as wheat, have broad responses to quanta of energy with relatively high efficiency of utilization in the green wavelengths, in addition to those of chlorophyll *a*. Other potential adaptations of plants to certain photic environments exist. For example, in the cyanobacterium *Microcystis*, the action spectra indicate that the accessory pigment phycocyanin gains importance when this organism is grown in red light and the cells lose chlorophyll *a*. Other auxiliary pigments supplement the excitation of chlorophyll *a* and improve the efficiency of photosynthesis at long wavelengths.

Photosynthesis of algae is clearly damaged by exposure to UV-B and especially UV-A radiation from natural solar irradiance. Physiological and genetic recovery occurs, and as a result a quasi–steady-state balance between damage and recovery processes is commonly observed (Cullen and Neale, 1994; Karentz *et al.*, 1994). Most species can repair damage to photosystems and DNA and commonly recover during diurnal periods of darkness or repeated and prolonged exposure to UV. Many species produce UV-absorbing pigments; mycosporine–like amino acids are an important and ubiquitous class of such compounds (Vincent and Roy, 1993; Xiong *et al.*, 1997). Many species have a variety of biochemical defenses against toxic end products of UV radiation, such as radical scavenging by carotenoid pigments and superoxide dismutase. Some species avoid intense UV by migration to deeper areas.

The metabolism of epilimnetic phytoplankton can be severely inhibited in the surface water layers. For example, UV-photoinhibition can result in major reductions of photosynthesis (> 80%) and of chlorophyll *a* (> 60%) when incubated at full natural UV (Bühlmann *et al.*, 1989; Moeller, 1994; Kim and Watanabe, 1993, 1994). UV-A penetrates further than does UV-B, and UV-A photoinhibition was found to be more severe than UV-B alone under natural conditions of UV attenuation.

UV radiation can impact zooplankton and fish directly in shallow water habitats. Direct effects can alter DNA, and UV-B photolysis can generate harmful photochemicals (free radicals, reactive oxygen species) (Hessen, 1994; Siebeck *et al.*, 1994). Although many animals can avoid UV-intense habitats, photoprotective pigments are often developed (cf. discussion on p. 453). Both movements to different habitats as well as development of pigments can alter the susceptibility of prey to predation by fish.

In addition to the adaptations of photosynthetic organisms to the aquatic photic environment, utilization of light by aquatic animals is also specific. The visual receptors of animals have a quantum efficiency of 1, the maximum possible. Among the invertebrates, for example, the opossum shrimp *Mysis* possesses visual receptors with a peak at 515 nm and is found only in deep portions of clear lakes, that is, in an optically blue environment. The water flea *Daphnia* migrates diurnally from deep to surface waters and is adapted for life in changing photic environments with four visual receptor peaks, at 370, 435, 570, and 685 nm (Chap. 16). The dragonfly, which spends much of its life cycle as an immature aquatic nymph, has visual receptors with a peak only in the green (530 nm) and possibly the blue (420 nm) portion of the spectrum (Ruck, 1965). Upon its shifting to the aerial adult stage, an increase in the number of receptor peaks (380, 420, 518, 530, and 550 nm) occurs. Similar situations are found among the fishes; those living only deep in a blue photic environment have maximum reception at approximately 485 nm, whereas shallow-living fishes possess receptors sensitive to longer wavelengths.

Behavioral adaptations to the utilization of light are also common. For example, *Daphnia* uses light as a cue in body orientation while swimming. The long axis

of the body is oriented with the vector of maximum light energy, which affects directional swimming of these crustaceans during vertical migrations; hence the distribution of *Daphnia* populations within the lake is light-dependent.

It is now essential that we consider, in addition to these direct physiological effects and utilization responses, the effects of absorption of solar energy and its dissipation as heat on the physical, chemical, and biotic structure of aquatic ecosystems.

IX. SUMMARY

1. Solar radiation is the major energy source for aquatic ecosystems. The productivity and internal metabolism of fresh waters are driven and controlled by energy derived directly from the solar energy utilized in photosynthesis. Photosynthetic biochemical conversions utilizing solar energy occur within fresh waters both directly by aquatic flora as well as indirectly by terrestrial and wetland plants within the drainage basin and imported to the streams and lakes as organic matter. In addition, absorption of solar energy and its dissipation as heat affects the thermal structure, water mass stratification, and hydrodynamics of lakes and reservoirs. These characteristics have marked attendant effects on all chemical cycles, metabolic rates, and population dynamics.
2. Solar radiation can be viewed as pulses of electromagnetic energy, ***quanta*** or ***photons,*** that moves, transversely in a wave conformation of characteristic wavelengths and amplitudes. Absorption of light by atoms and molecules occurs from the resonation of electrons of atoms and molecules at frequencies that correspond to the quantum energy state of impinging light. Each molecular or atomic species, whether photochemical organic compounds in biochemical reactions or inorganic, has a unique set of absorption frequencies at which quantum energy lost by the photon is gained.
3. Much of the incoming irradiance (> 50%) impinging on the surface of water bodies occurs at wavelengths in the infrared portion (> 1,000 nm) of the solar spectrum and has major thermal effects on aquatic systems. Within the visible portion of the spectrum, most of the energy is in the longer wavelengths (reds) of lower frequencies.
4. The amount and spectral composition of solar energy impinging on water bodies is influenced by many dynamic factors.
   a. The angle of light incidence is more perpendicular in equatorial regions, during summer and at midday, than in regions of higher latitude, winter, or at times of the day closer to dawn or dusk. As a result, light must pass through greater distances of atmosphere as the angle of incidence increases from the perpendicular. Selective absorption by oxygen, ozone, carbon dioxide, and water vapor occurs as light passes through the atmosphere, and shorter wavelengths of higher frequencies are rapidly removed (hence the red sky at dawn and dusk).
   b. Indirect solar radiation from the sky results from atmospheric molecular scattering. Short wavelength radiation of higher frequency is scattered more than longer wavelength light (hence the blue appearance of clear sky at midday).
   c. A portion of light reaching water is reflected away from the surface. The greater the departure of the angle of the Sun from the perpendicular, the greater the reflection. When the surface of the water is disturbed by wave action, reflection increases somewhat (10–20%). Cloudy ice and snow greatly increase the amount of reflected light.
5. Of the total light energy entering the water, a portion is scattered and the remainder is absorbed by the water itself, dissolved compounds, and suspended particulate matter. The total diminution of radiant energy by both processes is called ***light attenuation.***
   a. The scattering of light results from deflection of light energy by molecules of water, its solutes, and suspended inorganic and organic particulate materials. Therefore, the extent of this internal reflection varies greatly with depth, season, and the dynamics of inorganic and organic loading in relation to water stratification, productivity and distribution of organisms, and other factors.
   b. ***Light absorption*** is the diminution of light energy with depth by transformation to heat.
   c. The molecular structure of water results in selective absorption of light. Percentile absorption of light by water alone is very high in the infrared and red, lowest in the blue, and increases again somewhat in the violet–ultraviolet portions of the visible spectrum.
   d. Dissolved organic compounds, especially humic compounds, drastically increase absorption of light. Selective absorption is greatest in the infrared and red wavelengths; coupled to the high infrared absorption of water itself, the combined effect is rapid absorption and heating of surface water. Even very low concentrations of dissolved organic compounds absorb greatly the UV, blue, and green wavelengths. Hence, in stained waters,

the dominant wavelengths penetrating to significant depths are in the yellow and red portions of the spectrum.

e. Light absorption by particulate suspensoids, when not in extremely high concentrations, is relatively unselective at different wavelengths.

f. The vertical extinction coefficient (η per meter) is an expression of the exponential attenuation of irradiance at depth in relation to that at the surface. The total extinction (η_t) of natural waters is the sum of absorption by the water itself (η_w), dissolved compounds (η_c), and particles suspended in the water (η_p). Although the mean η_t varies considerably with depth and over a year, the annual mean is fairly representative of the transparency of a lake or reservoir.

g. Although clear, colorless ice absorbs little more light than water, cloudy ice (with air bubbles, irregular crystals) and snow attenuate light severely. Spectral attenuation by clear ice is similar to that of pure water.

V. Summary

The absorption of solar energy by lake water is, as we have seen, influenced by an array of physical, chemical, and, under certain conditions, biotic properties of the water. In addition, headwater areas of low-order streams and the edges of very small lakes can be shaded by terrestrial and floodplain vegetation. These characteristics are dynamic and change seasonally and over geological time for individual river and lake systems. Before discussing the distribution of heat in running waters, it is instructive to evaluate the sources of heat to water in general and its distribution in lakes.

The amount of light energy absorbed by a solution increases exponentially with the distance of the light path through the solution. For light of a wavelength of 750 nm, 90% is absorbed in 1 m, while only 1% transmitted through 2 m of pure water. Absorption is increased markedly by dissolved organic matter. Since much of solar energy is of low frequency in the infrared portion of the spectrum at wavelengths greater than 750 nm, the upper 2 m of lake water absorb over one-half of the Sun's incoming radiation.

The high specific heat of water permits the dissipation of light energy and its accumulation as heat. The retention of heat is coupled with factors that influence its distribution within the river or lake ecosystem: the physical work done by wind energy, currents and other water movements, the morphometry of the channel or basin, and water gains and losses. Resulting patterns of thermal succession and stratification influence in fundamental ways physical and chemical cycles of rivers and lakes, which in turn govern production and decomposition processes.

I. DISTRIBUTION OF HEAT IN RIVERS

The heat content of river water reflects the instantaneous balance among inputs, storage, and outputs. Inputs of heat to a particular section of a river include short-wave solar radiation and long-wave atmospheric and forest radiation from condensation and precipitation, and advection of heat from ground water, from upstream, and from tributary inflows (Walling and Webb, 1992). Heat energy is lost from the water through reflection of solar, atmospheric, and forest radiation, by back radiation from the water, by evaporation, and by outflow from that section of the stream. Energy can be gained or lost by convection and by conduction to or from the atmosphere, stream bed, and banks. Solar, atmospheric, and back radiation terms are dominant in the energy budgets (Brown, 1969). These parameters, and the volume of water, will affect

the rates of change of temperatures in streams and rivers.

Temperatures of streams and rivers vary in relation to air temperatures. A strong linear relationship often exists between air and river water temperatures, with some time lags by the water (Smith, 1981; Crisp and Howson, 1982). Departures from this linear relationship are common, as water rarely declines below 0°C even in extreme climates. Melting snow in the spring can keep temperatures well below that of air for weeks or longer, and precipitation on land can result in inflows of surface or ground waters of temperatures quite different from air temperatures for considerable periods (days). Clearly, hydrology is important in modifying the obvious interacting factors of climate and insolation (cf. Hynes, 1970; Ward, 1985) that determine the thermal régimes of running waters.

Even in the tropics, most rivers exhibit diurnal variations in water temperatures, particularly when shallow and exposed to direct solar irradiance. Small and heavily canopied streams exhibit only very small diurnal changes (ca. 2°C d^{-1}). On a large spatial scale, the amplitude of the annual oscillation or harmonic of temperature increases with increasing latitude and altitude (Walling and Webb, 1992). Maximum temperatures often increase progressively from the headwaters to the mouths of river ecosystems. These downstream changes in water temperatures formed the foundation for a widely used river zonation system that will be discussed later in relation to changes in benthic invertebrate and fish communities (Müller, 1951; Ilies, 1953). Within individual sections of a river, temperatures can also vary in response to marginal vegetation cover, groundwater seepage, channel depth and shape, orientation, substratum conditions, and silt content of the water (Walling and Webb, 1992). Submersed aquatic vegetation tends to increase annual mean temperatures and the amplitude of daily fluctuations (Crisp *et al.*, 1982). Within the hyporheic zone of stream sediments, streamwater infiltration occurs at the head of riffles and can alter temperatures of the interstitial water as much as 50 cm deep (White *et al.*, 1987; Crisp, 1990).

Ice formation on rivers is effective in reducing heat losses from the water. Complete ice cover is rare; often, small areas remain open to the atmosphere, particularly over riffles. Ice can form below the surface as well. Crystals of ***frazil ice,*** or slush ice, can form in turbulent, slightly supercooled water. Frazil ice consists of small discs of ice (1–4 mm in diameter and 1–100 μm in thickness) that form at rapids and other areas of open water (Martin, 1981). When moved with the water, frazil ice can scour the substratum and associated organisms. ***Anchor ice***, of much more rigid bonding (Hobbs, 1974), can also form on riffle substrata in shallow water, and impede water flow, increase water levels in pool areas, and cause flooding (Prowse, 1994). When moved by water currents, substrata are picked up with the anchor ice and can be transported large distances downstream. Ice breakup in rivers at high altitudes and latitudes is characterized by large increases in current velocity, stage, water temperatures, concentrations of suspended materials, and scouring of the substrata (Scrimgeour *et al.*, 1994). Major disturbances to biota associated with the substrata result.

Because temperatures within the range acceptable to most biota influence directly rates of metabolism, growth, and reproduction, the cumulative temperature above freezing varies greatly with the length of the growing season. A measure of the cumulative temperature experienced by biota, called ***degree-days***, is the sum of daily mean temperatures above 0°C over a standard period of time, usually a year. Because of the linear relation of water and air temperatures, annual degree-days increase with decreasing latitude at low elevations (Vannote and Sweeney, 1980).

II. DISTRIBUTION OF HEAT IN LAKES AND RESERVOIRS

It is evident from previous discussion that the greatest source of heat to lakes is solar radiation, and most is absorbed directly by the water. Some transfer of heat from the air and from the sediments does occur, but in lakes of moderate depth, this input is small compared to direct absorption. In shallow waters, sediments can absorb significant quantities of solar radiation, and this heat may be transferred in part to the water. However, terrestrial heat is generally very small in comparison to direct absorption of solar radiation by the water. Exceptions include lakes that receive significant percentages of their volume from surface runoff in short periods of time, such as small or shallow reservoirs that have short retention times. Indirect heating also can be significant in lakes that have high-volume inputs from groundwater sources and springs, especially in the case of hot springs and certain volcanic lakes. Condensation of water vapor at the water surface also provides some heat input to the lake from the air.

Some heat is lost from lakes by thermal radiation (cf. Chap. 5). However, because the thermal conductivity of water is very low, heat loss by thermal radiation is predominantly a surface phenomenon, restricted to the first few centimeters of water. Measurable amounts of heat are lost nonetheless by specific conduction both to the air and, to a much lesser degree, to the sediments. Heat is also lost through evaporation. The rate

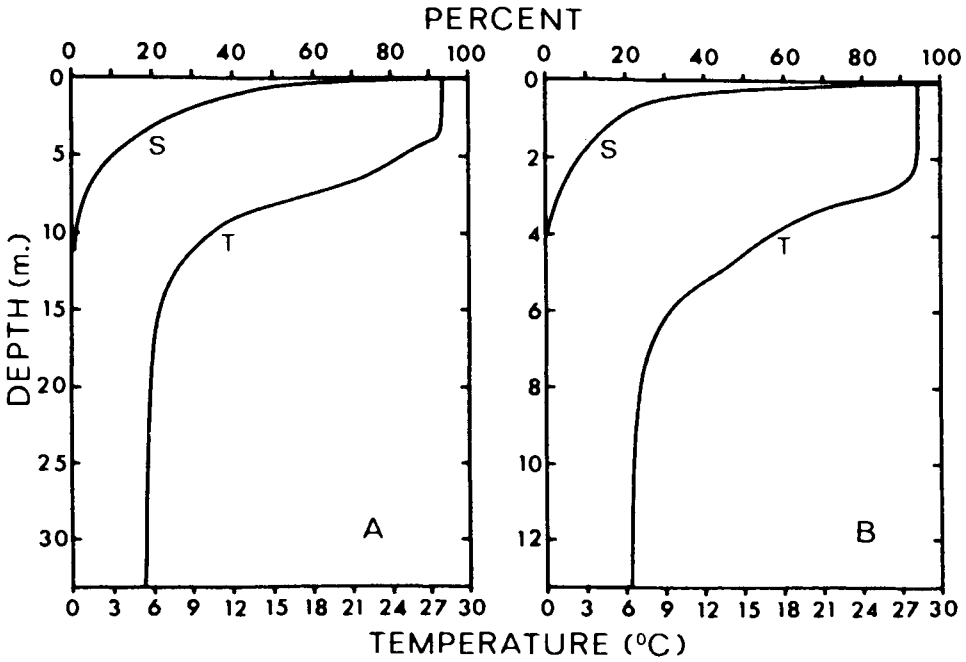

FIGURE 6-1 Vertical depth profiles of the penetration of solar radiation (*S*) and temperature (*T*) in (a) Crooked Lake and (b) interconnected, adjacent Little Crooked Lake, Noble-Whitley counties, Indiana, 18 July 1964. (From Wetzel, unpublished data.) Note differences in depth scales; Crooked Lake has a much larger surface area (79 ha) than Little Crooked Lake (5.3 ha).

of evaporation increases with higher temperatures, reduced vapor pressure, lower barometric pressure, and increased air movement over the water or ice surface and decreases with increasing salinity. When water at 0°C to freezes, 79.7 cal g^{-1} must be released,[1] and, conversely, when ice at 0°C melts to water at 0°C, an equal amount of heat must be absorbed. This latent heat of fusion is among the highest for known compounds. In addition, as ice sublimes to water vapor, 679 cal g^{-1} must be absorbed (see full discussion in Chap. 2). A significant portion of the heat increments to lakes or especially reservoirs can also be lost through outflow. Outflow usually consists of surface waters, and surface waters are often much warmer than underlying water strata.

The inputs and outputs of heat are therefore largely surface phenomena. Solar influx would be expected to dominate in the warmer seasons of the year, and the vertical thermal structure would then approximate the attenuation profile of solar radiation (Fig. 6-1). We might expect that warmer, less dense, and very stable heated water would successively overlie cooler and more dense water. Such is not the case, however, and what is observed (Fig. 6-1) is a relatively uniformly mixed upper portion of the lake that is isothermal often well below the photic zone.

Some convection currents do occur at night when the surface waters cool, become more dense, and sink. Similarly, surface waters can cool during brief shifts in local meteorological conditions, such as under cloudy conditions, increased evaporation rates, cold rain, et cetera, or after seasonal decreases in air temperatures. Surface influents, particularly in reservoirs, also may cool surface waters and induce convection currents. Under most conditions, in typical lakes of temperate latitudes mixing of the surface waters by convection currents is weak (up to 3 m) and insufficient to produce the thermal profiles observed during the heating period of thermal stratification.

Direct absorption of solar radiation accounts for only about 10% of the observed distribution of heat (Birge, 1916). Most of the heat distribution profile results from the action of the wind. As air currents move across the water interface, a frictional wind stress on the surface water generates mixing and currents proportional to the wind velocity (cf. Chap. 7). Very rapid (minutes) changes occur in the microstructure of the temperature profiles of the surface layers. The temperature, and thus the density, is rarely uniform in the surface layer, particularly when strong surface heating is

[1] The correct value is 79.72. The often-cited value of Weast (1970) and earlier editions is in error and is corrected in newer editions of this handbook (personal communication).

occurring or when wind stress is abating (Imberger and Hamblin, 1982; Imberger and Patterson, 1990).

A. Thermal Stratification

It is instructive to begin a discussion of thermal stratification in lakes by examining typical conditions of lakes of the temperate zone that experience strong contrasts in seasonal conditions. Most lakes are concentrated in the temperate and especially northern latitudes, and this permits some degree of generalization. Many exceptions to this general pattern can be found and will be indicated when applicable.

Ice cover on the lake commonly deteriorates in the spring in a relatively slow, progressive way until it is permeated with air columns and/or saturated with water. Warm rains often accelerate this process of ice erosion. The loss of ice cover is usually rapid, often taking place in a few hours, especially if associated with a strong wind. At this time, the water at all depths is near the temperature of maximum density. Slight changes from the temperature of maximum density, either cooling below or warming above 4°C due to vagaries in weather conditions, result in very small changes in density difference per unit change in temperature (cf. Chap. 2). As a result, there is relatively little thermal resistance to mixing, and only small amounts of wind energy are required to mix the water column. In most lakes, the amount of wind energy impinging on the surface is adequate to circulate the entire water column. Circulation, aided to some extent by convection currents induced by cooling at night and by evaporation, can continue for varying periods of time.

The duration of the ***spring turnover*** is governed by many factors. Lakes of small surface area, especially if protected from the wind by surrounding topography or terrestrial vegetation, may circulate only briefly in the spring, often for only a few days. Large lakes, in contrast, often circulate for a period of weeks, and, weather conditions permitting, the temperature of the entire water mass can increase to well above that of maximum density. During this period of mixing in spring turnover, the extent of heating is also a function of the volume of water that must be heated relative to net solar income. In very deep, large lakes such as the Laurentian Great Lakes and Lake Baikal, the heat income can be insufficient to increase significantly the temperatures of the deep water, even if the lake circulates completely. The spring period of circulation in shallow lakes, on the other hand, may allow water temperature to increase to well above 10°C.

As spring progresses, the surface waters of lakes of sufficient depth, usually greater than 6 m, are heated more rapidly than the heat is distributed by mixing.

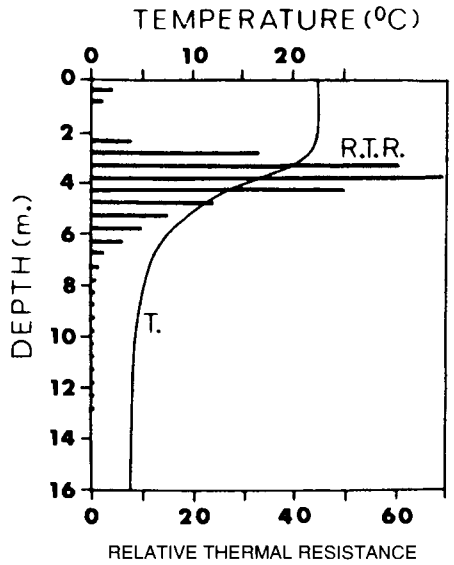

FIGURE 6-2 A summer temperature profile (*single line*) and relative thermal resistance to mixing (bars) for Little Round Lake, Ontario. The relative thermal resistance (R.T.R.) to mixing is given for columns of water 0.5 m deep. One unit of R.T.R. = 8×10^{-6}, that is the density difference between water at 5 and at 4°C. The R.T.R. of the lake water columns is expressed as the ratio of the density difference between water at the top and bottom of each column to the density difference between water at 5 and 4°C. (Modified from Vallentyne, 1957.)

Usually, the rapid surface heating occurs during a warm, calm period of several days. As the surface waters are warmed and become less dense, the relative thermal resistance of mixing increases markedly. A difference of only a few degrees is then sufficient to prevent complete circulation (Fig. 6-2; an identical analysis is given for Lake Mendota by Birge, 1916). From that time onward, the water column is thermally divided into three regions, which are exceedingly resistant to mixing with each other. The initial temperature of the lowest stratum (the ***hypolimnion***) is thus determined by the final water temperature during the spring turnover. The temperature of the hypolimnetic water changes little throughout the period of summer stratification, especially in deep lakes.

The period of summer stratification is characterized by an upper stratum of more or less uniformly warm, circulating, and fairly turbulent water, the ***epilimnion*** (Fig. 6-3). The epilimnion essentially floats upon a cold and relatively undisturbed region, the hypolimnion. The stratum between the epilimnion and the hypolimnion termed the ***metalimnion*** exhibits a marked thermal discontinuity. The metalimnion is defined as the water stratum of steep thermal gradient demarcated by the intersections of the nearby homoiothermal epilimnion and the hypolimnion (graphically depicted in Fig. 6-3). The term ***thermocline*** has been

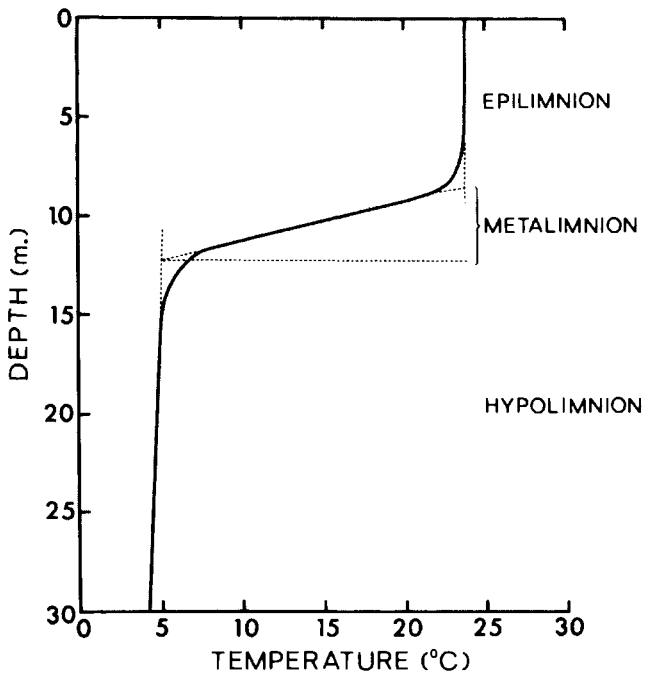

FIGURE 6-3 Typical thermal stratification of a lake into the epilimnetic, metalimnetic, and hypolimnetic water strata. Dashed lines indicate planes for determining the approximate boundaries of the metalimnion (see text).

defined variously but correctly refers to the *plane* of maximum rate of decrease of temperature with respect to depth. An extensive discussion of these terms and their conceptual basis is given by Hutchinson (1957). Terms in wide use that are functionally synonymous with the definition above of the metalimnion include the German *Sprungschicht* and *discontinuity layer* as used in the United Kingdom.

During the transition from spring turnover to summer stratification, the depth of the stratum of greatest thermal discontinuity (usually accepted as a change of $>1°C$ per meter) varies greatly among lakes and from year to year in relation to weather conditions. If the water is being heated rapidly and wind-induced mixing of water is moderately intense but insufficient to circulate the water from top to bottom, the stratum of greatest thermal change will occur deep in the water column (Fig. 6-4). This thermal discontinuity rises rapidly as further heating occurs and density differences increase (see also Fig. 6-9). In contrast, if the weather at this time is relatively calm and hot, strong thermal discontinuities will occur at the surface—in this case, the metalimnion essentially begins at the surface and moves deeper as wind-induced mixing establishes the epilimnion. From that time on, the epilimnion undergoes periods of temporary heating during hot, calm weather and alternates with periods of strong mixing by wind (Fig. 6-4).

The depth of the stratum of steep thermal change is gradually depressed as the upper portion of the hypolimnion slowly gains small amounts of heat throughout the period of thermal stratification (Fig. 6-4 and also particularly Fig. 6-8). It is clear from the early analyses of Ricker (1937) and of Hutchinson (1941) that the heating of a stratified lake proceeds by a combination of direct solar radiation, turbulent conduction, and density currents. The turbulence of the epilimnion is carried into the metalimnion and hypolimnion (Imberger and Patterson, 1990). The conduction of heat by turbulence decreases as the stability of stratification increases throughout the heating season, but within the hypolimnion, heat conduction

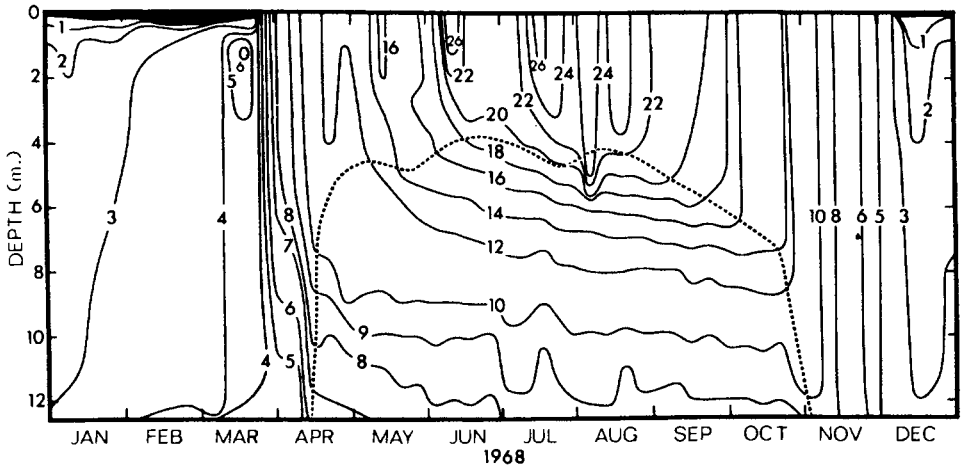

FIGURE 6-4 Depth–time diagram of isotherms (°C) in Lawrence Lake, Michigan, 1968. Dashed line indicates the upper metalimnetic–lower epilimnetic boundary. Ice cover drawn to scale. (Modified from Wetzel *et al.*, 1972.)

varies little with increasing depth. Chemical density currents follow the contour of the basin along the sediments, and as they move to the deepest portions of the basin they can be effective in heat transport. Heat generated by biological oxidations during decomposition is entirely inadequate to account for the observed heat gain by the hypolimnion.

Solar heating of the hypolimnion can occur in lakes that are particularly transparent, such as in alpine situations. In a small, clear mountain lake that is protected from much wind action, an estimated 65–85% of the heating of the upper hypolimnion can be accounted for by direct solar heating (Bachmann and Goldman, 1965; these estimates are likely too high, however; cf. Jassby and Powell, 1975). As might be anticipated, the relative importance of direct solar heating and the transport of heat by turbulence from the upper water strata varies greatly with the conditions of individual lakes. Wind-induced transport of heat to the hypolimnion is usually of greater importance than direct solar heating in most lakes, particularly where light is rapidly attenuated with increasing depth. Solar heating of the hypolimnion, however, can be a significant mechanism in certain clear lakes. Any factor that modifies transparency and penetration of solar radiation can affect thermal structure, seasonal stratification rates, and mixing depths of the epilimnion. Certainly, high concentrations of dissolved organic matter or of high particulate turbidity will increase absorption of infrared; temperatures of highly stained or turbid waters are often several degrees warmer than clear lakes (see Schreiner, 1984). The presence of zooplankton that remove by grazing large portions of the planktonic algae at certain times of the year have been purported to alter transparency, heating, and mixing depths of stratified lakes (Mazumder *et al.*, 1990), although the supporting data could not be separated from other influencing factors.

B. Stability of a Stratified Lake

Stability (S) per unit area of a lake is the quantity of work or mechanical energy in ergs required to mix the entire volume of water to a uniform temperature without addition or subtraction of heat (Birge, 1915; Schmidt, 1915, 1928; Idso, 1973). Therefore, during summer stratification, stability expresses the amount of work needed to prevent the lake from developing thermal stratification. More importantly, stability quantifies the resistance of that stratification to disruption by the wind and therefore the extent to which the hypolimnion is isolated from epilimnetic and surface movements.

The stability of a lake is very strongly influenced by its size and morphometry (Table 6-1). The amount of work (B) contributed by the wind in distributing heat throughout the lake increases proportionally as the size and volume of the lake decrease, whereas the stability (S) or amount of work per unit area to mix a lake to a uniform vertical density is greater in larger lakes. The sum of B and S is the amount of work per unit area (G) needed by the wind to distribute the heat in a lake uniformly at the minimum winter temperature. It should be apparent that the metalimnetic thermal discontinuity represents an effective mixing barrier. The depth of the metalimnion depends primarily on the surface area and can be estimated from knowledge of thermal density differences, morphometry, and maximum wind stress (Gorham and Boyce, 1989). Although not a total barrier, the metalimnion is nearly as effective as the sides of the lake basin. An immense amount of work is required to disrupt it.

TABLE 6-1 Work Required to Distribute Heat by Wind (B), to Render the Lake Homoiothermal (S), and to Maintain Hypothetical Homoiothermal Conditions Throughout the Heating Season (G) for Several Lakes[a]

Lake	*Area (km^2)*	*Maximum depth(m)*	*B (g-cm cm^{-2})*	*S (g-cm cm^{-2})*	*G (g-cm cm^{-2})*
Atitian (Guatemala)	136.9	341	3741	21,500	25,241
Pyramid (Nevada)	532	104	4055	10,255	14,310

Marion (British Columbia)	0.133	4.5	56	11	67

[a] Modified from Hutchinson (1957) and Johnson *et al.* (1978).

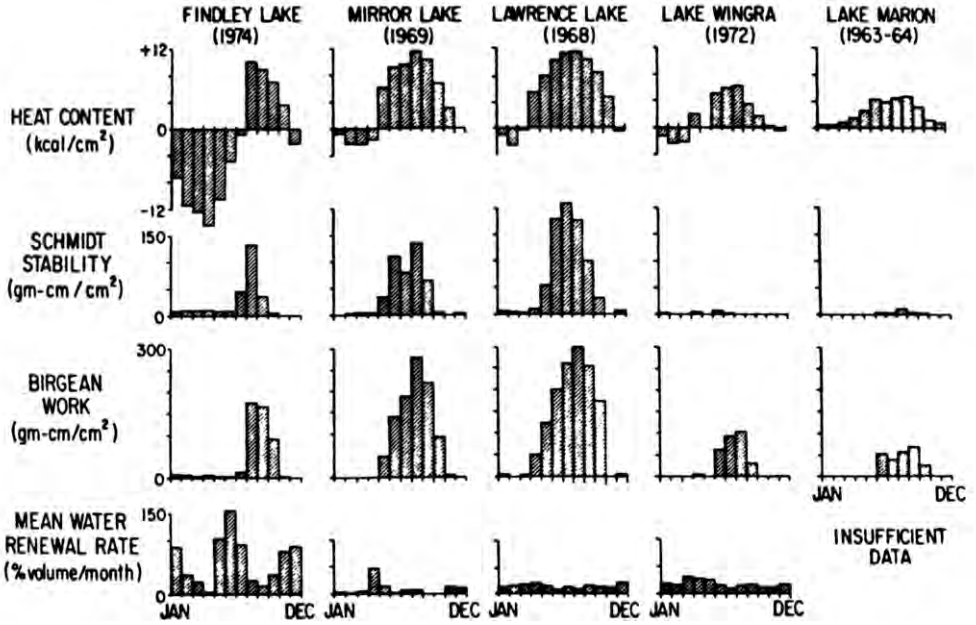

FIGURE 6-5 Monthly distribution of heat content, stability, Birgean work, and mean water renewal rate parameters in five North American lakes. (From Johnson *et al.*: *Verh. Int. Ver. Limnol.* 20:562–567, 1978.)

An excellent example of the usefulness of thermal energy and stability parameters is seen in the comparative analyses of five North American lakes (Fig. 6-5 and Table 6-1). The five lakes are all small, occur at similar latitudes, and, with the exception of alpine Findley Lake, are at similar elevations (Loucks and Odum, 1978). The maximum and mean depths of the lakes (Table 6-1) and water renewal times[2] differ considerably (Fig. 6-5), both seasonally and among the lakes (Johnson *et al.*, 1978). Marion Lake of this series has a renewal rate of about 76 times per year.

Lakes Wingra and Marion are distinctively unstable and exhibit an order of magnitude less stability (10^1 g-cm cm^{-2}) than lakes Lawrence, Mirror, and Findley (10^2 g-cm cm^{-2}). Lawrence and Mirror lakes are virtually identical with respect to their overall thermal and convective regimes, although Lawrence Lake is more stable than Mirror because of its smaller surface area and greater depth. The latent heat of fusion is the dominant factor in the thermal regime of Lake Findley, which is the coldest lake in this comparison. Winter stability is uniformly low ($S < 10$ g-cm cm^{-2}) for all five lakes, because the presence of ice cover prevents wind work from being exerted on the water column ($B \rightarrow 0$). Advection (horizontal movement of water) dominates the circulation of Lake Marion (approximately 76 renewals per year) compared with Mirror, Lawrence, and Wingra lakes (1–2 renewals per year). Advection is seasonally dominant in Findley Lake (>100% renewal per month during some months). The coincidence of the ice-free period with relaxation of advection (August–November) allows considerable stability to become established.

Density differences that regulate stratification in lakes are not always thermally induced. Differences in salinity can produce a similar stratification, often in combination with temperature differences. The stability so produced can exceed that resulting from thermal density differences and may lead to conditions where disruption of stratification is intermittent or never occurs (see discussion of meromictic lakes below).

C. Loss of Stratification

In late summer and fall, declining air temperatures result in a negative heat income to the lake, and loss of heat exceeds inputs from solar radiation. Surface waters cool and become more dense than underlying, warmer epilimnetic water. As the surface water sinks, it is mixed by a combination of convection currents and wind-induced epilimnetic circulation. The penetration of surface waters into the metalimnion continues as the lake continues to cool. A progressive erosion of the metalimnion from above can be observed as the stratum of thermal discontinuity is reduced and the homoiothermous epilimnion increases in thickness.

[2] ***Water renewal*** is the amount of water required to replace the lake volume during a given time interval (reciprocal water residence time).

On an annual basis, the result is an apparent lowering of the metalimnetic thermocline. The isopleth diagram of Figure 6-4 illustrates lines of equal temperature (isotherms) over time against depth. Depth–time diagrams of quantities or intensities of a given parameter are particularly useful in limnology because they aggregate hundreds and often thousands of data points taken at different depths and times into an annual picture that indicates the seasonal dynamics of physical, chemical, or biological properties of the lake. In the example from Lawrence Lake, it can be seen that stratification was maintained down to a depth of 11 m until late October. Finally, the entire volume of lake water was included in the circulation, and ***fall turnover*** was initiated. The transition from the final stages of weak summer stratification to autumnal circulation usually is abrupt and can occur in a few hours, especially if associated with the high wind velocities of a storm.

Circulation continues with the gradual cooling of the water column. The rate and duration of cooling are highly variable from lake to lake and are dependent upon basin morphometry, the volume of water that must be cooled, and prevailing meteorological conditions (Stewart and Haugen, 1990). For example, in Figure 6-4, Lawrence Lake, with a surface area of 5 hectares (ha) and a volume of 0.292×10^6 m^3, cooled down to and below the temperature of maximum density by early December. Waters of nearby Gull Lake, with an area of 827 ha and a volume of 102.1×10^6 m^3, usually circulate well into January before reaching comparable temperatures. Very large lakes, such as the Great Lakes, which are of similar latitudes to those just mentioned, circulate all winter and rarely reach conditions that permit the formation of an ice cover. In large, very deep lakes—for example, Great Bear Lake of the Canadian Northwest Territories—late summer circulation often does not extend to the lower depths (e.g., below 200 m), because stability at lower levels is sufficiently strong to prevent mixing (Johnson, 1966). The temperature of the maximum density of the water below 200 m is 3.53°C because of hydrostatic pressure. In cold years with slow spring heating, when the upper 200 m of water are cooled to 3.53°C in the autumn, the upper waters reach the same temperature of maximum density as the water strata below 200 m. Circulation then extends to the bottom, which is 450 m in Great Bear Lake.

D. Winter Stratification

As the temperature of the water reaches the point of maximum density (4°C), surface ice can form rapidly with such loss of heat as could occur on a calm, cold night. The difference in water density between 4 and 0°C is, as discussed earlier, very small and results in only a minor density gradient just below the surface. Hence, ***inverse stratification***, in which colder water lies over warmer water, is easily disrupted by a small amount of wind energy. Under stormy weather conditions common at this time of year, it is not unusual for a lake to continue to circulate and cool to well below the temperature of maximum density. Water temperatures of between 3 and 4°C are very common before conditions are such that ice cover can form, as for example is seen in Figure 6-4. Isothermy to less than 1°C has been observed frequently before the formation of ice cover, particularly in large lakes that are subject to much wind action.

After the lake has frozen, the ice cover effectively seals it off from the effects of the wind. Immediately below the ice, water of increasing density at the circulation temperature of the water prior to ice formation underlies water of 0°C. The steep thermal gradient near the undersurface of the ice is referred to as ***inverse thermal stratification***. The term *inverse stagnation* should not be used for this condition because it implies that the water beneath the ice is stagnant and not subject to water movement. Most lakes exhibit considerable water movement under ice (cf. Chap. 7).

Heating of the water under ice may occur throughout the winter to considerable depths (cf. Fig. 6-4). Although clear ice is, as we have seen, quite transparent to solar radiation, the type and amount of snow cover on the ice affect transmission of solar radiation. From the few detailed studies on winter heating, it is clear that most (>75%) is from solar radiation (Birge *et al.*, 1927). The relative contribution of heat stored in the sediments during the summer varies from lake to lake in relation to morphometry, summer heating conditions, and other factors (Hutchinson, 1957). Density currents, generated by heating of water through the ice in the shallow littoral areas, can flow toward the central portion of the basin along the sediments. Thermal–density instability is prevented by diffusion of solutes from the sediments, which raises the density slightly, especially as winter progresses, and accounts for the commonly observed temperatures of above 4°C near the sediments.

It is not unusual to observe apparent thermal–density anomalies under the ice. For example, in Figure 6-4, a cell of water in excess of 6°C was found centered around 1 m in late March in this extremely hardwater lake. The ice at this time was weak and porous from heavy, warm rains. Water very low in dissolved solutes, which had entered through the ice or possibly from the margins of the lake and was running under the ice, was less dense than that of the normal water high in

dissolved ions. By this means, solar heating through the ice was able to increase the temperatures in this dilute layer without producing instability. Most of these situations are quite transitory and variable (Kozminski and Wisniewski, 1935) and are likely related in part to air temperatures rising above freezing and advective inflows of warm water from the periphery of the lake (Ellis *et al.*, 1991).

A detailed résumé of the types and characteristics of lake ice is given in Hutchinson (1957), based primarily on the extensive work of Wilson, Zumberge, and Marshall. Two books by Pivovarov (1973) and Ficke and Ficke (1977) summarize in detail the diverse literature on the properties of ice and the thermal characteristics of lakes and rivers under differing conditions of ice cover.

E. Modifications in Stratification

The stratification picture just described, in which a typical temperate lake of moderate size undergoes two periods of mixing, one in the spring and one in the autumn, is called ***dimictic*** and is not always so consistent. Many variations are found in relation to local or regional differences in climate, individual characteristics of the lake morphometry, and movement of the water masses.

A common divergence from the typical summer stratification pattern is the formation of secondary or multiple discontinuity layers (Fig. 6-6). In these situations, which usually last only for a few days or weeks, secondary metalimnia are formed in the epilimnion of the initial stratification during the heating period. These conditions are common when intense heating alternates with periods of extensive mixing. The initial spring metalimnion forms at various depths, as discussed earlier, and stabilizes at a depth characteristic of the lake morphometry and prevailing meteorological conditions. This pattern can be seen in the general limits of the epilimnetic boundary approximately indicated by the dashed line in the example given in Figure 6-4. The mixing of the entire epilimnion can cease

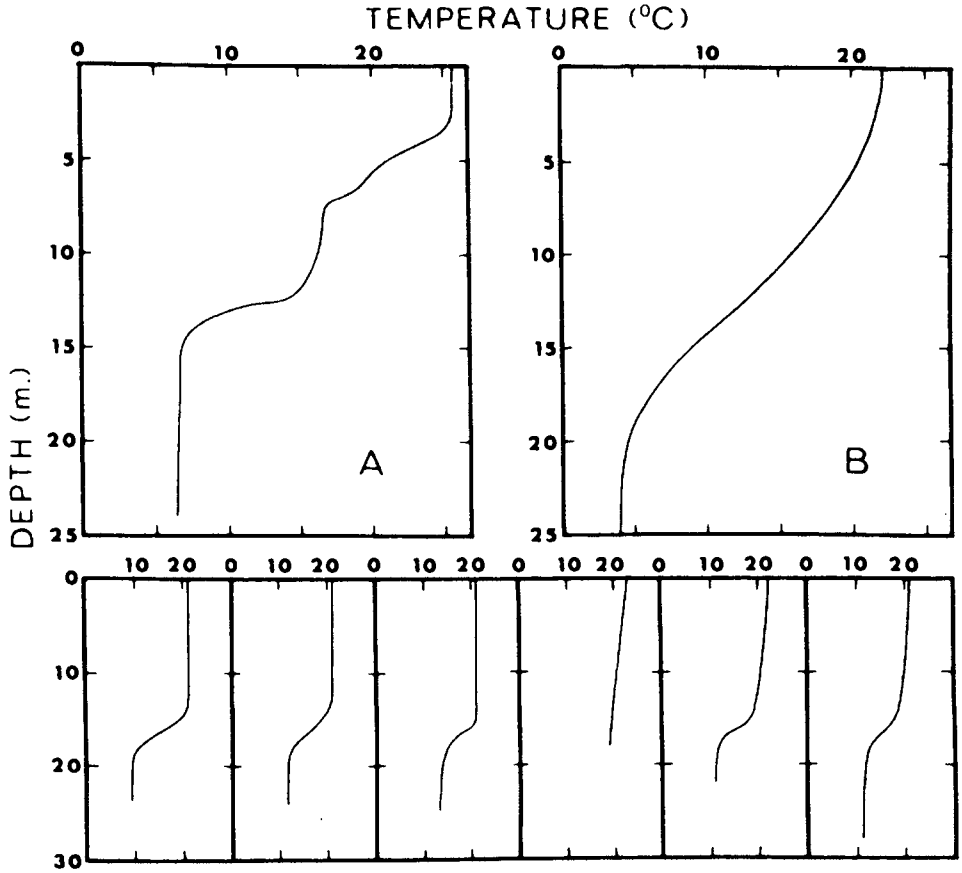

FIGURE 6-6 Variations in summer thermal stratification. (A) Example of multiple thermal discontinuities (generalized from several sources); (B) example of thermal discontinuity greatly reduced by high through-flow volumes (generalized). *Lower series:* Profiles of thermal stratification in submersed depressions of Douglas Lake, Michigan, 10–12 August 1929. (From data of Welch and Eggleton, 1932.)

during a calm, hot period, during which the surface waters can be intensely heated and perhaps mixed by light breezes for only a few meters of depth. In this way, a secondary metalimnion can be formed, overlying the first. The stability of these multiple metalimnia is usually not as great as the stability of the primary deeper one, and they are susceptible to disruption during periods of cooling and strong mixing of the epilimnion. The formation and disruption of these transient discontinuities can occur very rapidly (minutes to hours). Intense solar heating in the morning, wind mixing in the afternoon, and penetrative convective mixing during much of the night is a common pattern of variation in the epilimnion (Imberger, 1985). On a small scale, this process is analogous to normal autumnal erosion of the metalimnion and ensuing circulation.

Thermal stratification can be modified by inflow–outflow relationships, particularly if the volume of influent is large in relation to the volume of the epilimnion. For example, in reservoirs, high inflow from stream discharge, often cooler than the water of the epilimnion, can cause much turbulence and reduce the thermal gradient appreciably (Fig. 6-6b). A similar phenomenon is observed frequently in alpine and northern lakes that receive large flows of glacial or snow meltwater during the later portions of the summer stratification.

Many other variations occur in relation to individual characteristics of lake heating and mixing. Individuality is a prominent characteristic of the observed patterns of thermal structure and is governed strongly by climatic variations, volume of inflow and outflow in relation to the volume of the basin, basin configuration, surface area of the lake, position of the basin in relation to wind action, and other factors. Where the morphometry of the basin is complex, different stratification patterns can be observed within the same basin (see Wetzel, 1966a). Lakes with many submersed basin depressions characteristically exhibit variations in both the position and stability of the metalimnion (Fig. 6-6), which can strongly influence the productivity of these different regions. In the shallow water, depth is insufficient to maintain a typical epilimnion and hypolimnion, but these layers exhibit a reduction in temperature with increased depth. Such diminutive stratification is common in protected shallow areas of large lakes or in entire shallow lakes. Marked horizontal differences in thermal profiles are also observed in steepsided lake basins. For example, thermal microstructures increase as shallow water is approached along a steep lake-bottom slope (Caldwell *et al.*, 1978). These stepped thermal structures result from the mixing activity of internal waves, which are accentuated near the sides of the basin (cf. Chap. 7).

F. Types of Stratification

Density stratification patterns found in many lakes of the world deviate from that described for a typical dimictic situation. Interactions of climate, morphometry, and chemistry increasingly influence stratification and mixing.

F. A. Forel, who is often referred to as the "father of limnology", published extensive monographs on Lac Léman (Lake Geneva), Switzerland, in 1892, 1895, and 1904, that served as a classical foundation in the field for many years. Forel, who proposed a classification of lakes based on their thermal conditions, recognized three types: (1) temperate lakes, which undergo a regular annual alternation of summer and inverse winter stratification between two circulation periods at the temperature of maximum density; (2) tropical lakes, in which the water is never cooled below 4°C and is stratified except for a single period of winter circulation; and (3) polar lakes, in which temperatures never rise above 4°C and the water is inversely stratified except for a single period of summer circulation. However, these descriptions unfortunately suggest that differences depend on latitude, but many exceptions to the classification can be found. An ideal "tropical lake," for example, occurs in the northern temperate region.

Forel's terminology was modified in a number of ways, particularly by Whipple (1898, 1927), Birge (1915), and Yoshimura (1936). Whipple's widely adopted modification of this system subdivided each of the categories into orders on the basis of surface- or deep-water temperatures. According to his scheme, temperatures of bottom waters in first-order lakes remain at 4°C throughout the year. Circulation periods are often absent. In lakes of the second order, water at the greatest depth is near or above 4°C in the summer, and one or two complete circulation periods occur annually between the periods of thermal stratification. Third-order lakes are those in which thermal stratification never occurs, and circulation is more or less continuous, except when the lake is frozen.

As useful as these early categorizations were, it became apparent that alternative groupings were necessary as more information on polar, high-altitude, and tropical lakes became available. A lake classification based on stratification and circulation patterns introduced by Hutchinson and Löffler (1956) and Hutchinson (1957) was widely accepted because it possessed minimal ambiguity. The definitions centered on circulation patterns, as the roots of the names indicate, and

refer to lakes that are of sufficient depth to form a hypolimnion. Six lake types were specified:

1. ***Amictic***: Perennially ice-covered.
2. ***Cold monomictic***: Water temperatures never exceed 4°C, and with only one period of circulation in summer at or below 4°C.
3. ***Dimictic***: Circulate freely twice a year in the spring and fall, and are directly stratified in summer and inversely stratified in winter.
4. ***Warm monomictic***: Circulate freely once a year in the winter at or above 4°C and are stably stratified for the remainder of the year; not ice-covered.
5. ***Oligomictic***: Thermally stratified much of the year but cooling sufficiently for rare circulation periods at irregular intervals; not ice-covered.
6. ***Polymictic***: Frequent or continuous periods of mixing per year; not ice-covered. Ruttner (1963) divided polymictic lakes further into (i) ***cold polymictic*** lakes that circulate continually at temperatures near or slightly above 4°C. Such lakes are found in equatorial regions of high wind and low humidity where little seasonal change in air temperatures occurs. At very high altitudes in equatorial regions, cold polymictic lakes gain a significant amount of heat during the day, but nocturnal losses are sufficient to permit complete mixing during the night. (ii) ***Warm polymictic*** lakes are usually tropical lakes that exhibit frequent periods of circulation at temperatures above 4°C. Annual temperature variations are small in equatorial tropics and result in repeated periods of circulation between short intervals of heating and weak stratification, followed by periods of rapid cooling. Under these circumstances, convectional circulation is sufficient, in combination with wind, to disrupt stratification.

These six lake types, based on thermal and circulation characteristics, were generalized in relation to altitudinal and latitudinal distributions (Fig. 6-7). Elevation is relatively unimportant to lake classification however, except at the highest elevations, and many many exceptions to such generalizations exist, particularly at low altitudes, where there is a strong influence of oceanic climate. Figure 6-7 does, however, demonstrate a generally observed geographical distribution of these lake types.

Any classification system is subject to modifications as further information about natural variance is gained. The Hutchinson-Löffler scheme has been criticized by many workers, and various attempts have

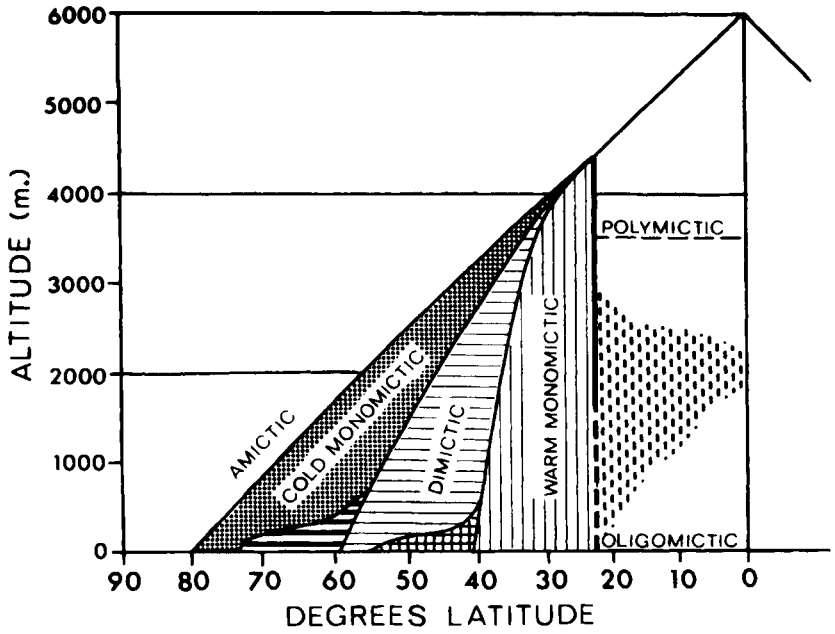

FIGURE 6-7 Schematic arrangement of thermal lake types with latitude and altitude. *Black dots:* cold monomictic; *black-and-white horizontal* bars: transitional regions; *horizontal lines:* dimictic; *crossed lines*: transitional regions; *vertical lines:* warm monomictic. The two equatorial types occupy the unshaded areas labeled oligomictic and polymictic, separated by a region of mixed types, mainly variants of the warm monomictic type (*broken vertical lines*). (Modified from Hutchinson and Löffler, 1956.)

been made for improve and modify it. Lewis (1983a) reviews some of the problems of this system in relation to shallow lakes, separation of meromixis, similarities among tropical lakes, and the rigidity of the 4°C boundary. A modified classification system based upon more recent information was proposed (Lewis, 1983a) and, although somewhat more complicated, does avoid certain intractable problems.

1. Amictic Lakes

Lakes defined as amictic are sealed off perennially by ice from most of the annual variations in temperature. Amictic, perennially ice-covered lakes are rare and largely limited to Antarctica (Goldman, 1972) or, more rarely, to very high mountains. Only a very few cases of such lakes have been recorded in the Arctic, mostly in Greenland, where general conditions necessary for the formation of a permanent ice cover are rare (Hobbie, 1973). It is clear that most of the heating of these lakes is by means of light transmission through the ice and conduction of heat from the surrounding land through the sediments (Ragotzkie and Likens, 1964; McKay *et al.*, 1985). The balance of heat inputs and losses is very constant and results in consistent ice thicknesses on individual lakes of between 3.5 and 6 m.

2. Cold Monomictic Lakes

Lakes with water temperatures never greater than 4°C and ice-covered most of the year with only one period of circulation in the summer at or below 4°C are called *cold monomictic* lakes. The category comprises, for the most part, Arctic and mountain lakes, which, although they may be ice-free for brief periods in the summer, are in frequent contact with glaciers or permafrost. The thermal cycles of Arctic lakes exhibit large variations in relation to their location and summer climate. Shallow lakes are extremely numerous in the subarctic but usually lack sufficient depth to stratify. Water temperatures often rise above 10°C, but never exceed 15°C (Hobbie, 1973). Very deep lakes that become ice-free for brief periods in the summer are truly cold monomictic lakes in which temperatures never reach 4°C. Others, such as Char Lake, Cornwallis Island, Canada (latitude 76°), warm to 4–5°C and are therefore technically dimictic (see below) but do not always stratify. Lake Schrader in the Brooks Range, Alaska, was dimictic and stratified in 1958, with the epilimnion at 10°C and the hypolimnion at 4°C. The following year, summer ice breakup occurred a month later, and the lake did not warm above 4°C; that is it was cold monomictic (Hobbie, 1961).

3. Continuous Cold Polymictic Lakes

Continuous cold polymictic lakes are ice-covered part of the year and ice-free above 4°C during the warm season. During the ice-free period, circulation is continuous or only interrupted by brief diurnal stratification. A great number of shallow north-temperate lakes exhibit this pattern of circulation (e.g., Harvey and Coombs, 1971).

4. Discontinuous Cold Polymictic Lakes

These lakes are ice-covered part of the year and ice-free above 4°C and thermally stratified during the warm season for periods of several days to weeks but with irregular interruption by mixing.

5. Dimictic Lakes

Lakes are called *dimictic* if they circulate freely twice a year in the spring and fall and are directly stratified in summer and inversely stratified under ice cover in winter. Dimictic lakes represent the most common type of thermal stratification observed in most lakes of the cool temperate regions of the world. Their characteristics were described in detail earlier in this chapter. Such lakes also are found commonly at high elevations in subtropical latitudes.

6. Warm Monomictic Lakes

In warm monomictic lakes, temperatures do not drop below 4°C; these lakes circulate freely in the winter at or above 4°C, and they stratify stably in the summer. Warm monomictic lakes are common to warm regions of the temperate zones, particularly those influenced by oceanic climates, and to mountainous areas of subtropical latitudes. Most lakes of the central and eastern portions of North America and the interior of Europe exhibit a distinct continental type of dimictic stratification, whereas a warm monomictic stratification is prevalent in many coastal regions of North America and Northern Europe.

7. Discontinuous Warm Polymictic Lakes

Lakes with frequent or continuous circulation are called *polymictic*. Discontinuous warm polymictic lakes have no seasonal ice cover and stratify for days or weeks at a time but mix more than once per year.

8. Continuous Warm Polymictic Lakes

Mixing in these lakes is more or less continuous, with stratification lasting only for a few hours at a time. No seasonal ice cover occurs, and generally these lakes are tropical with repeated periods of circulation between very short intervals of heating and weak stratification.

This discussion of thermal lake types refers to lakes with sufficient depth to form a hypolimnion. Numerically speaking, when considering the millions of small, relatively shallow lakes that virtually cover the tundra and northern temperate region, it becomes evident that most lakes do not become stratified or be-

come stratified only briefly during ice-free periods. The depth required to become thermally stratified varies so greatly with surface area, latitude, elevation, basin orientation in relation to prevailing wind, depth–volume relations, protection by surrounding topography and vegetation, and other factors that generalizations in this regard would be misleading.

G. Meromixis

The types of stratification discussed thus far describe circulation that occurs throughout the entire water column, as is the case with ***holomictic*** lakes. A number of lakes do not undergo complete circulation, and the primary water mass does not mix with a lower portion. Such lakes are termed ***meromictic*** (Findenegg, 1935; Hutchinson, 1937). In meromictic lakes, the deeper stratum of water that is perennially isolated is the ***monimolimnion***; this stratum underlies the upper ***mixolimnion***, which periodically circulates. These two strata are separated by a steep salinity gradient, the *stratum* of which is the ***chemolimnion***, the *plane* of density change is called the ***chemocline.***

Although the causes of chemically induced stratification have been treated and named variously, the divisions of Hutchinson (1937) and Walker and Likens (1975) (cf. also Dickman and Hartman, 1979) are particularly appropriate. As pointed out in Chap. 2, a salt concentration of 1 g liter^{-1} increases the density of water by approximately 0.0008. This change in specific gravity is very large in relation to density changes associated with temperature. For example, the density difference between 4 and 5°C is 0.000008, and it would only require 10 mg liter^{-1} of salt to give the same effect in resistance to mixing. The salinity gradient with depth during stratification is almost always much greater than 10 mg liter^{-1}. In most lakes, salinity gradients are insufficient to increase stability to a point where wind energy does not cause holomixis. A large number of lakes, however, do exhibit temporary or permanent meromixis as a result of salinity gradients. In such cases, the term *concentration stability*, in contrast to the thermal stability of holomictic lakes discussed earlier, is more appropriate (Berger, 1955).

1. Ectogenic Meromixis

The condition that results when some external event brings salt water into a freshwater lake or fresh water into a saline lake is called *ectogenic meromixis*. The result in either case is a superficial layer of less dense, less saline water overlying a monimolimnion of saline, more dense water. As might be expected, such situations are found often along marine coastal regions where catastrophic intrusions of salt water from storms associated with unusual tidal activity are fairly common events. In estuarine lakes, such events also occur routinely. A more strict definition of ectogenic meromictic lakes includes only those that are isolated from routine marine influxes of water. Such isolation may be recent or long-standing. An example of the latter is the southern Norwegian Lake Tokke, which most likely has been permanently meromictic for about 6000 years; the isolation of the lake probably took place during a period when the former fjord depression and the surrounding land were elevated some 60 m above sea level (Strøm, 1955).

A most interesting variant of ectogenic meromixis is found in many saline lakes of arid regions or in small depressions that occasionally receive saltwater intrusions (Hudec and Sonnenfeld, 1974). Often, these saline lakes overlie large deposits of such soluble salts as magnesium sulfate and are only a few meters in depth. The infusion of large amounts of fresh water, either naturally during wet periods or artificially as a result of increased irrigation of nearby land, creates a strong meromictic stratification that may persist for many years.

Whatever the causes of this type of meromixis, many of these lakes exhibit marked differences in temperature with depth in which the chemocline is functioning as a heat trap of solar energy. Such ***heliothermic lakes*** contain a solar-heated stratum of warm, saline water beneath a surface layer of cooler, less saline water (cf. review by Kirkland *et al.*, 1983). Much of the sunlight that penetrates the chemocline is transformed to heat, which cannot escape by radiation because water is opaque to infrared and which cannot be released by convection because the specific gravity of the dense water of the monimolimnion below is not significantly decreased by the increasing temperatures. Losses of heat to the air by conduction are slow. As a result, temperatures rise within the chemocline, often to very high temperatures approaching the boiling point.

A striking example is Hot Lake, a shallow (3.5 m) saline body of water occupying a former epsom salt excavation in north central Washington (Anderson, 1958; Kirkland *et al.*, 1983). Solar radiation energy passing through the overlying mixolimnion of fresh water accumulated as heat in the chemolimnion and monimolimnion, where circulation was absent. The resulting temperatures can be in excess of 50°C, and even when the surface of the lake is frozen, a temperature of nearly 30°C can be found at a depth of 2 m (Fig. 6-8). These ***dichothermic*** conditions, in which the monimolimnion is considerably warmer than the overlying water of the chemolimnion, are frequently observed in shallow meromictic lakes (Fig. 6-8 and Kirkland *et al.*, 1983).

Human activities have been known to form meromictic lakes. Creating a connecting channel

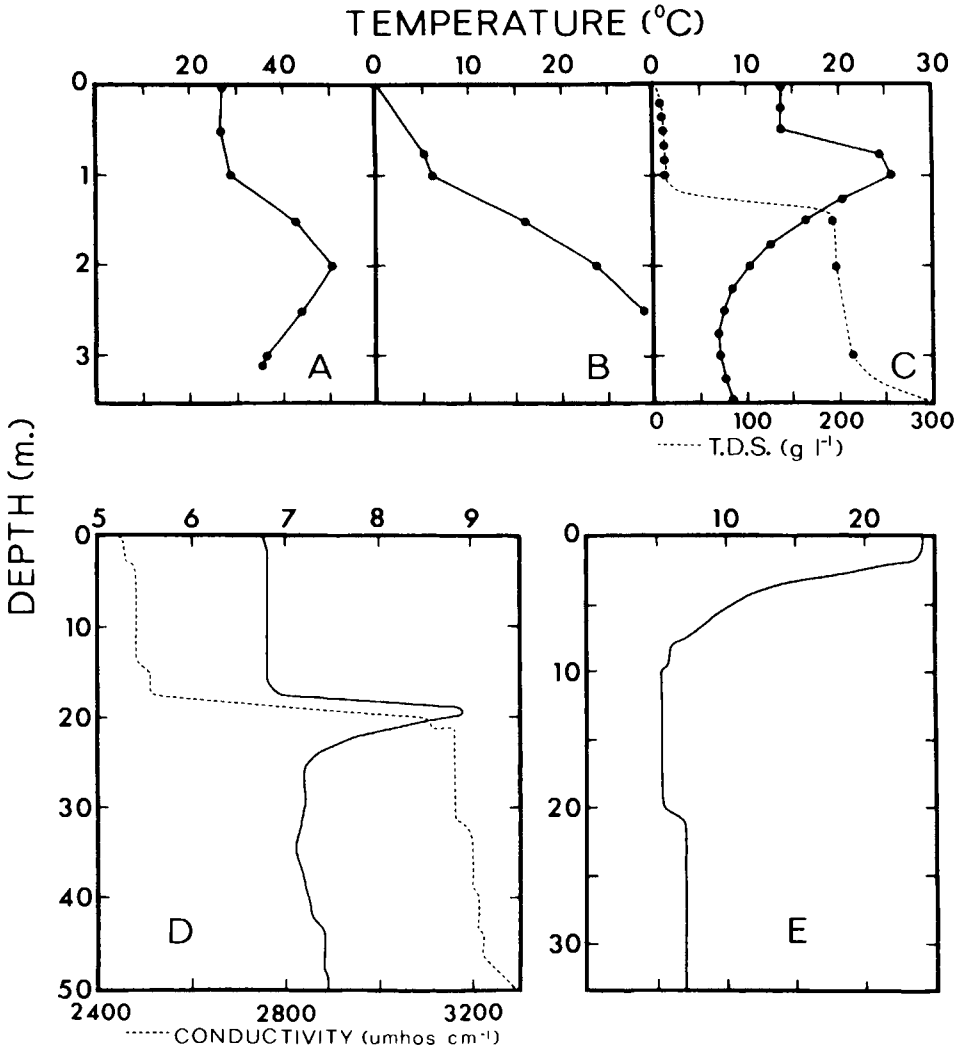

FIGURE 6-8 Thermal discontinuities in meromictic lakes. *Upper series:* Hot Lake, Washington (after Anderson, 1958): (a) 23 July 1955; (b) Heating under thin ice cover, 7 December 1954; (c) Heating in a deeply colored layer, 0.5–1.0 m, 1 May 1956, T.D.S. = Total dissolved solids on evaporation. *Lower series:* (d) Depth distribution of temperature and conductivity, Fayetteville Green Lake, New York, 16 December 1966 (from Brunskill and Ludlam, 1969); (e) Thermal stratification in Ulmener Maar, Germany, 8 August 1911. (Modified from Ruttner, 1963, after Thienemann). The thermal gradient observed earlier in Ulmener Maar has subsequently been modified (cf. Stewart and Hollan, 1975). Note variations in depth and temperature scales.

between a freshwater lake and the sea for purposes of navigation can result in the intrusion of saline water into the lake and cause permanent meromixis. Another event that can form a large number of small meromictic lakes is the introduction of salt caused by runoff from street de-icing (Judd, 1970; cf. also Chap. 8). The excellent analyses of the paleolimnological record of Längsee, Austria, by Frey (1955) clearly show how the clearing of forests surrounding the lake in prehistoric times introduced ectogenic meromixis. The resulting silt-laden runoff flowed into the hypolimnion and initiated a monimolimnion, which was augmented subsequently by salinity inputs of biogenic origin (see further on).

2. Crenogenic Meromixis

Crenogenic meromixis results from submerged saline springs that deliver dense water to deep portions of lake basins. The saline water displaces the water of the mixolimnion. The chemolimnion will stabilize at a depth related to the rate of influx, density differences, and the degree of wind mixing of the mixolimnion. Crenogenic meromixis is really a subclassification of

the general group of externally mediated (ectogenic) meromixis (Walker and Likens, 1975).

Examples of crenogenic meromictic lakes are numerous. In Ulmener Maar (Fig. 6-8e), the temperature of the monimolimnion stabilized at 7°C. Meromictic lakes of this type recently have been found in interior Alaska, where subsurface springs introduce saline water into small, deep lakes originating in the thawed craters of ***pingos*** (Likens and Johnson, 1966). Pingos are formed when water, rising by hydraulic pressure through gaps in the permafrost, freezes and uplifts a mound of ice covered by a layer of alluvium. The overburden usually ruptures and the ice of the depression can thaw to form small lakes. In some cases, geothermal and saline waters form complex meromixis with warm, saline waters underlying cooler waters (see Drago, 1989).

3. Biogenic Meromixis

Biogenic or endogenic meromixis results from an accumulation of salts in the monimolimnion, which are usually liberated by means of decomposition in the sediments and from sedimenting organic matter. Often biogenic meromixis is initiated when abnormal meteorological conditions prevent circulation of a normally dimictic lake. Hypolimnetic accumulation in biochemically derived salinity may be sufficient to permit meromixis to persist either temporarily or permanently. Temperature inversions are usually found in the monimolimnion, such as is seen in Figure 6-8d. The high temperatures observed in the chemolimnion are the result of absorption of solar radiation by the dense bacterial plate that occurs at this level. The processes associated with the increasing temperatures in the lower monimolimnion, which are consistently observed, are less obvious. It is clear that the heat of metabolism in decomposition is inadequate to account for such increases (Hutchinson, 1941). When direct solar heating is not possible because of the depth, such heating is likely to be the result of warmer salt-laden water near the sediments that form density currents from overlying strata and descend into the basin along its contours. Heat from the surrounding land and conduction through the sediments is a minor heat source.

Biogenic meromixis is common in lakes that are very deep. For example, nearly all of the extremely deep lakes of the equatorial tropics are meromictic. But biogenic meromixis is also common among lakes of small surface area and moderate depth and that are sheltered, especially in continental regions that experience long, severe winters. ***Partial or temporary meromixis,*** when a normally dimictic lake skips a circulatory period (usually the spring period), is a result of dynamic processes of decomposition in the lower strata of the lake under unusual weather conditions (Findenegg, 1937). For example, after an unusually long and severe winter followed by a rapid thaw and warm conditions, Martin Lake did not undergo spring circulation (Fig. 6-9); the chemically stabilized water of the temporary monimolimnion was carried over from winter accumulation and was augmented throughout the subsequent summer (Wetzel, 1973). Particularly notable is the carryover of low temperatures from the circulation during the preceding fall, which persisted

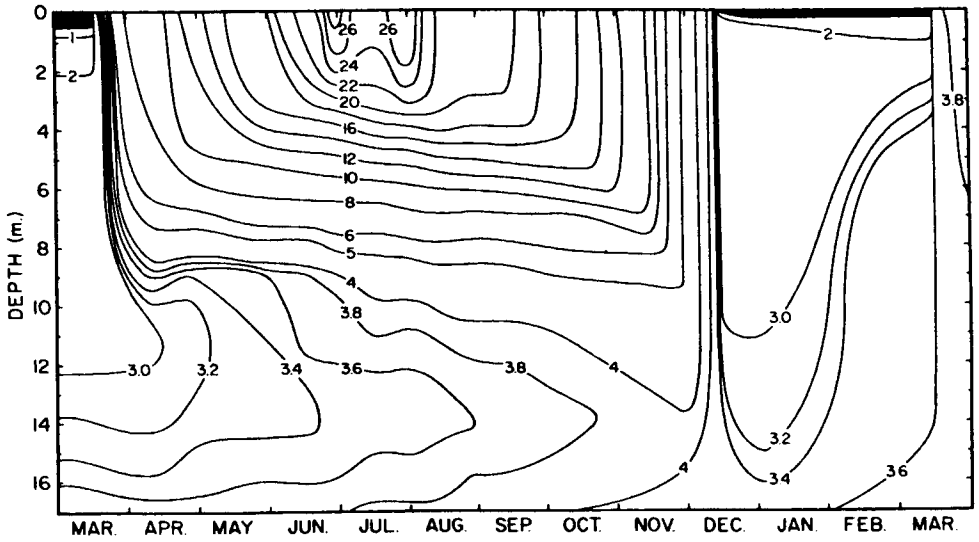

FIGURE 6-9 Isothermal variations (°C) in the major depression of Martin Lake, LaGrange County, Indiana, 1963–64. (From Wetzel, R.: *Hydrobiological Studies* 3:91–143, 1973.)

throughout the summer and fall, prior to the formation of the ice cover. Autumnal circulation in this protected lake did not occur until December, and then only briefly before ice formation. The following spring, a normal complete circulation was observed. This type of temporary, partial meromixis was also found in 2 other lakes in northeastern Indiana, of the 13 investigated during the same period (Wetzel, 1966b). In his classical work on phosphorus cycles and enrichment effects in the small eutrophic Schleinsee, Einsele (1941) found that complete spring turnover occurred, on the average, only every other year. In Lawrence Lake, a small (4.9 ha), deep (12.6 m) hardwater lake of southern Michigan, temporary meromixis occurs about every third year (Wetzel *et al.*, 1972, and unpublished data). Many other examples exist, but these are adequate to emphasize that this phenomenon of intermittent biogenic meromixis is quite common. It is not difficult to envision a combination of circumstances that can shift a lake from temporary to permanent meromixis. Both conditions have profound effects on biota and productivity, as will be discussed later.

Another, quite different cause of endogenic meromixis apparently occurs as a result of precipitation of salts in the upper water strata by "freezing out" from the surface ice layer. The precipitating salts may accumulate in deeper waters in sufficient concentrations to cause meromixis. In Algal Lake, Antarctica, this condition has been termed ***cryogenic meromixis*** (Goldman *et al.*, 1972; cf. also Priddle and Heywood, 1980).

III. THERMAL ENERGY CONTENT: HEAT BUDGETS OF LAKES

Heat content (H, in calories) is a function of the mass (M, in g) of the substance, temperature (t, in °C), and the specific heat (s, in cal g-°C^{-1}). Then,

$$H = M \times t \times s$$

Earlier, we evaluated the thermal radiation in water in relation to gains and losses of heat content (Chap. 5). Because of the high specific heat of water, large volumes of water change temperature relatively slowly. Large lakes moderate local climates and provide longer growing seasons for aquatic biota. This energy stored as heat further alters mixing rates and stratification patterns.

Temperature and density stratification in lakes are dominant regulators of nearly all physicochemical cycles and consequently of lake metabolism and productivity. It is important, therefore, to understand a lake's relative energy content (budget) or thermal capacity[3] both in the amount of heat energy required to develop stratification and the amount of heat a lake must lose in order to overcome density differences.

Heating capacity and energy demand to reach a given state are governed, in the case of a lake, by heat inputs, the volume and accessibility of the water at depth to heat incomes, and heat losses. Although many means of determining the heat content of lakes were developed in the pioneer days of limnology, particularly by Forel, the extensive works of Birge (1915, 1916) on this subject provide the basis for much of the ensuing discussion (cf. also Ragotzkie, 1978).

The heat content of a body of water is the amount of heat in calories that would be released on cooling from its maximum temperature to 0°C, or the amount of heat that has been transferred to the lake to heat it from 0°C to its maximum temperatures at various depths. Of course, the lowest temperatures of many lakes are not near 0°C or even its point of maximum density at 4°C. Hence, the minimum and maximum temperatures of the individual strata are used to determine the heat content of a lake. Although the specific heat of water is unity, which simplifies computations, calculations of the heat budget of a lake require the consideration of changes in volume with depth, since the lower strata contain smaller water volumes and make a smaller contribution to the total heat content than do the upper water layers.

A Birgean heat budget for a typical dimictic lake can be defined as follows (Birge and Juday, 1914; Birge 1915; Hutchinson, 1957):

Summer heat income (θ_s) is the amount of heat necessary to raise the temperature of the lake from an isothermal condition at 4°C to the maximum observed summer heat content. This heat income is primarily a result of the heating of the surface layers by direct insolation and the distribution of this heat by wind. It therefore has been called (Birge, 1915) the *wind-distributed heat*, even though not only wind energy is involved in its distribution.

Winter heat income (θ_w) is the amount of heat necessary to raise the temperature from its minimum heat content to 4°C. The winter heat income is usually not considered as wind-distributed, even though wind is involved in loss of heat prior to the lake's reaching the minimum temperature during autumnal–early winter cooling. Accurate winter heat incomes must be corrected for the latent heat of ice fusion. This correction can be sizable when the ice cover is considerable.

[3] The use of the word *budget* here is incorrect in terms of its normal definition. Reference actually is to the heat storage capacity of the lake, but the term *budget* is firmly entrenched in limnology.

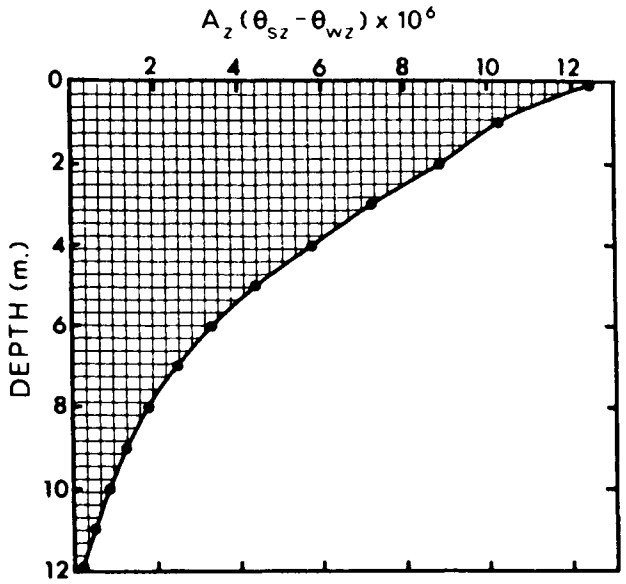

FIGURE 6-10 Curve generated for calculation of the annual heat budget of Lawrence Lake, Michigan, 1968. Calculations resulted in a budget, including a correction for ice, of 10,918 cal cm^{-2} yr^{-1}. (From Wetzel, unpublished data.)

One-cm-thick ice is equivalent to about 66.7 cal cm^{-2} (79.72 cal g^{-1}, where $\rho_{ice} = 0.9168$) or a correction of about 835 cal cm^{-2} for 12.5 cm of ice (see Adams and Lasenby, 1978, and Wetzel and Likens, 2000).

Annual Heat Budget (θ_a) is the total amount of heat necessary to raise the water from the minimum temperature of winter to the maximum temperature of summer. From the standpoint of the whole lake, this refers to the total amount of heat needed between the period of its lowest and its highest heat content.

The heat budget may be calculated by plotting the product A_z ($\theta_{sz} - \theta_{wz}$) against depth z, where θ_{sz} and θ_{wz} are the respective maximum summer and minimum winter temperatures and A_z is the area of the water stratum in cm^{-2} at depth z. The area of the resulting curve is integrated by digitization or planimetry[4] and divided by the surface area of the lake (A_0) because lake heat gains and losses are primarily surface phenomena. To separate the heat budget into summer or winter heat incomes, 4°C is substituted for the respective summer and winter temperatures at depth. A sample computation is given in Figure 6-10 for a small dimictic lake of moderate depth in southwestern Michigan. Note particularly the decreasing contribution of lower water strata to the overall heat budget of a rather typical lake.

[4]The proper use of these ingeniously devised instruments is described in detail in Welch (1948) and Wetzel and Likens (2000).

A large number of annual heat budgets have been computed; about 100 are listed in Hutchinson (1957), and many have appeared in the literature since then. A few exemplary values are given in Table 6-2 to emphasize several points in regard to factors influencing the observed heat budgets. Although most heat budgets have been derived for large, deep lakes, a few generalizations are possible. In temperate lakes that are sufficiently deep to maintain hypolimnetic temperatures at or near 4°C, annual heat budgets are usually between 30,000 and 40,000 cal cm^{-2} yr^{-1}, and most heat (60–80%) is gained during the spring–summer transition. Very few lakes have an annual heat budget in excess of 50,000 cal cm^{-2} yr^{-1}. Notable exceptions include Lake Baikal and Lake Michigan. Annual heat incomes of polar region lakes are small (θ_s values are in the range of 10,000 cal cm^{-2} for large lakes). However, annual values are likely to be very much larger than this when the latent heat of fusion for melting ice is included. The same is true for the apparently low heat budget values of lakes at high altitudes. In the temperate zone, annual heat budgets are strongly correlated with mean depth, area, and lake volumes and rise continuously with lake dimensions, though at a decreasing rate (Gorham, 1964; Allott, 1986). For lakes of a given volume, deeper ones of lesser area take up slightly more heat than shallower lakes of greater area. Dimictic lakes have slightly higher heat budgets than warm monomictic lakes of similar size.

The heat content of a lake can vary significantly (10%) within two or three days; accurate determinations of annual heat budgets therefore require frequent measurements over long periods (Stewart, 1973). Variations in the completeness of vertical mixing from year to year in warm monomictic lakes can cause marked variations in heat storage capacities (Ambrosetti and Barbanti, 1993). Examples of this variation are given in Table 6-3.

The annual income and loss of heat in tropical lakes is very small compared with that of lakes at higher latitudes or altitudes. Also, the mixing patterns are complex, often variable or polymictic in nature. Lewis (1973) demonstrated the weak, variable stratification with the repeated formation of multiple, temporary metalimnia common to many tropical lakes of large size. The minimum yearly heat content, given as negative values in brackets in Table 6-2, represents the heat content above 4°C in lakes that never cool to that temperature. In such lakes at northern latitudes, as in England, these values are very small; they are of course high in equatorial regions.

The stratification patterns and thermal structure of reservoirs with high throughflow volumes are most complicated (Wunderlich, 1971). Where withdrawal of

major volumes of water occurs daily and intermittently, the patterns can be further disrupted and altered. Although drawdown usually occurs from the epilimnion, sometimes water is drawn from the hypolimnion. Influent waters also vary greatly in relation to surface runoff, heat content, and retention time in series of reservoirs in tandem on major river systems. Normal Birgean heat dynamics must be modified considerably in order to be applicable to complex reservoir systems. Among the most detailed analyses are those of the

Slapy Reservoir in Czechoslovakia, where seasonal thermal dynamics have been determined for over a decade (Hrbáček and Straškraba, 1966; Straškraba *et al.*, 1973), and of Lake Powell, Utah–Arizona (Johnson and Merritt, 1979).

A. Heat of Lake Sediments

Sediments of lakes absorb an appreciable amount of heat from the water during the warmer periods of the year and transmit heat to the water during the winter period. Although few detailed studies are available, data from Lake Mendota illustrate this characteristic (Birge *et al.*, 1927). It will be noted from Figure 6-11 that the temperatures of the surface sediments at a water depth of 8 m followed the annual cycle of the epilimnetic water temperatures rather closely. This thermal variation is attenuated with depth in the sediments, so that at a depth of 5 m into the sediments, little seasonal oscillation was observed. A similar relationship was observed in the sediments of the hypolimnion at a water depth of 23.5 m, but the amplitude and heat energy exchange were much less (Fig. 6-11). The heat content of the sediments lagged behind the hypolimnetic water temperature, and the lag duration increased about one month per meter depth of sediment.

This process of transfer of heat from the water to lake sediments during the summer and release from lake sediments into the water during the winter period under ice cover is true on a seasonal average basis. The sediment heat exchange, however, is dynamic and fluxes occur in both directions from and into the sediments (Fang and Stefan, 1996). The direction of heat flux can reverse on shorter, even daily, time scales, particularly in shallow lakes.

Spatial variations in temperatures within the sediments at similar water depths have been found that are apparently due to the type of adjacent land forms of the basin (Matveev, 1964). Shoreline sediments of deep bog lakes were found to be considerably warmer than sediments beneath the open water, but annual variations were largely damped at a sediment depth of 4 m (Likens and Johnson, 1969). Heat flux from the relatively warm shoreline sediments occurred both lakeward and landward. In a shallower bog lake, deep sediments beneath the open water were found to be warmer than those of comparable depth beneath shoreline sediments (Reif, 1969), indicative of a heat flux away from the lake. Differences between the thermal characteristics of these lakes may be related to their maximum depths, because in the shallower lake, absorption of solar energy by the sediments is greater (cf. also Dale and Gillespie, 1977).

Determinations of the heat budget of sediments based on the differences between their minimum and maximum mean temperatures showed that in sediments at a lake depth of 8 m, this value was 2950 cal cm^{-2} yr^{-1}; at 12 m, it was 2200, and at the maximum of 23.5 m, it was 1100 cal cm^{-2} yr^{-1}. An estimated average heat budget of all of the lake sediments was ca. 2000 cal cm^{-2} yr^{-1} for Lake Mendota. As lakes become more shallow, the heat budget of the sediments becomes a greater portion of the whole (Table 6-4). All of the examples of annual heat budgets of lakes cited here (Tables 6-2 and 6-3) are based on water temperatures and ignore sediment temperatures. Although in

large, deep lakes such a simplifying assumption may be justified, it should be noted that the sediments of shallow lakes are significant to their heat budgets.

IV. COMPARATIVE ANALYSES: THERMAL CHARACTERISTICS OF RIVERS, RESERVOIRS, AND NATURAL LAKES

As discussed earlier, temperatures of streams and rivers vary rapidly on diurnal and seasonal bases, often in close relation to fluctuating air temperatures. Very few rivers are not regulated to some extent by human activities of channel modification or impoundment. Many studies have demonstrated that reservoir impoundment of a river and associated regulation usually increase the mean temperature, reduce or eliminate freezing conditions, depress summer maxima, delay annual temperature cycles, and reduce diurnal temperature fluctuations (Palmer and O'Keeffe, 1989; Webb and Walling, 1993; McRae and Edwards, 1994). These effects persist for a distance of usually several kilometers below the dam; thermal recovery distances showed a positive lognormal relationship with reservoir discharge. In contrast, thermal properties tend to be much more stable in natural lakes, with slower and less marked variations (Table 6-5).

Thermally induced density stratification patterns are rare in river ecosystems and become increasingly complex as water movements slow (Table 6-5). Because

TABLE 6-5 Thermal and Stratification Properties of Rivers, Reservoirs, and Natural Lakes[a]

Property	*Rivers*	*Reservoirs*	*Lakes*
Temperature variations	Rapid, large	Rapid in riverine zones, moderate in lacustrine zone; decreased rates and magnitude of fluctuations	Slow, stable
Thermal density stratification	Rare	Variable, irregular; often too shallow to stratify in riverine and transitional zones; often temporary stratification in lacustrine zone	Common, regular, particularly in dimictic and monomictic lakes
Spatial differences (summer)	Cold headwaters, increasing downstream	Increased mean temperatures; reduced or no freezing	Warm upper strata (epilimnion) and colder lower strata (hypolimnion)
Groundwater effects	High ratio of ground water to surface drainage, decreased temperatures	Relatively small	Significant only in seepage lakes and can reduce temperatures slightly
Tributary effects	Considerable if different from mainstream	Moderate to small	Small, localized to influent area
Shading effects	Considerable, usually seasonal in headwater zones; can enhance thermal stability	Small to negligible	Usually very small or negligible
Ice formations	Transitory	Usually transitory	Persistent; ameliorate variations
Ice scouring effects	Robust, extensive	Usually minor	Localized to windward, near-shore littoral areas

[a] Extracted from numerous sources, particularly Ryder and Pesendorfer (1980) for rivers and Wetzel (1990a) for reservoirs and lakes.

relatively few lakes are strongly influenced by subsurface groundwater influents, the effects of ground water on temperature is much greater in headwater areas of streams than in large rivers, reservoirs, and most lakes. The ice of streams and rivers tends to impact, particularly in scouring effects, and disturb the ecosystem much more than it does in lakes.

V. SUMMARY

1. The high specific heat of water results in dissipation of much of the incoming light energy and its accumulation as heat. In lake systems, the way retained heat is distributed and altered is governed by a number of coupled factors: the physical work of wind energy, currents and other water movements, basin morphometry, and water losses. Resulting patterns of density-induced stratification influence physical and chemical properties and cycles of lakes and, in turn, govern their productivity and decomposition.
2. Temperature is a measure of the *intensity* (not the amount) of heat stored in a volume of water. Heat is measured in calories and is the product of the weight of the substance (in grams), temperature (°C), and the specific heat (cal g-°C^{-1}).
3. Temperatures of streams and rivers vary directly with air temperatures, with some time lag by the water. Most rivers exhibit diurnal variations in water temperatures. The size of annual oscillations increases with greater latitude and altitude. Temperatures of streams usually increase downstream.
4. Heat income results from several processes:
   a. Direct absorption of solar radiation; usually the dominant source
   b. Transfer of heat from the air
   c. Condensation of water vapor at the water surface
   d. Transfer of heat from sediments to the water
   e. Heat transfer from terrestrial sources via precipitation, surface runoff, and groundwater inputs
5. Heat losses occur by:
   a. Specific conduction of heat to the air, and, to a lesser extent, to the sediments
   b. Evaporation
   c. Outflow, especially of surface water
6. Although differential heating and cooling of surface waters, as well as influents, can cause convection currents, mixing of surface waters by convection is weak and insufficient to produce the long-term stratification patterns commonly observed in most lakes. Wind energy mechanically distributes most of the heat in a lake.
7. In temperate and other regions, many lakes of moderate depth (approximately > 10 m) exhibit ***thermal stratification.***
   a. During warmer periods of the year, the surface waters are heated, largely by solar radiation, more rapidly than the heat is distributed by mixing. As the surface waters are warmed and become less dense, the ***relative thermal resistance*** to mixing increases.
   b. The lake becomes stratified into three zones (Fig. 6-3):
      i *Epilimnion:* An upper stratum of less dense, more or less uniformly warm, circulating, and fairly turbulent water.
      ii. *Hypolimnion:* The lower stratum of more dense, cooler, and relatively quiescent water lying below the epilimnion.
      iii. *Metalimnion:* The transitional *stratum* of marked thermal change between the epilimnion and hypolimnion.
   c. The ***thermocline*** is the *plane* or surface of maximum rate of decrease of temperature in the metalimnion.
   d. The resistance of thermal- and chemical-density stratification to mixing is a measure of the lake's mechanical stability.
      i. ***Stability*** per unit area of a lake is the quantity of work or mechanical energy in ergs required to mix the entire volume of water to a uniform temperature by the wind without the addition or loss of heat. Stability quantifies the resistance of the stratification to disruption by wind.
      ii. The amount of work by the wind per unit area needed to mix a lake to a uniform vertical density increases as the size and volume of the lake increases.
8. At the end of thermal stratification when loss of heat exceeds heat inputs, surface waters of the epilimnion cool, become more dense, and are mixed with deeper strata of similar density by wind-induced and convection currents. The metalimnion is progressively eroded as the relative thermal resistance to mixing is reduced. Eventually, the entire volume of water is included in the circulation and ***fall turnover*** is initiated. Fall turnover continues with progressive cooling, often to the temperatures of maximum density of 4°C or less.
9. Ice cover forms on the surface under calm, cold conditions. ***Inverse stratification*** of water temperatures occurs under the ice, in which colder,

less dense water overlies warmer, more dense water near the temperature of maximum density at 4°C. Some gradual heating of the water occurs during the winter under ice cover.

10. When the ice cover melts in the spring, the water column is nearly isothermal. If the lake receives sufficient wind energy, as is commonly the case, the lake circulates completely and undergoes ***spring turnover.***
11. Lakes undergoing complete circulation in spring and fall separated by thermal summer stratification and winter inverse stratification are called ***dimictic*** lakes. Dimictic lake types are very common among temperate lakes of moderate size.
12. Many other types of density-related stratification patterns occur among lakes in relation to the interacting effects of climate, morphometry, and chemistry. The types of lakes are classified on the basis of circulation patterns and include lakes of sufficient depth to form a hypolimnion.

Type of lake	*Annual vertical mixing*	*Dominant factors contributing to or preventing vertical mixing*
1. Amictic	No appreciable amount	Permanent ice cover; slow internal mixing
2. Holomictic	Complete, at least once	Predominantly wind energy; convection currents
a. Monomictic	Once	
b. Dimictic	Twice	
c. Polymictic	More than twice	
3. Meromictic	Permanently stratified or interruption of stratification patterns at irregular intervals	Chemically enhanced density stratification
a. Ectogenic	Permanently stratified	1. Surface inflow of (a) fresh water overlying a preexisting saline stratum, (b) saline water underlying a preexisting fresh stratum, or (c) turbidity currents of particulate-laden water. 2. Subsurface inflow of fresh or saline water (= ***crenogenic***)
b. Endogenic	Permanently or temporarily stratified	
i. Biogenic	Permanently stratified	Chemically enhanced density stratification contributed by biological processes with accumulations of bicarbonate or iron/manganese ions in lower stratum and shelter afforded by morphometry of lake basin and surrounding topography
ii. Temporary biogenic	Temporary elimination of complete circulation (spring or fall)	Same factors as biogenic meromixis but borderline conditions where unusual climatic conditions lead to omission of spring or fall circulation and accumulation of hypolimnetic ions
iii. Cryogenic	Permanently stratified	Deep-water accumulation of salts precipitated by freeze concentration from a surface ice layer

13. Water strata of permanently stratified meromictic lakes are named differently but analogously to those of holomictic lakes:
    a. ***Mixolimnion:*** The circulating upper stratum
    b. ***Monimolimnion:*** The deeper stratum of water that is perennially or periodically isolated
    c. ***Chemolimnion:*** The interfacing *stratum* of steep salinity (density) gradient between the mixolimnion and the monimolimnion
14. The heat budget of a lake is a measure of the heat storage capacity under existing conditions of morphometry and the climate to which it is exposed. The annual heat budget is the total amount of heat accumulated between the period of its lowest and its highest heat content. The annual income and loss of heat in tropical lakes is small in comparison to that of lakes at higher latitudes and altitudes. Annual heat budgets of lakes of the temperate zone generally increase with mean depth, area, and lake volume. The sediments of lakes absorb considerable heat from the water during warmer periods of the year and transmit heat to the water during the winter period.
15. The thermal properties of rivers, reservoirs, and lakes are similar but differ considerably in rates of change. Changes in temperature are more rapid in rivers and the magnitude of those differences is usually greater than is the case in reservoirs and especially in natural lakes.

I. HYDRODYNAMICS OF WATER MOVEMENTS

As water aggregates into stream channels and flows down elevational gradients, complex turbulent movements occur. The flow is influenced by drag at the air–water interface and at the substratum, where it is affected by the degree of roughness. Velocity of flow in a channel is approximately inversely proportional to the logarithm of the depth. The flows modify the environment markedly and influence gas and nutrient exchanges and substratum properties and generally set the habitat characteristics for the biota. Often, streams and rivers form the primary influents to lakes and modify the hydrodynamics of the receiving basins.

Lakes behave like large mechanical oscillators. They respond in numerous, complex ways to applications of force and are frictionally damped by viscous forces associated with turbulence. Water movements generated by the transfer of wind energy to the water give rise to a spectrum of rhythmic oscillations, both at the water surface and internally deep within the basin. The oscillations and their attendant currents may be in phase or in opposition; their final fate is to degrade into arrhythmic turbulent motions. Each basin has its own set of free modes of oscillation, both surface and internal, which depend on gravity, on basin shape and size, and on the internal distribution of water density. Which of these modes is brought into play during any particular disturbance or storm depends on the duration, the periodicity, and the spatial distribution of the applied force. In other words, the morphometry of the lake basin, the lake's stratification structure, and its exposure to wind are important factors that determine water movement.

Turbulence resulting from water movements is of major significance to the biota and productivity of the lake. Limnological thought is still pervaded by the idea that summer and winter density stratification results in stagnation of lake strata. There is little basis for this view. Water movements are integral components of the aquatic ecosystems, and consideration must be given to their effects on changes in distribution of temperature, dissolved gases and nutrients, and other chemical parameters. Water movements influence not only the

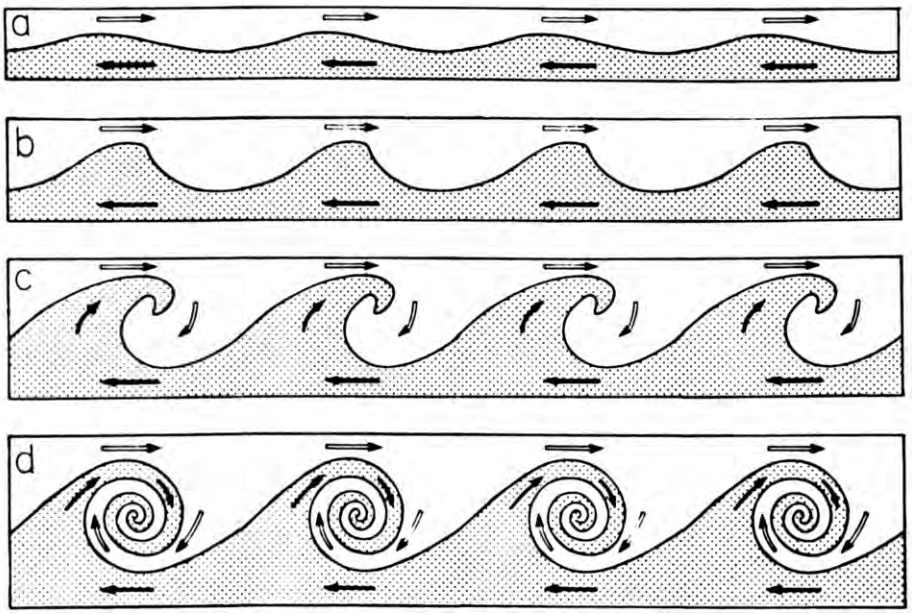

FIGURE 7-1 Stages in vortex formation during shear instability on the interface of a stratified two-layer system of differing densities. (From Mortimer, C. H.: *Mitteilungen Int. Ver. Limnol. 20*:131, 1974.)

aggregation and distribution of nutrients and food but also the distribution of microorganisms and plankton.

II. FLOW OF WATER

A. Turbulent and Laminar Flow

At sufficiently slow speeds, water flowing in a smooth tube moves along the interface in an apparently orderly manner. If the velocity of movement is increased at the interface, a critical speed is reached above which the smooth and unidirectional laminar flow becomes disordered or turbulent. The transition from laminar to turbulent flow also occurs at the interface of two miscible fluids moving in opposing directions. An example would be opposing horizontal movements between two water strata of differing densities, such as the epilimnion and metalimnion of a lake.

Appreciable experimental work on turbulent shearing stresses (Reynolds stresses) has demonstrated that only a low velocity is needed to shift from laminar flow to turbulent current. The critical velocity is a function of the fluid viscosities and densities and decreases in proportion to an increase in size of the channel or tube. Velocities of only a few mm sec^{-1} can induce turbulent flow, at which point disturbances arising on the interface between the layers will no longer be suppressed by buoyancy (gravity) forces, which tend to keep layers of different densities separated. As a result, laminar flow is almost never found in aquatic systems. It is important that the basic properties of turbulent flow and diffusion be understood in order to appreciate the magnitude of the resultant alterations in distribution of physicochemical parameters and biota.

If a critical velocity difference along a given density interface is exceeded, disturbances grow in amplitude and break into vortices (Fig. 7-1) (Mortimer, 1961, 1974; Smith, 1975; Denny, 1988; Vogel, 1994). Such vortex formation increases the mixing of the two layers by generating a transitional layer, across which there is both a velocity gradient (shear) and a density gradient. This model represents in simplified form what occurs when layers of nearly uniform velocity and density stream parallel to one another, as in the movements in the epi- , meta- , and hypolimnion discussed further on.

If the rate (a) of supply of energy to turbulent vortices or ***eddies***[1] from the shear stresses exceeds the rate (b) at which they have to do work against gravity in disrupting the density stratification, turbulence increases (Richardson, 1925; Mortimer, 1961). Rate a is proportional to the square of the shear, while rate b is proportional to the density gradient. The magnitude of the ratio b/a determines whether turbulence increases or decreases. In nondimensional form, that ratio is the

[1]The rotating region of fluid, an eddy, refers to an assemblage of shear waves of a spectrum of many lengths or "eddy diameters" (Mortimer, 1974).

Richardson number (R_i) expressed as

$$R_i = \frac{g(d\rho/dz)}{\rho(du/dz)^2}$$

where

g = acceleration of gravity
ρ = density
u = velocity
z = depth

When R_i of a stratified fluid subjected to shearing flow falls below about one-quarter, flow becomes unstable. Or, put in another way, when R_i falls below 0.25, there is a sudden shift in the eddy spectrum from the molecular microturbulence of stable flow toward macroturbulence of the large vortices associated with unstable flow. The shift is accompanied by increases in friction and in mixing *perpendicular* to the direction to the current.

Thus, in a river or lake with stratified shear layers, little mixing and friction between the layers occurs as long as the flow remains stable ($R_i > 0.25$). When flow increases and becomes unstable ($R_i < 0.25$), the stirring action of vortex formation (macroturbulence) increases the interfacial area many times. Mixing is then rapidly completed by microturbulence and molecular diffusion. Soluble components (nutrients) and suspensoids (microalgae, microfauna) are carried along with this dispersion of water into the newly formed, thicker layer in which density and velocity gradients are less than those that were initially present.

The shear instability that results when R_i falls below 0.25 causes a sudden shift in turbulent energy and the layers dissipate and collapse into a complex array of turbulent patches of nearly uniform density (Fig. 7-2). These patches are exceedingly transient in nature, and only the composite final product, after stability is restored, is what is most often observed. The thermal microstratification, commonly observed in detailed studies of the metalimnion (Whitney, 1937; Simpson and Woods, 1970; Baker *et al.*, 1985), is possibly a result of the dissipation of shear instabilities in the thermocline region.

B. Eddy Diffusion and Conductivity

The distribution of turbulent motion must be viewed in a statistical sense, for the distribution of fluid properties such as heat or solute content is a composite of many small random movements. The diffusion models for fluids, developed by Taylor and by Schmidt (Mortimer, 1974), are analogous to those that measure random movement of molecules in molecular diffusion but are obviously on much larger scales.

Heat transfer across a thermal gradient within a layer in a lake may be used to estimate the extent of turbulent transport, because turbulent mixing and heat conduction are quite similar. In a hypothetical layer of water devoid of motion but with a temperature gradient, heat equilibrium is brought about only by conduction. If flow is applied across that gradient and it is turbulent ($R_i < 0.25$), the equalization of temperature is greatly accelerated. Thus, heat (relatively warm water) is transported through a plane perpendicular to the gradient by eddy turbulence. The rate of transport (diffusivity or conductivity) across a fluid plane is the product of the gradient perpendicular to the plane and an exchange coefficient (K_z). If expressed as a substance dissolved in the water across the gradient, it may be written as the gradient concentration per unit volume of water in terms of passage across unit area, g cm^{-2} sec^{-1}.

Thus, the *coefficient of eddy diffusion* (K_z) is a measure of the rate of exchange or intensity of mixing across the plane. It is not a constant but varies with

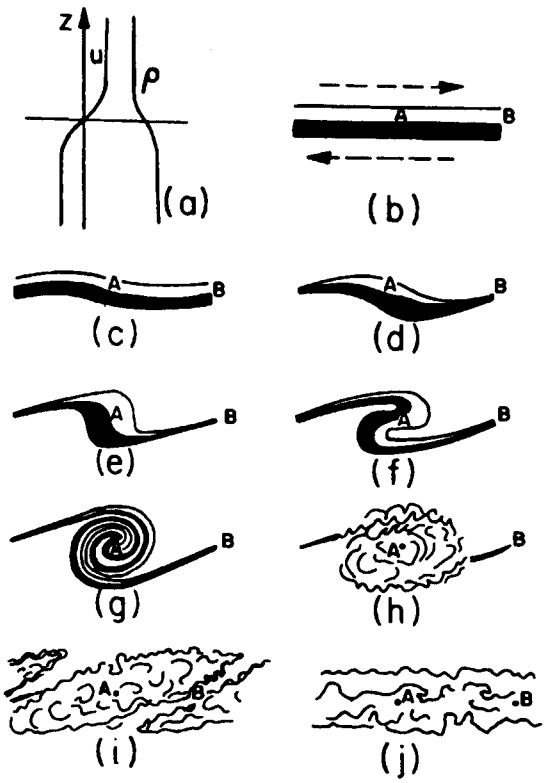

FIGURE 7-2 Growth of shear instability leading to turbulent mixing in a stratified fluid with the velocity and density (ρ) distribution shown in *a*. A and B are fixed points, the arrows indicate direction of flow, and the lines represent surfaces of equal density. (From Mortimer, C. H.: *Mitteilungen Int. Ver. Limnol. 20*:134, 1974, after Thorpe.)

average density, velocity of vertical motion, and mixing length. The horizontal dimensions of lakes are very much larger than the vertical dimensions of stratification; therefore, large differences exist between the magnitudes of horizontal and vertical eddy diffusion coefficients. The concept of an average K_z is subject to many variations related to the distance and is therefore an oversimplification. In reality, dispersion and mixing occur as a result of eddy movements over a wide range of spatial scales in which smaller eddies occur within larger ones. It is necessary to view the turbulent movements and consequent diffusion as taking place across a spectrum of turbulence (the eddy spectrum of Mortimer, 1974).

Turbulent transport causes particles to move apart at right angles to the direction of flow. When particles are close together, their rate of separation is governed by the small eddies of turbulent motion. But as the distance of separation increases, the dispersion of the particles is influenced by eddies of increasing size. Over significant ranges of dispersion, the mean rate at which particles diffuse is proportional to the 4/3 power of the distance between them (Stommel, 1949), a law that has been found to hold true for separation of particles over a range of 10 to 10^8 cm (Olson and Ichige, 1959; Verduin, 1961). The most probable value of turbulent diffusion velocity is in the range of 0.3–1.0 cm sec^{-1}, with a single diffusion velocity of approximately 1.0 cm sec^{-1} being valid for all scales of diffusion processes (Noble, 1961).

The coefficient of eddy diffusion is, for practical purposes, identical to the coefficient of eddy conductivity, which permits, in a general way, estimations of turbulence from changes in temperature. Estimations of eddy conductivity coefficients are useful, as they permit insight into the magnitude of current-induced turbulence in the hypolimnion. The magnitude of K_z and changes observed vertically with stratification, however, depend very much upon the methods of analysis and assumptions about the magnitude of direct solar heating of the upper hypolimnion, convective currents, lateral exchanges of water by internal seiche movements, lateral heating from the sediments, and the accuracy of measurements of small temperature differences (Hutchinson, 1957; Dutton and Bryson, 1962; Lerman and Stiller, 1969; Hesslein and Quay, 1973; Powell and Jassby, 1974; Jassby and Powell, 1975; Di Cola *et al.*, 1977; Imboden and Emerson, 1978; Maiss *et al.*, 1994). A lucid theoretical discussion is given in Denny (1988).

Coefficients of eddy diffusion in the hypolimnion decrease with increasing stability. Therefore, in lakes of large area and depth that have longer fetch for wind exposure, eddy diffusion coefficients of the hypolimnion are greater than in smaller, shallow, stratified lakes (Mortimer, 1941, 1942). In addition, the K_z of a turbulent epilimnion is markedly greater than the K_z in the more stable metalimnion of a stratified lake (Fig. 7-3). This relationship holds seasonally as well. As the gradient of thermal density stratification increases from spring to summer, the coefficient of eddy diffusion decreases, that is, K_z is inversely proportional to stability. In some lakes, particularly high-altitude clear lakes, diurnal heating can markedly alter temperatures of surface strata and form temporary thermal stratification and, with wind-induced mixing, metalimnia (Powell *et al.*, 1984). Marked diurnal changes in eddy diffusivity result. In the deep hypolimnion, K_z tends to increase slightly, especially near the bottom where the effects of other water movements further complicate analyses of turbulent transport (Coleman and Armstrong, 1987). The eddy diffusivity of the hypolimnion of stratified reservoirs increases markedly as hypolimnetic water is discharged at the dam (Sugawa, 1987).

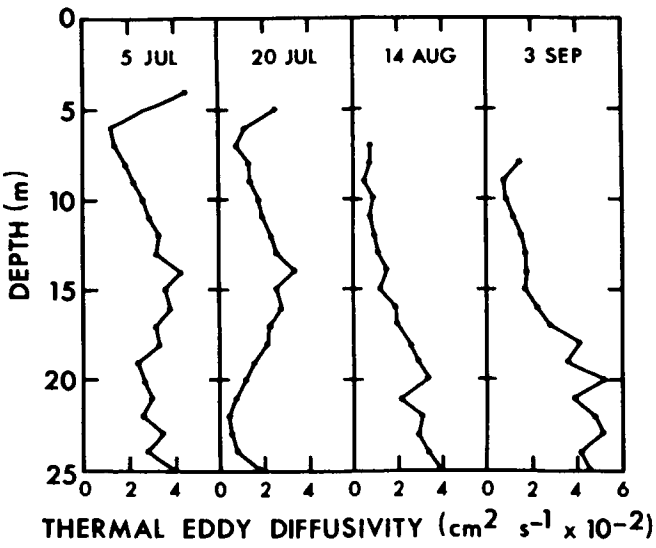

FIGURE 7-3 Selected depth profiles of the vertical thermal eddy diffusivity in Castle Lake, a small cirque lake in northern California, during the summer of 1972. The first value on each date marks the average top of the metalimnion at that date. (Drawn from data of Jassby and Powell, 1975.)

III. IN-STREAM HYDRAULIC MOVEMENTS

Streams and rivers are basically linear channels in which water flows directionally along a declining elevational gradient. The geomorphology and the roughness of the substrata of river channels, however, are variable. Coupled to variable discharge (cf. Chap. 3), water

movements are highly dynamic both spatially and over time.

A. Current Velocity

Downstream water movement in a stream channel is referred to as ***current.*** Current is the foremost factor affecting organisms in the channel. The current erodes the channel substrata and determines the extent and type of particle deposition and thus the nature of sediments.

Current velocity, although driven by the gravitational weight of the water moving downslope, is balanced by the frictional resistance of the water against the channel boundaries. Nonturbulent laminar flows are restricted to small but important boundary-layer regions at the substratum–water interface (discussed later). Turbulent flows emanate from the frictional shear forces and propagate logarithmically into the overlying water. Turbulent flows have been separated into hydrodynamic regimes based on the ratio between inertial and viscous forces, the latter related to the particle size of the sediments of the stream bed (Davis and Barmuta, 1989; Carling, 1992).

Current velocity is zero at the substratum surfaces and increases logarithmically within the ***boundary layer*** (Fig. 7-4). The thickness of the boundary layer decreases with the increasing current velocities of bulk water. This stratum is important to biota, particularly microbiota, because, lacking macroturbulence, the transport of gases and nutrients through this stratum are by molecular diffusion processes. Above this layer, current velocities increase and are usually maximum centrally within the channel (Fig. 7-4). Velocities decrease just below the water surface because of frictional shear with the atmosphere. Current velocities are altered by local roughness of the bed materials, and the logarithmic layer usually extends to 10–15% of the channel depth (Carling, 1992). The increase in velocity can extend to close to the surface in shallow streams.

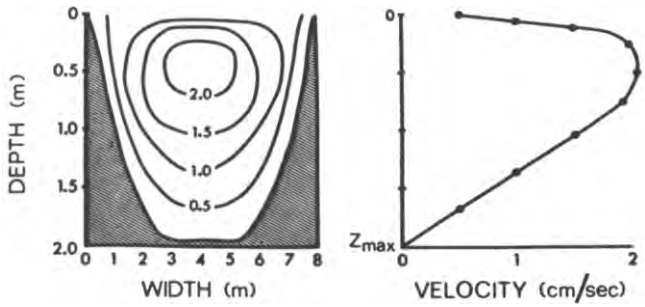

FIGURE 7-4 Idealized current velocity in cm sec^{-1} in a channel cross section (*left*) and in profile at the midpoint of the cross section (*right*). (From Wetzel and Likens, 1991.)

TABLE 7-1 Relationship of Current Velocity to Sediment Composition[a]

Velocity range (cm sec^{-1})	*General bottom composition*	*Approximate diameter (mm)*
3–20	Silt, mud, small organic debris	< 0.02
20–40	Fine sand	0.1–0.3
40–60	Coarse sand to fine gravel	0.5–8
60–120	Small, medium, to large gravel	8–64
120–200	Large cobbles to boulders	> 128

[a] Modified from Einsele (1960).

The shear forces generated by turbulent water movements are transferred to particles and cause them to move along or above the channel substrata. The suspended sediment load is particles that are entrained into the bulk water moving in the channel. The ***bedload*** is particles that are moved downstream in nearly continuous contact with the streambed (Beaumont, 1975). Both movements are, of course, a function of the current velocity. Larger particles may be transported by higher current velocities, and the sediment composition in subsequent sedimentation processes reflects the effects of current in erosion and transport (Table 7-1).

B. Channel Flows

Very few natural river channels are straight. However, small sections of many rivers have the dominant properties of straight channels with relatively uniform flow. Comparing flow in straight vs. the more common meandering channels is instructive. Flow in natural channels is three-dimensional, and because width-to-depth ratios are generally greater than about 13 (Carling, 1992), the effects of the banks are small on the central two-thirds of the flow. However, channel roughness in natural channels causes upwelling and secondary flow cells to develop along the banks (Fig. 7-5). In wide channels, flow may exhibit more than one flow cell, each exhibiting a secondary spiraling flow (Fig. 7-5). Resistance along the channel and banks increases with natural variations in morphometry and protrusions, particularly higher aquatic plants. These variations in resistance can result in secondary flow cells with reverse flow upstream along the bank. The result is alternating scouring and deposition variations in the channel topography at relatively uniform distances (3–10 times stream widths). Current velocities then vary with the roughness and depth variations and result in deeper sections, termed ***pools,*** and shallow sections, called ***riffles.*** Variations in flow resistance and the secondary cells formed by bank shears result

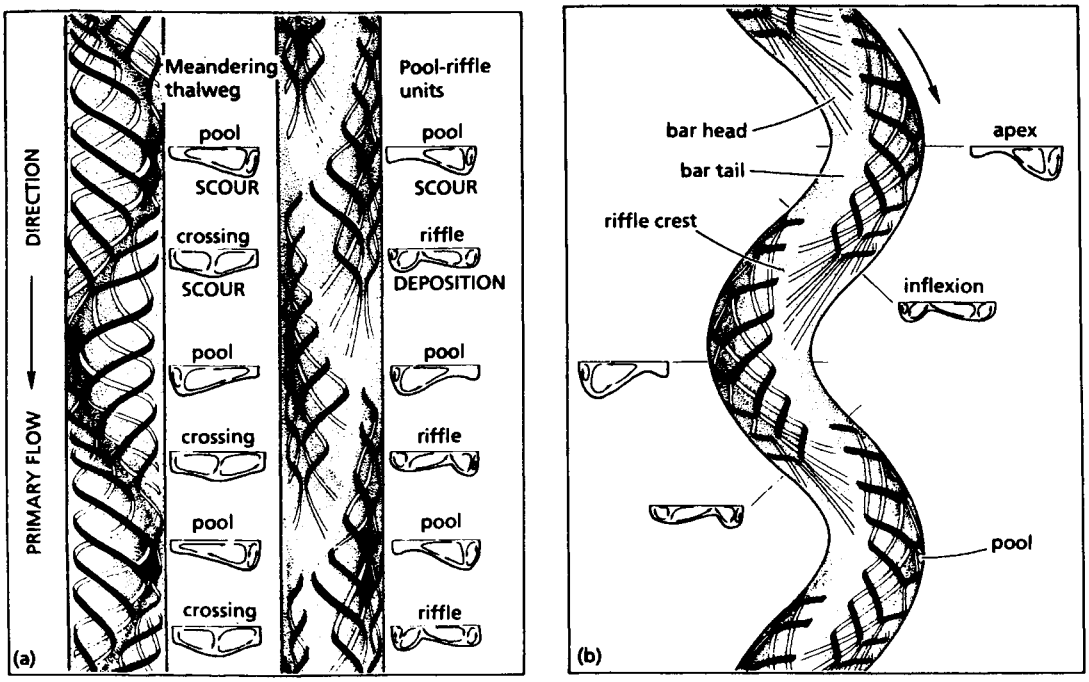

FIGURE 7-5 Models of flow structure in (a) straight and (b) meandering channels. (From Carling, 1992, after Thompson, 1986. Secondary flows and the poolriffle unit: a case study of the processes of meander development. Earth Surface Processes and Landforms *11*:631–641, © John Wiley & Sons Limited. Reproduced with permission.)

in the spiraling flows and shifting within the channel from side to side. As a result, even in relatively straight channels, flow is meandering and erodes the deepest part of the channel, termed the ***thalweg,*** in a meandering pathway.

In curved river channels, the fast-flowing surface water of the large cells flows toward the outer bank and is accompanied by downwelling and erosion (Fig. 7-5). Reduced velocities occur on the opposing side and are accompanied by upwelling and deposition and the formation of a ***bar.*** Many areas of slowly flowing or relatively quiescent water occur in areas opposite the primary inertial flow regions of the channel. These water masses mix only slowly across a shear zone with the main advective flow (Chatwin and Allen, 1985; Carling, 1992; Rutherford, 1994).

Any obstruction within the stream channel creates shear forces and can introduce turbulence and modify flow patterns and sediment transport in the localized region of the obstruction. Thus, enormously diverse habitats are created, and all are continuously changing with fluctuations in water discharge. This habitat diversity is important to inhabiting biota, particularly as in-stream flow refugia (Lancaster and Hildrew, 1993) and as sites for accumulation and production of organic matter. These sites can also offer protected habitats of sufficient duration for completion of life cycles before disturbance by high-water spates.

Of many natural obstructions that modify channel flows, two particularly significant agents are wood debris and aquatic plants. Plant materials of many types enter streams either by erosion with water or by direct falling into the channels from adjacent forest trees. Although many leaves, needles, cones, twigs, branches, bark, and rootwads enter streams, most of these are transported downstream until becoming entangled against some larger obstruction, forming a localized ***debris dam.*** Retention of leaves and similar materials increases as stream discharge decreases (see Bilby and Likens, 1980; Raikow *et al.,* 1995). Major flow alterations occur from large obstructive debris, such as tree stems and associated root balls of a size greater than ca. 20 cm in diameter that have fallen or been washed as driftwood into the stream or river channel (Maser and Sedell, 1994; Wondzell and Swanson, 1999). Fallen trees extending partially across a channel deflect current laterally, widen the streambed, and increase the hydraulic complexity. Scouring downstream of the obstruction creates pools; backwaters of greatly reduced flow occur upstream from the obstruction along the stream margin. Secondary channels often form around tree obstructions and broaden the width of the stream within the valley.

The growth of aquatic macrophytes in streams and rivers is often in aggregated clumps. Great variations in hydraulic resistance to flow occurs among the many

species of aquatic macrophytes adapted to living in flowing water (Dawson, 1978; Haslam, 1978). Long-narrow-leaved species offer the least hydraulic resistance to flow and are most common in streams of moderate discharge, although great variations occur. Water velocities are very low within a plant clump and decline sharply from the edge (<3 cm from the edge) to very low velocities within the plant aggregate (Madsen and Warncke, 1983; Machata-Wenninger and Janauer, 1991; Losee and Wetzel, 1993). Current flows tend to compress the trailing leaves downward and laterally, and water flows around the plant aggregates. Velocities tend to increase between the plants. Markedly reduced flows within the plant clumps lead to increased deposition, often of finer particles than normally occur within the streambed. Faster flows between clumps tends to be more erosive, and particle sizes are larger than within the plant clumps (Marshall and Westlake, 1990). Dense development of aquatic macrophytes can markedly impede stream flows; for example, submersed macrophytes reduced water velocities as much as fourfold during summer in a lowland Danish stream and promoted extensive organic sedimentation (Sand-Jensen *et al.*, 1989).

C. Flows at and within River Sediments

The flow of water over loose sediments may deform the materials and create a variety of bedforms in silt, fine sand, and gravels (Fig. 7-6). Once a critical shear stress is exceeded, ***ripples*** develop in fine sand (<0.6 mm) as crested, triangular, and gentle upstream slopes (Carling, 1992). Ripples move downstream by erosion on the upstream slope and deposition on the steeper downstream (lee) slopes. Heights are less than 4 cm with wavelengths below 60 cm.

At higher water velocities, ripples are replaced by larger ***dunes*** that may be meters in height with wavelengths of tens of meters (Fig. 7-6). Ripples may occur on the upstream slope of dunes. Backflowing turbulence vortices occur on the lee slopes, and the turbulent water above them is termed ***boils.*** With further increases in stream velocities, bedload transport increases and dunes are eroded to transitional stages of relatively flat beds (Fig. 7-6). Further increases in current velocities induce water waves with upstream backflows and turbulence. Bedform patterns can be similar among cohesive sediment muds, but the structures are less predictable in relation to flow velocities.

Water moving within a channel encounters substrata variations. These differences induce localized pressure variations in the channel that force water and contained solutes by advection into interstitial spaces within the substratum (Vaux, 1962; Thibodeaux and Boyle, 1987). The penetration of overlying stream water into the substrata varies greatly with the geomorphology of the drainage basin, elevational changes, sediment composition, and particle size, as well as flow characteristics. The saturated interstitial areas beneath the streambed and into the stream banks that contain channel water to the depth to which overlying stream water actively infiltrates by advection is the ***hyporheic zone*** (White, 1993; termed the ***surface hyporheic zone*** by Triska *et al.*, 1989). This advective infiltration zone may extend for several centimeters to well over a meter in depth. Below the surface zone, the ***interactive hy-***

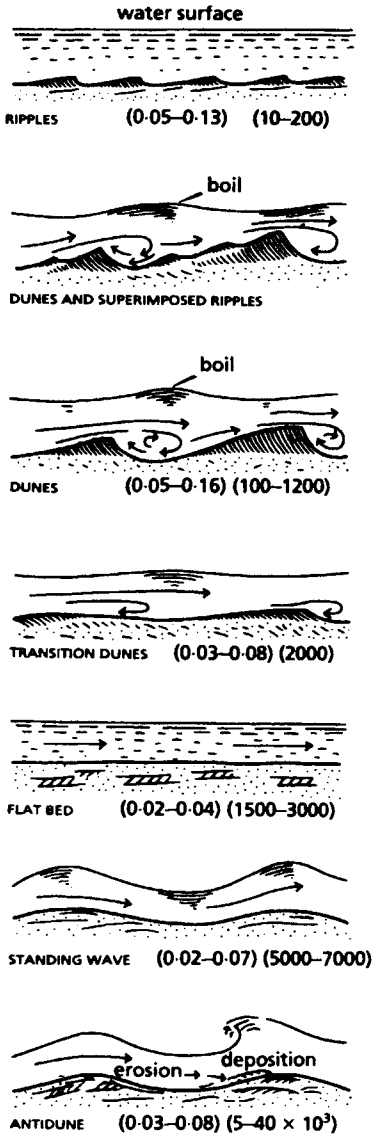

FIGURE 7-6 Sandy bedforms generated as current velocity increases. Parenthetic values refer to a relative friction factor and to the bedload transport rate (ppm). (From Carling, 1992, after Richards, 1982, *Rivers: Form and Process in Alluvial Channels.* Methuen, London, Rutledge. Reproduced with permission.)

porheic zone contains less stream water and more ground water. The boundary between these two hyporheic zones can be considered the hydrological boundary of the stream even though there are active chemical and biotic exchanges between them, because ground water represents water beneath the water table that has not yet been influenced by channel processes (Freeze and Cherry, 1979). The penetration of the interstitial habitat of the hyporheic zone by riverine animals can be viewed as an indicator of spatial and temporal variations in hyporheic boundaries and conditions (Stanford and Ward, 1988).

The hyporheic zone can confer stability to stream ecosystems as potential microbial and invertebrate refuge sites in the alluvium and its sustenance of microbiota important in biogeochemical processes, particularly by storage of nutrients (Grimm *et al.*, 1991; Valett *et al.*, 1994). Geomorphic processes, particularly major floods, alter the spatial extent of the hyporheic zone, however, as well as its volume and hydrologic residence times. For example, during major floods of 50- to 100-year recurrence intervals, water movements and transported large woody debris can rework, disturb, and move sediments of most of the hyporheic volume (Wondzell and Swanson, 1999). The effects on the hyporheic biota would depend on the extent of the hyporheic zone, depth of scour, and species-specific patterns of utilization of the zone.

Stream water penetrates interstitial spaces of sediments to a greater depth on the upstream side of ripples and dunes and less so on the lee side (Grimm and Fisher, 1984; Hendricks and White, 1991). The exchange of dissolved gases and nutrients is consequently much greater in areas of more extensive penetration, which generally increases the distribution and productivity of surface colonizing and interstitial biota in these leading-edge areas.

The sources of water to stream ecosystems vary greatly, but ground water often constitutes the dominant input to base flows. The groundwater dominance often prevails in headwater reaches of streams (Fig. 7-7a). Streamwater penetration into the hyporheic zone of the sediments may be less extensive in these headwater areas. Changes in localized geomorphology and reduction in streambed elevation commonly occur further downstream, with extensive development of riffles and pools (Statzner and Higler, 1986). This flow pattern can result in extensive penetration of surface water into the streambed (Fig. 7-7b), and likely results in a complex of alternating upwellings of ground water and downwellings of stream water through the sediments, as was implicated by the analyses of Godbout and Hynes (1982). Subsurface flow paths do occur in certain coarse substrata beneath the channel, with a slow hyporheic movement (m h^{-1} to m d^{-1}) in straight lines, possibly using relic channels, from one meander to another (Triska *et al.*, 1993). Groundwater sources can constitute a major source of base flows (Williams and Pinder, 1990). In downstream sections of rivers of higher order where the channels widen into flood plains and deltas, elevational gradients and groundwater inputs usually decline. The advective forces of moving water through the sediments also decline. The boundaries between river water and ground water extend laterally further from the river channel as flood plains widen (Fig. 7-7c).

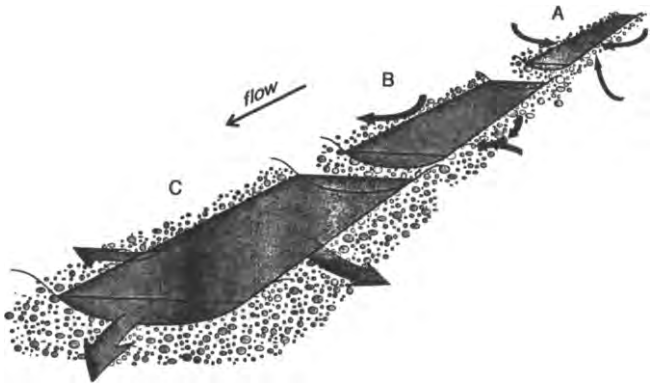

FIGURE 7-7 Directions of water movements within longitudinally connected stream beds. (A) A headwater stream; (B) a mid-reach stream with pool-riffle-pool sequence; and (C) a larger river with a well-developed flood plain. (After White, 1993.)

At bankfull stages (Chap. 3), high discharge can overflow the banks and inundate the adjacent, flat floodplain areas. Thus, the flood plain encompasses areas that are periodically inundated by the lateral overflow of rivers. Overbank flow induces large-scale vorticies into the floodplain areas (Fig. 7-8). The faster-moving water in the main river channel and the slower-moving water on the flood plain produce a shear layer laterally across the system (Knight and Shiono, 1996). The mean velocity decreases from the river to lower values on the flood plain, and the flows are dependent on the average river bank height and the depth of water on the flood plain in relation to the depth of the main river channel. Because of the decreased shear during the later flooding movements of water in the flood plain, the kinetic energy is dispersed over large areas. As a result of shear against the substratum and often many obstructions such as trees, an appreciable sediment load can be deposited from the water. Under very high discharge conditions, materials of the flood plain can be eroded and carried downstream.

The periodicity of inundation of the flood plains covers a wide hydrological spectrum from short (few days) to long duration (several weeks) and from unpre-

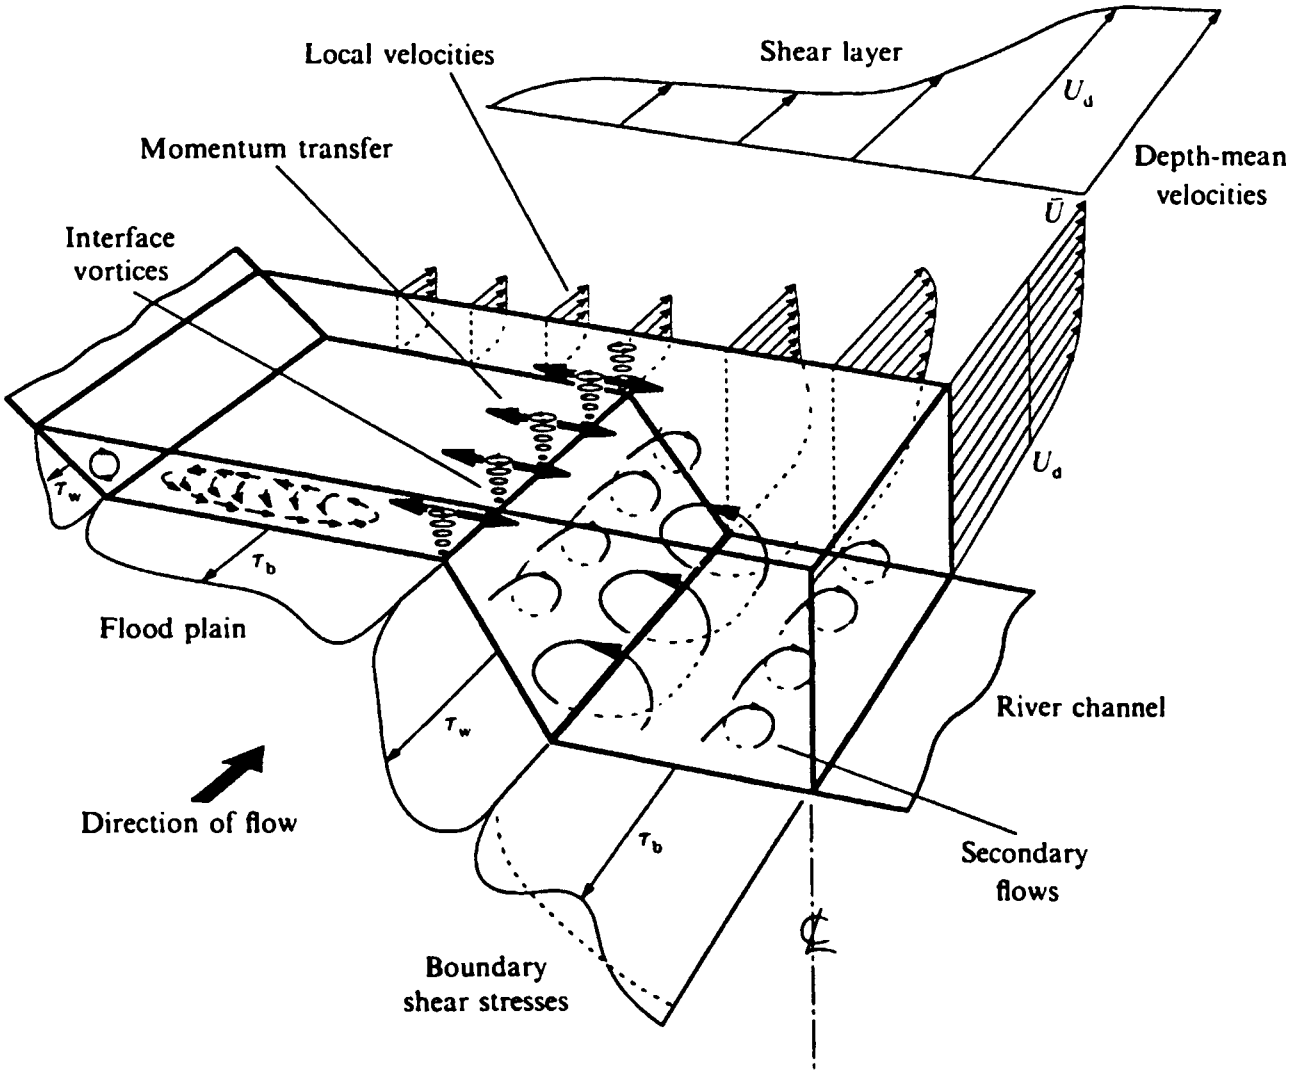

FIGURE 7-8 Hydraulic parameters associated with overbank flows onto and within the flood plain. (After Knight, D. W. and Shiono. 1996, River channel and floodplain hydraulics. In M. G. Anderson, D. E. Walling, and P. D. Bates, eds. Floodplain Processes. John Wiley & Sons, Limited, Chichester. Pp. 139–181. Reproduced with permission.)

dictable to predictable timing (Junk *et al.*, 1989; Bayley, 1995). Among many streams and rivers of the temperate region, flooding is relatively rare and unpredictable, although the long-term frequency is moderately predictable (Chap. 3). Low-order streams have an irregular flood pattern with many peaks that are influenced by local precipitation events. The influence of these events diminishes with increasing size of the drainage basin and become minor in the hydrographs of very large rivers.

The large catchment basins of large rivers offer a strong hydrological buffering capacity, and flooding responses result from (a) seasonality of precipitation and (b) seasonality of evapotranspiration. In tropical and subtropical regions, the hydrographs of large rivers commonly reflect the annual rainy season and typically exhibit only one pronounced flooding event per year. Because of the large size of the rivers and their drainage basins, the downstream flood pulse can persist for long periods of time (weeks to months) after the rainy season has subsided in the upper portions of the drainage system (Junk *et al.*, 1989; Junk, 1997a,b). Many riverine lakes and wetlands can develop in depressions of the flood plain; they become isolated from the main channel for months or years and only become hydrologically connected during periods of high water.

In temperate regions, most rivers have flow régimes altered by dams and channelization. Where medium-sized to large rivers have been unmodified, they also are characterized by low gradients, broad

flood plains, and frequent flooding. Flooding in these regions is less predictable and of shorter duration than in regions with large tropical rivers. Because precipitation tends to be less seasonal and more evenly distributed over the year, flooding tends to be controlled primarily by seasonal differences in evapotranspiration (Benke *et al.*, 2000). Runoff and flooding decrease during the summer periods of high losses of water by evapotranspiration.

As rivers and tributaries join, mixing occurs at the confluences. Although many morphological factors influence mixing rates, mixing of water between the confluent rivers is nearly always completed before a downstream distance of 25 channel widths is achieved (Gaudet and Roy, 1995). Turbulence and mixing rates are increased if one of the rivers is appreciably shallower than the other at the confluence zone (Best and Roy, 1991). Shear and scour occur at the junction, with entrainment of the main river water and rapid mixing.

IV. SURFACE WATER MOVEMENTS

A. Surface Waves (Progressive Waves)

The frictional movement of wind blowing over water sets the water surface into motion, producing a wind drift. Wind also sets the surface into oscillation and produces ***traveling surface waves.*** If these waves become large enough to break, their energy flux and dispersion are transferred to the water. Although to an observer looking at a lake or very large river, these surface waves are the most conspicuous periodic characteristic, their limnological importance is largely confined to shore areas. Traveling surface waves are confined to surface layers and cause little displacement of the deeper water masses.

Short surface waves cause the surface water particles to move in a circular path or orbit. In cross section, the path is ***circular*** (Fig. 7-9), with very little significant motion other than slow horizontal translocation (Smith and Sinclair, 1972). In a given wave, water is displaced vertically and returned by gravity to an equilibrium state. Similarly, neighboring short surface waves oscillate periodically in circular fashion. In synchrony, these movements result in a traveling wave whose path may be described as analogous to a point on the rim of a wheel moving along a plane where the hub is at the mean surface of the water (Fig. 7-9). Except in shallow beach areas, the wavelengths (λ) of short surface waves are less than the water depth and, consequently, they are dispersive, that is, they travel at speeds proportional to $\lambda^{1/2}$ of deepwater gravity waves (discussed later).

Of greater interest than the small horizontal movement of short surface waves is the influence such periodic oscillations have vertically, although the height (h) of this vertical oscillation is attenuated rapidly with depth (Fig. 7-9). The decrease of vertical motion with increasing depth can be approximately described as a halving of the cycloid diameter for every depth increase of $\lambda/9$. As we will see shortly, the amplitude or height of surface waves is not directly proportional to wavelength, although a ratio of about 1:20 of h:λ is a common average. If, for example, short surface waves had a λ = 18 m and h = 1 m, the vertical oscillation at a depth of 4 m ($2/9\lambda$) would be 25 cm, at 8 m or $4/9\lambda$, 6.25 cm, and at 18-m depth, 1.95 mm. In other words,

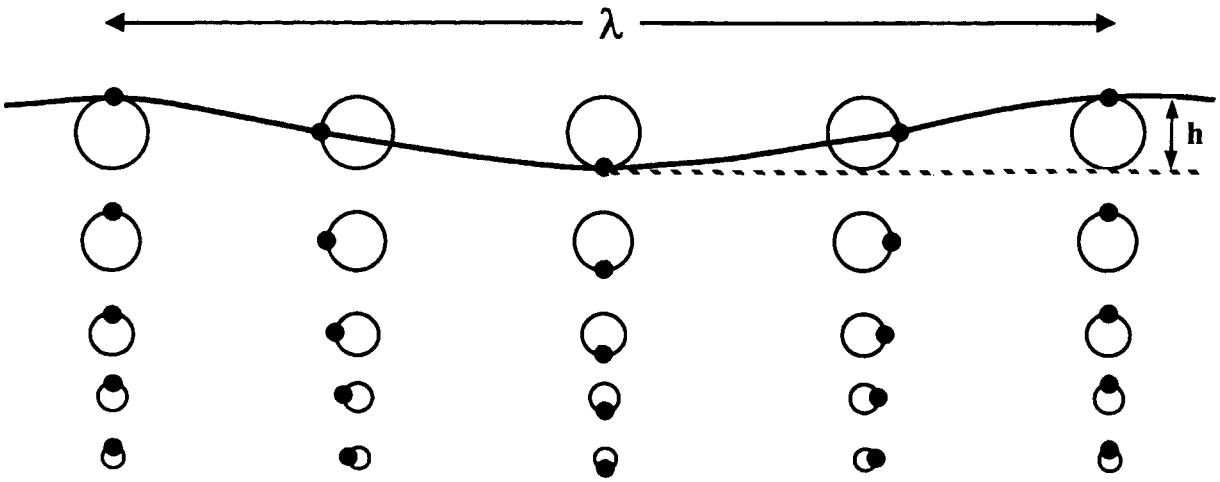

FIGURE 7-9 Circular motion of fluid particles in a sinusoidal wave of length (λ) traveling from left to right on deep water. The height (h) of the circular movement is attenuated with depth by $h/2$, the displacement positive or negative from the equilibrium in a sinusoidal wave. (Modified from Lighthill, 1978.)

the magnitude of vertical displacement at a depth equal to the wavelength will be 1/512 (i.e., $1/2^9$) of that at the surface.

Short surface waves with a wavelength greater than 6.28 cm (2π cm) are referred to as ***gravity waves.*** Waves of a length less than this minimum are called ***ripples*** or ***capillary waves,*** where surface tension effects become appreciable. The ratio of wave height (h) to wavelength (λ) is highly variable within the range of 1:100 to about 1:10. At great height, the crests of the waves sharpen and become less stable. When the angle of the wave height exceeds a h:λ ratio of about 1:10, the peak collapses and some apical water may be blown off, forming a ***whitecap.*** The occurrence and density of whitecaps increases abruptly as the wind velocity increases from ca. 7 to 8 m sec^{-1} (Monahan, 1969).

For a given wind speed, wave height appears to be nearly independent of depth in small lakes, but in lakes of great area, wave height and length increase with increasing water depth (Hutchinson, 1957). The height of the highest waves observed on a lake appears, without good theoretical explanation, to be proportional to the square root of the ***fetch,*** or distance over which the wind has blown uninterrupted by land. Thus, the maximum height (cm, crest to trough), where x = the fetch distance in centimeters, is expressed as

$$h = 0.105\sqrt{x}$$

For example, the maximum wave height observed in Lake Superior was 6.9 m with a fetch of 482 km (4.82×10^7 cm), which agrees well with a maximum of 7.3 m predicted by this relationship.

Surface wind shear stress on the water surface is often unevenly distributed because of interference by surrounding topography. In the lee of trees, hills, and rocks, surface wind shear stress will remain zero over a length of 6 times the height of the sheltering feature (Ottesen Hansen, 1979). Fully developed wind shear stress and associated growth of turbulent energy at the surface layer requires an additional further distance of 7 times the height. Therefore, the relationship between fetch and surface waves can be greatly modified in small lakes by the surrounding topography.

The waves described in the foregoing paragraphs are "deepwater" or "short" waves, in which wavelength is much less than water depth. Where this condition no longer holds, and the wavelength becomes more than 20 times the water depth, the wave is transformed into a "shallow water" or "long" wave, and the circular motions are transformed into a to-and-fro sloshing, which extends to the bottom of the water column (Fig. 7-10). Hence, the circular orbits found in deepwater waves shift to more elliptical orbits and flatten as they approach the bottom. Shallowwater waves are no longer energy dispersive, because their speed is proportional to the square root of the water depth rather than being determined by wavelength. Therefore, as deepwater waves enter shallowwater areas, their velocity decreases as the square root of depth decreases, and there is a simultaneous reduction in wavelength (Iverson, 1952; Mason,

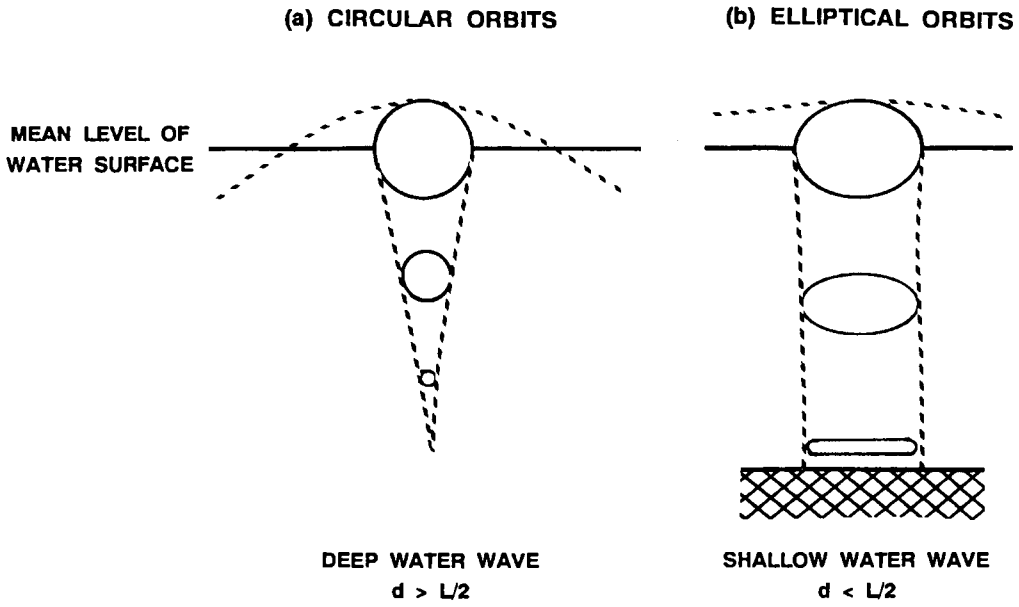

FIGURE 7-10 Orbital motions of water beneath waves. (a) Deepwater waves where water depth (d) is greater than the wavelength $\lambda/2$. (b) Shallow water waves where $d < \lambda/2$. (Modified from Denny, 1988.)

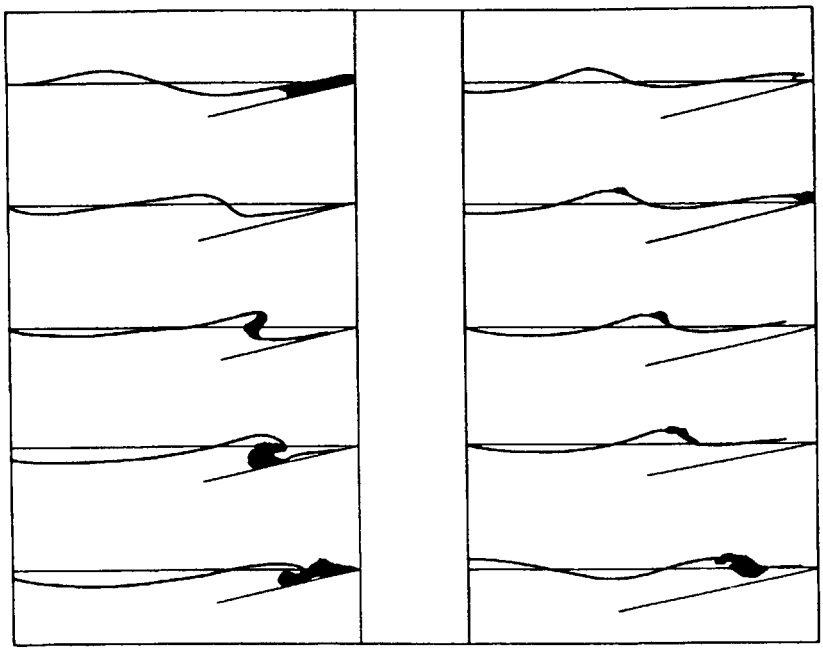

FIGURE 7-11 The breaking of waves on beaches. *Left:* Plunging breaker. *Right:* Spilling breaker. (From Hutchinson, G. E.: *A Treatise on Limnology*. Vol. 1, New York, John Wiley & Sons, Inc., 1957; after Iversen, 1952, and Mason, 1952.)

1952; Hutchinson, 1957). Wave height first decreases slightly, then increases markedly and becomes asymmetrical and unstable. The collapse of water over the front of this now asymmetrical wave is termed a ***breaker*** and occurs in a spectrum of forms between two extreme types (Fig. 7-11). In a ***plunging breaker,*** the forward face of the wave becomes convex and the crest curls over but collapses with insufficient depth to complete a vortex. The crest of a ***spilling breaker*** collapses forward, spilling downward over the front of the wave.

At an early stage of wave development when a fresh wind blows over the water surface, relatively long-lived short gravity waves form in crescent-shaped or "horseshoe" patterns (Dias and Kharif, 1999). These waves are rather steep with sharpened crests and flattened troughs, and they have a front–back asymmetry (Fig. 7-12). The specific horseshoe shape of the wave fronts is always oriented forward.

Where the offshore gradient is low and an abundance of loose sediment exists, the swash from breaking waves can lead to **beach-ridges** of linear mound-shaped ridges of sediment approximately paralleling the shore line (Taylor and Stone, 1996). Beach-ridges are often transient but over a long period of time can prograde with sedimentation and lead to modified shore lines toward the lake basin.

Because in shallow water the wave action extends to the bottom, sedimentation can be prevented in sufficiently shallow water and movement may be too severe for most aquatic plants to grow. In lakes with high rates of sedimentation in the littoral zone, such as in calcareous hardwater lakes where marl banks or benches extend out from the shore line for many meters, recently sedimented material is constantly resuspended and removed to deeper areas. As a result, in suitably shallow water of about a meter, marl benches on the steep sides of these lakes do not increase in height. In a hardwater lake of northern Indiana, for example, the surface sediments of a submersed lakemount island were found to be very old (Wetzel, 1970). The lakemount ceased accretion of sediments abruptly 1 m from the lake surface about 2740 years ago, for more recent sediments were continually moved into deeper parts of the lake.

B. Surface Currents

Currents are nonperiodic water movements generated by external forces. Forces responsible for producing currents include the wind, changes in atmospheric pressure, horizontal density gradients caused by differential heating or by diffusion of dissolved materials from sediments, and the influx of water into a lake. The latter subjects have been treated in other chapters, and the following remarks are therefore concerned primarily with wind-derived surface currents of open-water masses.

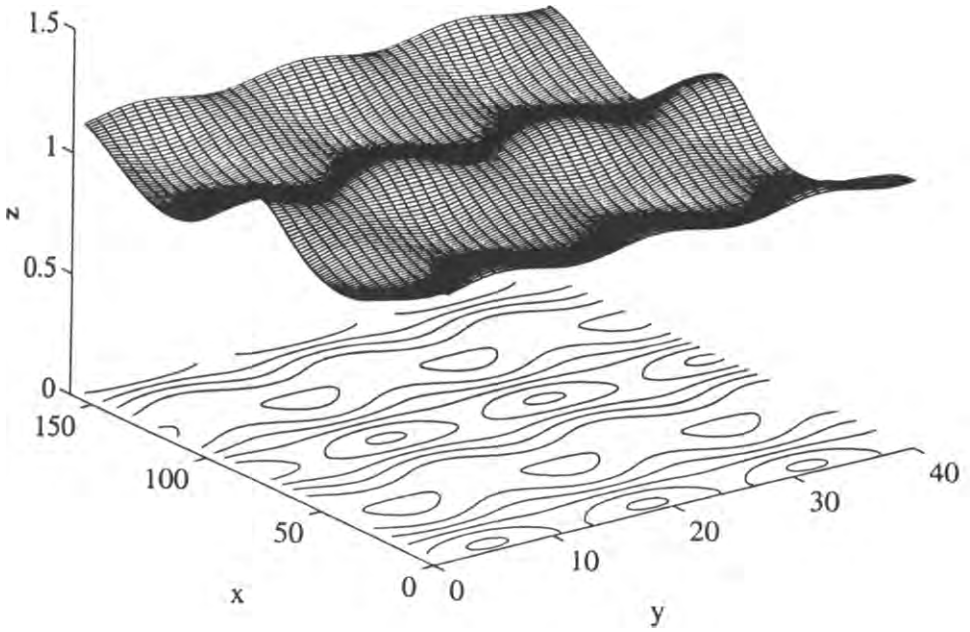

FIGURE 7-12 Crescent-shaped or "horseshoe" patterns of surface gravity waves in their phase of growth with their wave fronts oriented forward. The waves are propagating from right to left. (From Dias and Kharif, 1999, after work of C. Skardrani.)

Geostrophic effects of the deflecting (Coriolis) force due to the Earth's rotation are found in all currents in moderate- to large-sized lakes. In the Northern Hemisphere, surface water currents are deflected to the right relative to the direction of the wind. In the Southern Hemisphere, the Coriolis force causes surface waters to deflect to the left relative to the wind direction.

The combined effects of wind and geostrophic deflection cause surface water to move downwind and to the right in the Northern Hemisphere. Under stratified conditions, there is also a tendency for denser water to collect on the left side of the current and less dense water on the right side of the current. The resulting wind-drift current is deflected 45° from the direction of the wind in a spiral manner (the Ekman spiral) in open waters of large, deep lakes. As the size, and especially the depth, of the lakes decrease, the magnitude of the deflection angle decreases until, in a lake with a depth of less than about 20 m, the angle of declination becomes insignificant. In Lake Mendota, which is of moderate size (39.2 km^2) and depth (25.6 m), a rotation of wind-driven surface currents had an average angle of deflection of 20.6° to the right (Shulman and Bryson, 1961). The depth of frictional influence in Lake Mendota was found to be between 2 and 3.5 m. Stress exerted by the wind on the water surface was found to be a linear function of wind speed.

The wind factor, defined as the ratio of surface water current velocity to wind velocity, is quite variable. In general, the velocity of wind-driven currents is about 2% of the speed of the wind generating them and is largely independent of the height of the surface waves. An average wind factor of 1.3% for the upper half-meter of water was found in Lake Mendota at low wind velocities (Haines and Bryson, 1961). Water velocity in the surface layers increases with wind velocity until a critical wind speed is reached. Above the critical speed, surface water velocity decreases, and the wind factor becomes nonlinear. In Lake Mendota, the critical wind speed was 5.7–6.1 m sec^{-1}.

The surface currents of very large lakes tend to circulate in large swirls or ***gyrals***. Lake Michigan, for example, is typically exposed to predominantly westerly winds during summer, and its large, conspicuous gyrals are clearly influenced by geostrophic rotational forces (Noble, 1967). In this and other examples, gyral movements are complicated by numerous other water movements related to standing water motions (see later discussion). Inertial currents on a smaller scale also occur in all of the Laurentian Great Lakes, not only at the surface but at all depths and in all seasons (Verber, 1964, 1966). The geostrophic right-hand acceleration of currents also occurs under ice cover. Many complex flow patterns have been observed: straightline, sinusoidal o2 oscillatory, repeated crescent, circular or spiral, and rotary or screw flows. Gyrals in lakes the size of Lake Michigan are not simply the result of geostrophic forces; their direction is strongly modified

by large, long waves and especially by shifts in duration of strong prevailing winds.

C. Langmuir Circulations and Streaks

Turbulence generated by surface water movement and wave action is often sporadic and independent of wave direction. Sporadic turbulence occurs, for example, in the dispersion of wave energy in the mixing of the epilimnion when the lake is stratified or during the mixing of the general water mass. Langmuir (1938) demonstrated that under some circumstances the motions associated with turbulent transport are organized into vertical helical currents in the upper layers of lakes (Fig. 7-13). Convection from this vertical motion generates streaks, which are oriented approximately parallel to the direction of the wind. Streaks coincide with lines of surface convergence and downward movement and are marked by windrows of aggregated particulate and surface-active materials. Between the streaks are zones of upwelling. Such ***Langmuir circulation*** occurs in all waveswept lakes of any significant size at wind speeds above 2–3 m sec^{-1}. The streaks are seldom observed at wind speeds above about 7 m sec^{-1}, even though the Langmuir circulations are still occurring (Scott *et al.*, 1969; Ottesen Hansen, 1978), for at high wind speeds, surface turbulence is apparently great enough to disrupt the surface aggregations.

The mechanisms responsible for the generation of Langmuir circulations in lakes have been the subject of much debate (Stewart and Schmitt, 1968; Myer, 1969; Scott *et al.*, 1969; Faller, 1971; Harris and Lott, 1973). It is evident from Faller's (1969, 1978) and Faller and Caponi's (1978) laboratory work that the primary mechanism generating Langmuir circulations probably is the wave and shear-flow interaction mechanisms described in a series of theoretical analyses by Craik and Leibovich (Craik and Leibovich, 1976; Craik, 1977; Leibovich, 1977). In these experiments, the helical circulations were present only when both the wind and the wave patterns existed at the same time, in agreement with the theoretical predictions that both a shear flow due to wind and the Stokes drift of progressive waves (see later) are essential. From this complex interaction, wind energy is converted into organized helical circulations as well as into waves, random turbulence, and the mean shear flow. The resulting Langmuir circulation is one of the primary ways in which turbulence is transported downward and the upper layers of water are mixed.

The Langmuir convectional helices form a series of parallel clockwise and counterclockwise rotations that result in linear alternations of divergences and convergences (Fig. 7-13). In Lake George, New York, Langmuir found the velocity of downward convergence currents to be 1.6 cm sec^{-1} with a wind speed of 6 m sec^{-1}.

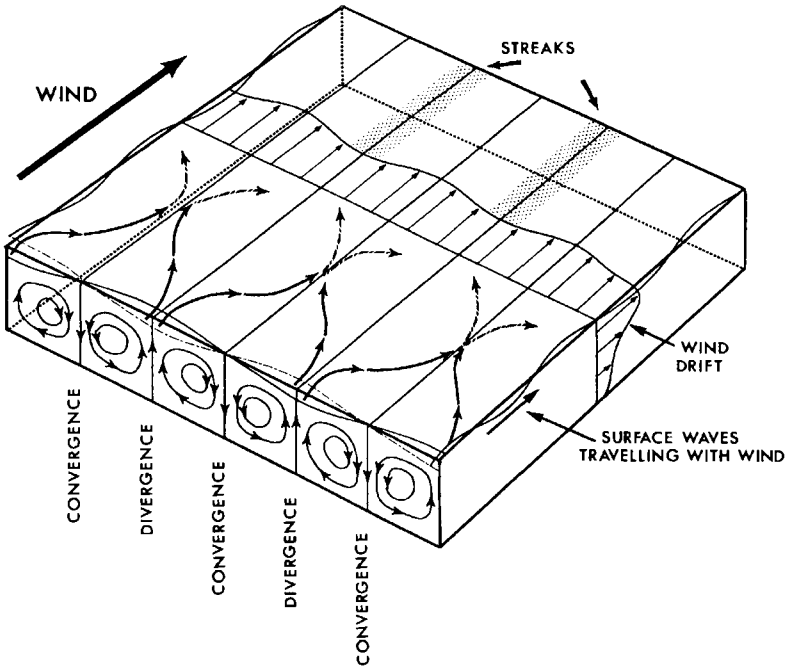

FIGURE 7-13 Diagrammatic representation of the helical flow of Langmuir circulations in surface waters with streaks of aggregated organic matter occurring at lines of divergence. (Based on the experimental work of Faller, 1978, and others.)

At this time, there was a horizontal surface current of 15 cm sec^{-1} and a current of 10 cm sec^{-1} at a depth of 3 m. Downward movement velocities at convergences were about three times the upward current velocities at divergences. Such currents are sufficient to markedly influence the distribution of microflora and fauna suspended in the surface waters of lakes. Algae and zooplankton, with limited or no powers of locomotion, tend to be aggregated in streaks in areas of water divergence (George and Edwards, 1973). The result is a patchiness in horizontal distribution that is important not only in the sampling of the microorganisms for estimates of population size and distribution and in metabolic measurements but also in determining the distribution of predators, which congregate in these zones of higher prey density.

V. INTERNAL WATER MOVEMENTS

A. Metalimnetic Entrainment in Stratified Lakes

Surface waves and Langmuir circulations cause turbulence, but the barrier formed by the density gradient in the metalimnion suppresses the transmission of turbulence into the metalimnion and hypolimnion. However, as wind blows over the surface for a reasonable period of time, wind drift causes water to pile up, with a rise in surface level at the lee end of the lake. The accumulated mass of water is pulled downward by gravity and, when it encounters the more dense water of the metalimnion, it flows back in a direction opposite to that of the prevailing wind (Fig. 7-14). The thermocline, or plane separating the two layers of different density (termed *pycnocline* by Hutchinson, 1957), is tilted in the process. We will return to the vertical movement of this entire water mass in the following section, after discussing the circulation pattern.

Progressive erosion of the metalimnion occurs by ***entrainment,*** with a corresponding lowering of the thermocline level (Mortimer, 1961). This erosion, which is characteristic of the autumnal cooling phase, begins when the net heat flux across the water surface changes from downward to upward and ends in the fall overturn. During the early stages of entrainment (Fig. 7-14a), when the return current above the thermocline and the entrained layers below it both are moving upwind, shear turbulence in the metalimnion is low. As long as R_i does not fall below the critical value, the thermocline remains a slippery surface of low frictional shear with little mixing across it. If the shear at the thermocline increases ($R_i < 0.25$), flow becomes unstable and large vortices appear in the return current at the downwind end (Fig. 7-14b, c). These vortices are carried upwind, where they become mixed into the surface drift. This process increases the density gradient at the downwind end until it offsets the local shear to produce neutral turbulence stability, with R_i near 0.25. The resultant whole-basin disposition of isotherms becomes fan-shaped (Fig. 7-14d), and the shape of the metalimnetic density profile varies in different regions of the basin correspondingly.

As the wind velocity decreases in a subsequent calm, the displaced layers slide over each other to redistribute into a new equilibrium. The oscillations so created may or may not be sufficient to create internal instability and waves. The resulting thermal profile retains much of its original form, but the mean metal-

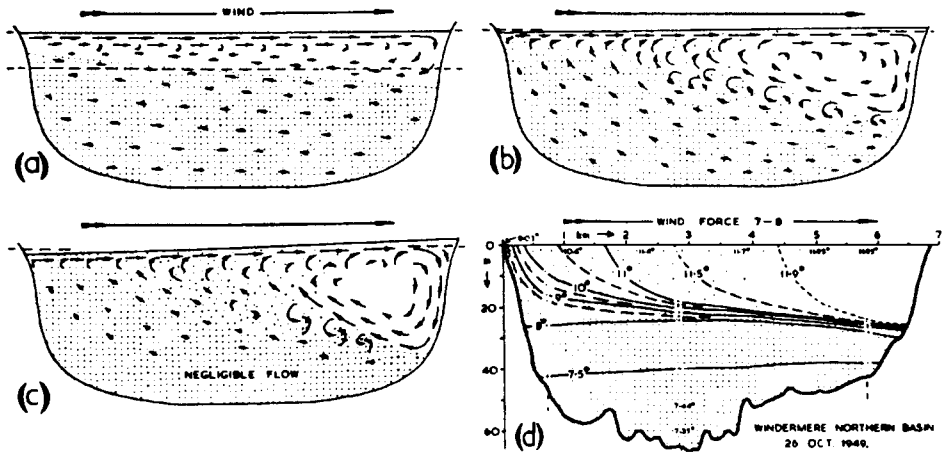

FIGURE 7-14 Stages of wind drift and circulation that led, after about 12 hours of strong wind, to the thermal situation depicted in (d), Lake Windermere, England, in late fall. Broken lines show equilibrium levels of water surface in (a), (b), and (c), and of the thermocline in (a). The initial layer below the thermocline is stippled; speed and direction of flow are roughly indicated by arrows. (From Mortimer, C. H.: *Verhandlungen Int. Ver. Limnol. 14*:81, 1961.)

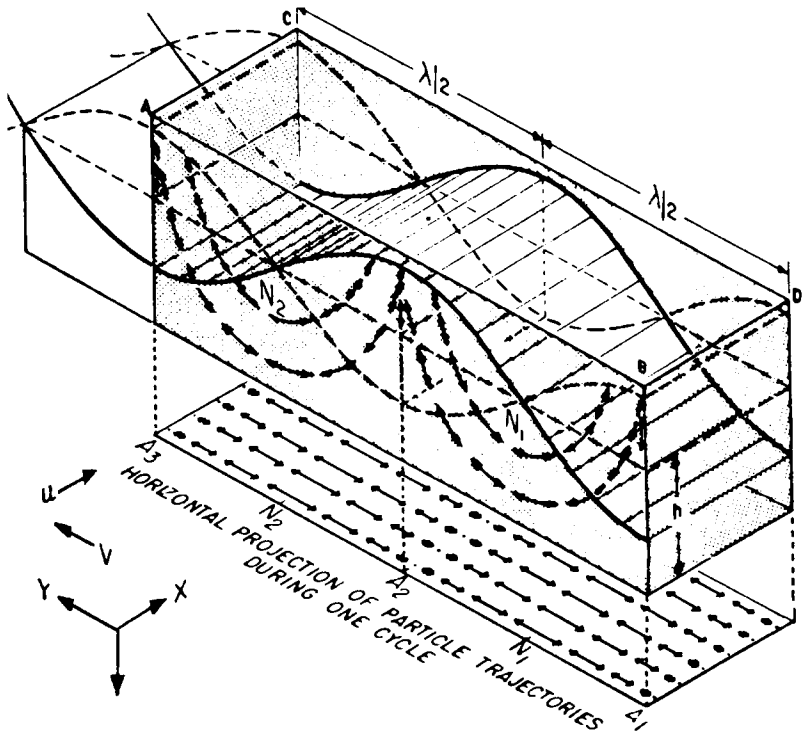

FIGURE 7-15 A long standing wave, without rotation, in a uniform depth (h) model. N: nodal line; A: antinodal line. (From Mortimer, C. H.: *Mitteilungen Int. Ver. Limnol. 20*:157, 1974.)

imnion depth has been pushed to a lower level, depending upon the amount of eddy conductivity. It is important to emphasize that this type of internal water motion is not continuous. Entrainment and metalimnetic erosion are progressive and forced by storms. Erosion can be counteracted by calm periods of heating, but in the fall, when cooling exceeds heating, the erosion continues in stepwise progression with storms. A strong inverse relationship occurs between the magnitude of entrainment and the mean density gradient across the metalimnion, and a strong positive correlation exists between entrainment and basin dimensions (Blanton, 1973).

Entrainment rates are obviously of major importance in the control of the extent of heat intrusion into the metalimnion and nutrient return from the hypolimnion to the epilimnion. A certain degree of compensatory motion occurs in the hypolimnion in a direction opposite that in the metalimnion. Turbulence in the hypolimnion is very much weaker than in the overlying layers but increases in large lakes where space is sufficient for the development of large-scale entrainment.

Surface and epilimnetic water movements and the effects of internal metalimnetic and hypolimnetic currents can be demonstrated very clearly in simple laboratory models of lakes (cf. Mortimer, 1951, 1954; Vallentyne, 1967; Stewart and Hollan, 1984; Stewart, 1988; Wetzel and Likens, 2000). Such models, stratified either thermally or with colored solutions of different chemical densities, are so effective in demonstrating entrainment, seiches, and internal waves (discussed in the next section) that their use is strongly urged in all introductory courses. For example, the upwelling areas of the epilimnion (Fig. 7-14) are seen clearly with tracer dyes in these models. Even more strikingly shown are the vortices of internal turbulence (curved arrows of Fig. 7-14b, c) which, with strong wind, become unstable and break as waves.

VI. WATER MOVEMENTS AFFECTING THE WHOLE LAKE

A. Long Standing Waves

Displacement of the water mass of the whole lake, as illustrated in Figure 7-14, gives rise to rhythmic motions, including both oscillations of the water surface and internal oscillations of isothermal depth. These motions take the form of very long waves, which have wavelengths of the same order as basin dimensions. These long waves are reflected at the basin boundaries and combine into standing wave patterns. The water surface or the thermocline oscillates up and down like

a seesaw about a line of no vertical motion (a ***node,*** Fig. 7-15), which coincides with regions of maximum to-and-fro horizontal motion of the water masses. Such standing waves, surface or internal, are referred to as ***seiches,*** a term originally referring to the periodic "drying" exposure of shallow littoral zones. Figure 7-15 illustrates a constant-depth model with two nodes, beneath which the horizontal to-and-fro sloshing of the whole water mass is at a maximum. Seiche motion, particularly the internal variety, has far-reaching effects on the vertical excursion of water masses, much larger than observed at the surface, and on their horizontal motions in the form of alternating currents.

The most common cause of seiches is the wind-induced tilting of the water surface and of the thermocline, as described in the previous section. As the wind slackens and the wind stress is removed, the tilted water surface and the tilted thermocline flow back toward equilibrium. Momentum, however, is great and equilibrium is overshot (Fig. 7-15), which results in a rocking motion about one or more nodal points. No vertical movement occurs at the nodal point, whereas maximum vertical movement takes place at the ends, or ***antinodes.*** The nodal point is in reality a nodal line in this nonrotating rectangular situation running the width of the basin.

1. Surface Seiches

The most conspicuous example of long standing waves is the ***surface seiche,*** which conforms to one or more resonant oscillatory frequencies (free modes) of a particular basin. The free mode of the surface seiche is a barotropic, or surface, wave, which affects the motion of the entire water mass of the lake, whether stratified or not, and attains its maximum amplitude at the surface. The surface seiche contrasts with the baroclinic or internal seiche, discussed further on, which is associated with the density gradient in stratified basins and attains its maximum amplitude at or near the thermocline.

The periodicity of vertical movement at the antinodes is a function of the length and depth of the basin. Particles at the node move back and forth horizontally with the same oscillatory rhythm as the vertical motion at the antinodes. The horizontal oscillation at the nodal line is large when the basin is very long in relation to depth, even though the vertical amplitude of the seiche is small at the antinodes. In a simple rectangular situation, analogous to many lakes in which the length greatly exceeds the mean depth, the period of the uninodal surface oscillation is approximated by

$$t = \frac{2l}{\sqrt{g\bar{z}}}$$

where

t = period (seconds)
l = length of the basin at the surface (cm)
$\bar{z}$ = mean depth of the basin (cm)
g = acceleration of gravity (980.7 cm sec^{-2})

Once surface seiches are set into motion, frictional and gravity damping of the oscillations begins and the water mass gradually returns to equilibrium. The magnitude of damping varies with water depth and the complexity of basin shape. In deep lakes of uncomplicated shapes, for example, weakly damped oscillations may persist with slowly diminishing amplitudes long after the impact of the storm that set them into motion has passed. A few examples in Table 7-2 illustrate the periods of the surface seiche modes, which correspond to values calculated from hydrodynamic theory. In most lakes, the period of the second mode (t_2) is more than half of that of the f)rst mode (t_1).

In long, narrow lakes, transverse seiches are found with periodicities and amplitudes much less than those of longitudinal seiches, which move the length of the longest axis—for example, the conspicuous transverse seiche of 132-min period in Lake Michigan (Mortimer, 1965). Where lake length differs little from breadth, complicated seiches can result when wind direction changes.

Uninodal seiches, as described earlier, are common even in very large lakes. If pressure is exerted on the surface in the center of a basin and released, or periodically exerted and released, binodal surface seiches are generated. Multinodal seiches, with up to 17 nodes, have been observed.

The amplitudes of surface seiches are generally rather small in comparison to internal seiches. For example, in Lake Mendota, the amplitude of a surface seiche was 1–2 mm with a periodicity of 25.8 min, although larger amplitudes of surface seiches (ca. 13 cm) of identical periodicity have been observed in this lake under unusual meteorological conditions (Stewart, 1993). In larger Lake Geneva, Switzerland, the maximum observed surface seiche amplitude was 1.87 m (t = 73 min), although the amplitude damped gradually in two weeks to less than 10 cm. In still larger lakes, such as Lake Erie, where amplitudes of surface seiches can exceed 2 m (t = 14 h), the effects can have both destructive and beneficial results, for example, the flushing of river delta and harbor areas. Surface seiches can occur under ice cover in similar ways.

True lunar tides, the result of gravitational attraction of water masses by the Moon and Sun, have been poorly investigated in lakes. However, it is certain that true tidal movement, even in the largest lakes, is small (a few millimeters). The maximum observed ampli-

tudes in Lake Baikal, Russia, are less than 15 mm, and in Lake Superior, 20 mm (Hutchinson, 1957). All observations are about one-half or less of the theoretical value. The elastic yielding of the Earth to the tide-generating forces presumably accounts for the difference (Mortimer, 1965).

2. Internal Seiches

We have seen that the amplitude of surface seiches is relatively small, even in large lakes, and that their periodicity increases with basin dimensions (Table 7-2). When the lake is stratified, water layers of differing density oscillate relative to one another. Most conspicuous is the successive oscillation of the metalimnion (Fig. 7-16), in which both the period and amplitude of this internal standing wave, or ***internal seiche,*** are much greater than those of the surface seiche (Fig. 7-17).

In a simple, rectangular, troughlike lake or lake model, without considering rotation, one observes the resultant horizontal flow depicted in Figure 7-16. Horizontal flow in this oversimplified stratified situation, which contains only an epilimnion and hypolimnion of differing densities, is maximal at the equilibrium point (node) of the oscillation; it ceases at the point of maximum vertical deflection. Because of the much greater water movement associated with internal seiches, resulting currents that rhythmically flow back and forth in opposing directions are the major deepwater movements of lakes. These currents lead to vertical and horizontal transport of heat and dissolved substances and significantly alter the distribution and productivity of phytoplankton and zooplankton, either directly or indirectly, by means of changes in thermal and chemical stratification (cf. Thomas, 1951).

In the simplest model, consisting of a rectangular basin with a homogeneous "epilimnion" of thickness z_e and density ρ_e and a "hypolimnion" of thickness z_h and density ρ_h, the period (t) of the first internal seiche mode is given by

$$t = \frac{2l}{\sqrt{\dfrac{g(\rho_h - \rho_e)}{\dfrac{\rho_h}{z_h} + \dfrac{\rho_e}{z_e}}}}$$

where

l = length of the basin (cm)
g = acceleration due to gravity (980.7 cm sec^{-2})

It should be noted that this equation is simply an extension of that for the periodicity of a surface seiche in which the density of the upper medium, air, was neglected as very small in comparison to that of water. Although more elaborate formulae have been devel-

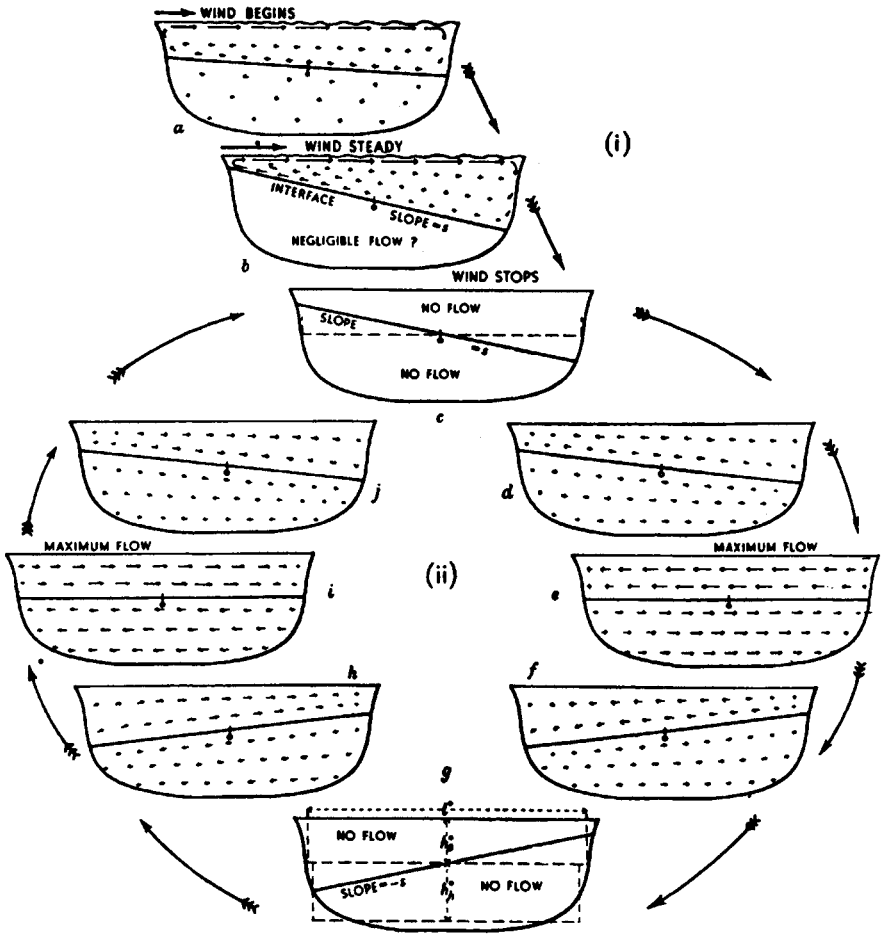

FIGURE 7-16 Movement caused by (*i*) wind stress and (*ii*) a subsequent internal seiche in a hypothetical two-layered lake, neglecting friction. Direction and velocity of flow are approximately indicated by arrows. o = nodal section. (From Mortimer, C. H.: *Proc. Royal Soc. London, Series B 236*:355, 1952.)

oped for continuous density gradients in stratified lakes, this formula yields reasonable estimates of internal seiche periodicity.

The detailed analyses of internal seiches by Mortimer (1952, 1953) permit a few generalizations (Table 7-3). Of all internal waves that are theoretically possible in stratified lakes, the one most commonly set in motion is a uninodal seiche on the metalimnetic boundary (thermocline). In basins of fairly regular shape ranging in length (Table 7-3) from 1.5 km (Lunzer Untersee) to 74 km (Lake Geneva), the uninodal internal seiche along the medial axis always appears as the main resonance. In basins possessing topographic features that may impede a uninodal internal seiche, such as constrictions, islands (Kodomari, 1984), or shallows, as in the southern end of Lake Windermere, the observed period is appreciably longer than the theoretical period. In nearshore areas where local land topography modifies wind fetch, horizontal turbulent mixing rates are altered and often reduced (cf. Lemmin, 1989; Imberger and Patterson, 1990). Multinodal internal seiches form a dominant type of resonance in very large lakes, especially when forced and damped by wind and other short-period disturbances.

Wind energy in the epilimnion dissipatas markedly with increasing depth. Even in large lakes, only about 5% of wind energy flux occurs below about 2 m of depth, but energy dissipation was about eight times higher in the shear zone of the thermocline than in the bottom boundary layer (Kocsis *et al.*, 1998). Energy dissipation increases markedly, particularly where turbulence increases as internal seiches encounter submersed sills in lakes with multidepression hypolimnia.

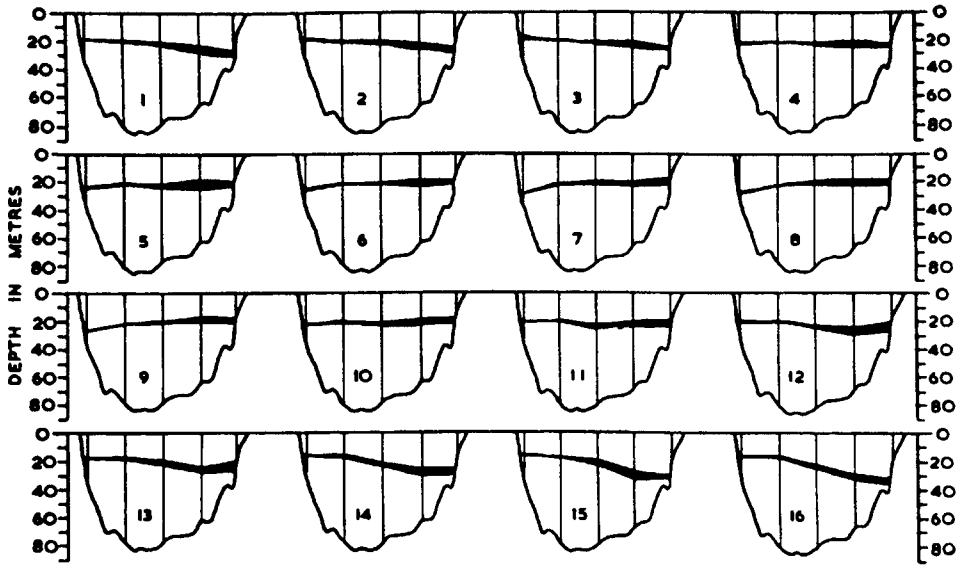

FIGURE 7-17 Successive hourly positions (0100 to 1600 hours, 9 August 1911) of the metalimnion bounded by the 9 and 11°C isotherms on a longitudinal section of Loch Earn, Scotland. (From Mortimer, C. H.: *Schweiz. Zeitschrift f. Hydrologie 15*:94, 1953, after Wedderburn.)

B. Geostrophic Effects on Seiches

Coordinates that appear fixed to an Earthbound observer are in fact rotating relative to coordinates in space (Mortimer, 1955). Inertia causes a moving water mass to attempt to follow a straight line in space, and the resultant track appears curved to the Earthbound observer. Such curvature is equivalent to a small force, the Coriolis force, directed at right angles to the line of motion. This force, which produces a deflection to the right in the Northern Hemisphere and to the left in the Southern Hemisphere, is zero at the equator and

[a] From data cited in Mortimer (1953), from various sources, Imboden *et al.* (1983), Hirata and Muraoka (1984), Horn *et al.* (1986), Chikita *et al.* (1993), and Stevens and Lawrence (1997).

maximum at the poles; it is a function of latitude and is proportional to the speed of the current. In sufficiently large lake basins in which frictional forces are small and constraints of the basin sides are negligible, a water mass, once set in motion, follows a circular track, owing to the effects of the Coriolis force. The time taken to complete an "inertial circle" of this type depends only on latitude. If the basin is stratified, this motion may be associated with internal waves, the period of which is referred to as the *period of the inertia oscillation.* For example, in Loch Ness, Scotland, at a latitude of 57°16′, when the velocity of a water mass was 10 cm sec^{-1}, the radius of the circle would be 810 m with a period of the inertia oscillation of 14.2 h (Mortimer, 1955).

Motion in the inertia circle will be encountered only in basins whose width is many times the radius of the inertial circle. In lakes whose width is of the same order or less than that radius, side constraints may be expected to modify the movement. If a lake is stratified and conforms to the simplified two-layered situation in Figure 7-16, then the flow depicted in that figure will be deflected by the Coriolis force onto the right-hand shore (Northern Hemisphere) in the manner indicated in Figure 7-18. This rotating counterpart of the nonrotating conditions of Figure 7-16 has been demonstrated very clearly in Loch Ness (Mortimer, 1955) and subsequently in Lake Michigan, Lac Léman (Bohle-Carbonell, 1986), and other large lakes. In addition to the morphometric parameters of the basin, important control factors include the timing of wind stresses, the time required to tilt the thermocline plane, and the period of the internal seiche.

The amplitude of internal seiches and the currents generated by them are of major importance. For example, in Lunzer Untersee, with a fetch of 1.6 km, an internal seiche with a period of 4 h had an antinodal amplitude of 1 m and generated horizontal currents of 1 cm sec^{-1} at the node. Similarly, currents of 1 cm sec^{-1} were found in Lake Mendota. In larger lakes, for example at the ends of the long basin of Loch Ness and in Lake Michigan, amplitudes of >10 m are common, with horizontal currents of >10 cm sec^{-1} near the nodes.

C. Internal Progressive Waves

The horizontal water movements associated with shearing flow at the metalimnetic interfaces can generate large ***internal progressive*** waves if the Richardson number falls below the 0.25 stability criterion (see Fig. 7-2). Internal waves on the thermocline are roughly an order of magnitude or more larger than waves found on the surface of large lakes. Examples include:

	Period	*Mean amplitude*
Lake Mendota (Bryson and Ragotzkie, 1960)	1.5–7.9 min	0.15 m (max 1.0 m)
Lake Michigan (Mortimer, McNaught, and Stewart, 1968)	3–5 min	1.03 m (max 6 m)
	7 min	0.6 m
	10 min	0.3 m

Internal progressive waves propagate and break much the same as surface waves do (Bryson and Ragotzkie, 1960). Again, these wave movements can be demonstrated clearly in simple lake models containing dyed strata of differing densities (thermally or by salinity) (cf. e.g., the photographs of Mortimer, 1952). The turbulence associated with internal waves is analogous to that at the surface but occurs on a much larger scale and is influential in the transfer of heat and other properties through the metalimnion. Since the large internal waves break at the sides of the basin, their effects, coupled with the vertical movement of the internal seiche on which they move, are particularly significant.

In very large lakes, large circulatory cells of water movement can develop over the troughs of internal progressive waves and extend through the epilimnion to the surface. The result is a series of large, widely spaced convergences and divergences that operate analogously to Langmuir currents in the aggregation and dispersion of suspensoids at the surface. Such aggregations are referred to as ***slicks*** and are much larger and more dispersed than the streaks of Langmuir currents. It is important to note, in addition, that the origins of these circulation patterns are quite different.

VII. OTHER WATER MOVEMENTS

A. Long Surface and Internal Waves

Up to this point, discussion has centered on long standing waves and short progressive waves. In the latter case, the wavelengths (λ), except at the beach, are less than water depth. Consequently, short waves are dispersive, that is, they travel at speeds proportional to $\lambda^{1/2}$ (Mortimer, 1963, 1974). In contrast, ***long waves,*** with a λ long in comparison to and much greater than the water depth, are nondispersive and travel at a speed independent of wavelength. A nonrotating model of such a wave, traveling in water of uniform depth, is illustrated in Figure 7-19. Its speed of progression is gz (in which g is the acceleration of gravity and z is the water depth), and the wave crests are horizontal. A combination of

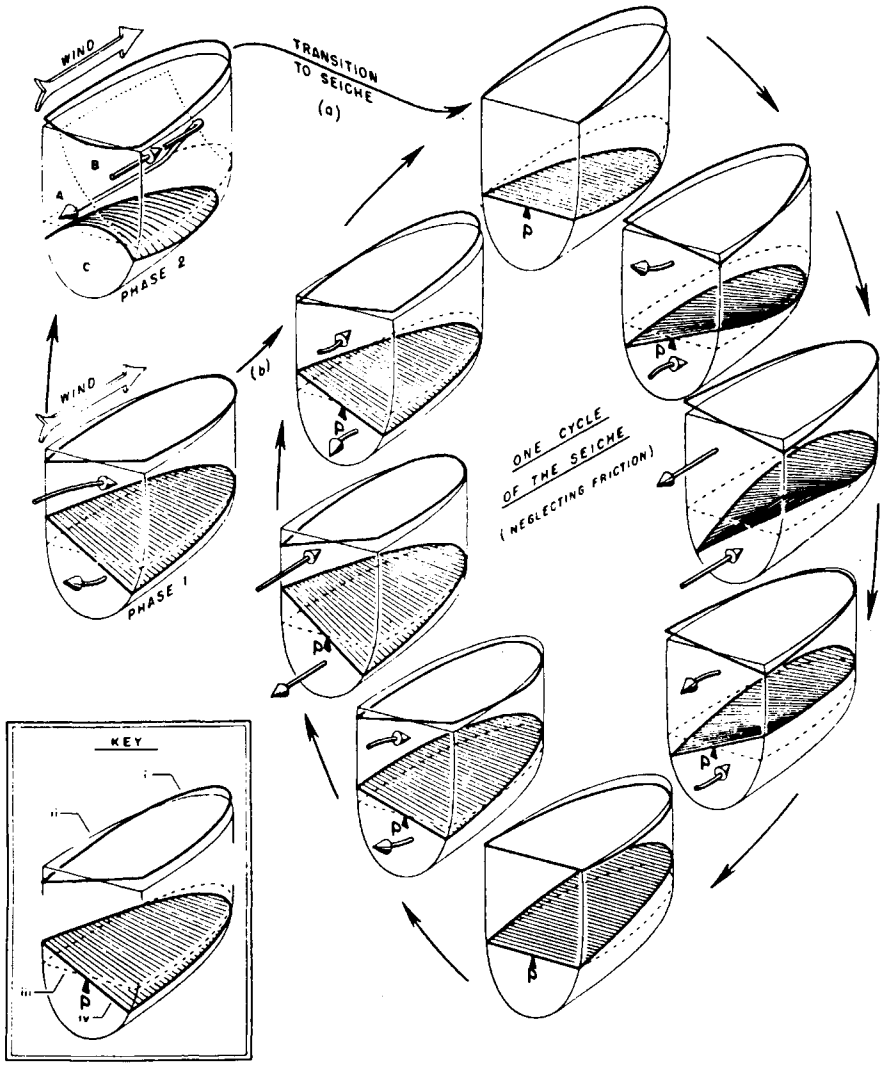

FIGURE 7-18 An internal seiche in a rotating two-layered lake model. In the inset key diagram, (*i*) the oscillating lake surface is shown by a heavy line (this is the surface signature of the internal seiche mode, that is, is not a surface seiche mode); (*ii*) the equilibrium lake surface position is shown by a thin line; (*iii*) the equilibrium interface position is shown by a broken line; and (*iv*) the oscillating interface is shown by a shaded surface.

The two diagrams at upper left illustrate a hypothetical distribution of the layers during the application of the wind stress, which set the seiche in motion. B and A respectively indicate the wind-driven surface and return currents in the upper layer, both deflected to the right by the Coriolis force. C indicates the lower layer, the greater part of which has become displaced out of the half-basin shown.

Eight phases of one oscillation cycle of the first mode internal seiche are shown. Directions of flow in the upper and lower layers are shown by heavy arrows. The nodal point, *P*, the only point of zero elevation change, takes the place of the nodal line in the nonrotating model. Around this point, the internal seiche and its surface (out-of-phase) counterpart rotate counterclockwise. (From Mortimer C. H.: *Mitteilungen Int. Ver. Limnol. 20*:169, 1974.)

two such progressive waves, of equal amplitude and traveling in opposite directions, yields a model of the long waves (seiches) described earlier (Fig. 7-15).

The nonrotating models represented by Figures 7-15 and 7-19 provide simplified descriptions of events in small lakes. When basin dimensions exceed about 15 km, the geostrophic effects of the Earth's rotation must be introduced, and two separate model components emerge to provide the simplest interpretations of long surface and internal waves (Mortimer, 1963,

1974, 1975). Both model components, applicable to channels and basins of constant depth, were developed many years ago in connection with tidal theory and are named after the mathematicians concerned. The first component, associated with a shore line, is illustrated in Figure 7-20. In the ***Kelvin wave*** model, the rightward deflection by the Earth's rotation (Coriolis force) is everywhere exactly balanced by the components of gravity along a wave crest that slopes downward from right to left in the direction of progress (Northern Hemisphere), so that the right hand shore line coincides with maximum wave amplitude. The condition of exact cancellation of the Coriolis force can only be met by an exponential decay of wave amplitude and wave-associated currents along a line normal (perpendicular) to the shore. The result is that the currents are parallel to the shore, which satisfies the boundary condition of zero onshore current component along the shore.

As progressive Kelvin waves travel in opposite directions along a lake basin channel, the long undulations induce currents along the shores (Fig. 7-21). These wave-induced currents are parallel to the direction of the wave progression and the shores of the basin sides. As portions of the water mass rise, others are depressed in a geostrophic balance (Mortimer, 1975). The balance keeps the currents parallel to the shore, with no cross-channel (basin) current at the basin sides. It should be noted that when rotation from geostrophic effects becomes significant in lakes of medium-to-large width, the nodal line in the nonrotating models (comparable to those of small lakes) is replaced by a single midchannel nodal point (*P* in Fig. 7-21).

In very large lakes, such as the Laurentian Great Lakes, the basin width is sufficiently large to permit the long waves to travel without the interference of the shore basin boundaries. These ***Poincaré waves*** are also influenced by Coriolis geostrophic effects, but in this case the wave amplitude does not decrease exponentially away from the shore as in Kelvin waves. That is, Poincaré waves occur in the open water of large lakes, and their reflection generates Kelvin waves

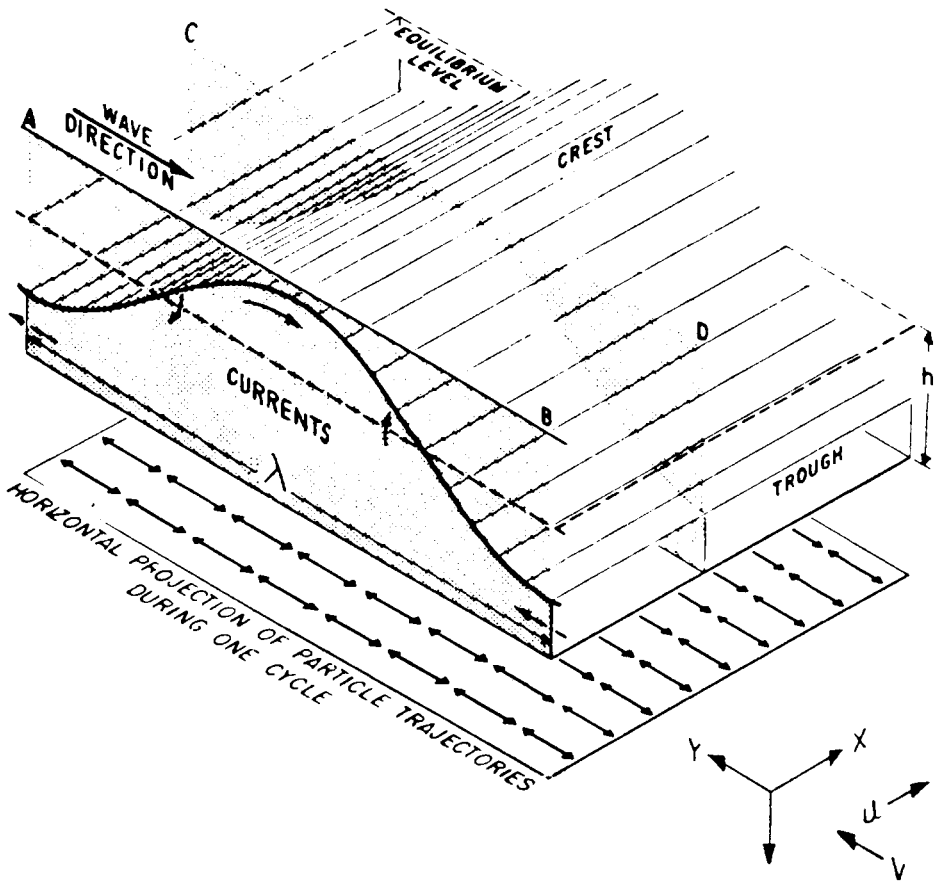

FIGURE 7-19 A long progressive wave, without rotation, in a uniform depth (*h*) model basin. (From Mortimer, C. H.: *Mitteilungen Int. Ver. Limnol. 20*:155, 1974.)

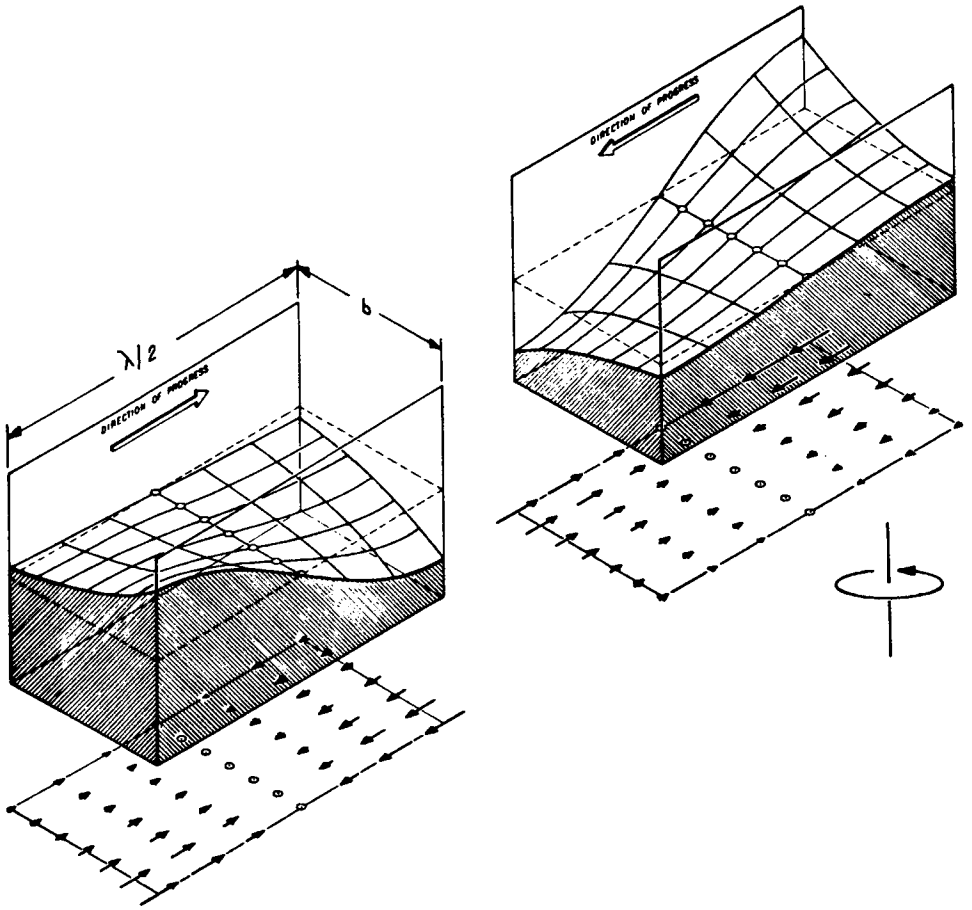

FIGURE 7-20 Long Kelvin waves traveling in opposing directions in straight, rotating (counterclockwise) channels. Half-wavelength portions are shown. Horizontal components of the wave currents are projected as vectors onto the plane below the channels. (From Mortimer, C. H.: *Verhandlungen Int. Ver. Limnol. 19*:65, 1975.)

when encountering shore boundaries. Poincaré waves undulate in a standing wave pattern both across and along the model channel or basin, yielding a cellular pattern of alternating rising and falling hills and valleys with a corresponding cellular pattern of wave-associated currents (Fig. 7-22). Their direction rotates clockwise once every wave cycle. In very large basins—for example, Lake Michigan—the period of observed internal Poincaré waves, equivalent to the Figure 7-22 model, is a little less than the period of motion of the inertial circle. This period depends on latitude and is 17.5 h for the central part of Lake Michigan.

The important difference between the Kelvin wave and the Poincaré wave components is that the Poincaré wave extends with undiminished amplitude right across the channel or basin, whereas the Kelvin wave decreases in amplitude away from the shore and is thereby "trapped" or constrained to travel along the shore. In actual basins we must speak of Kelvin-type and Poincaré-type waves, although the mathematical models illustrated in Figures 7-20, 7-21, and 7-22 (in which the wave surfaces can be visualized either as a water surface or a metalimnetic interface surface) are valid only for constant-depth conditions not met in natural lakes. Nevertheless, even though they are oversimplified, the models do provide useful interpretations of what is observed in large basins (Mortimer, 1963, 1974, 1975).

When the Kelvin wave model is applied to typical conditions of summer stratification in a lake of "medium" or "large" width, for example, Lac Léman and Lake Michigan, with respective widths of the order of 10 and 100 inertial circle radii, Table 7-4 predicts that an internal Kelvin wave traveling along one shore will have decreased to about one-sixth of its initial amplitude on the other shore in Lac Léman and to a negligible amplitude on the opposite shore of Lake Michigan. In the open water of the latter lake, therefore, the Poincaré component should theoretically

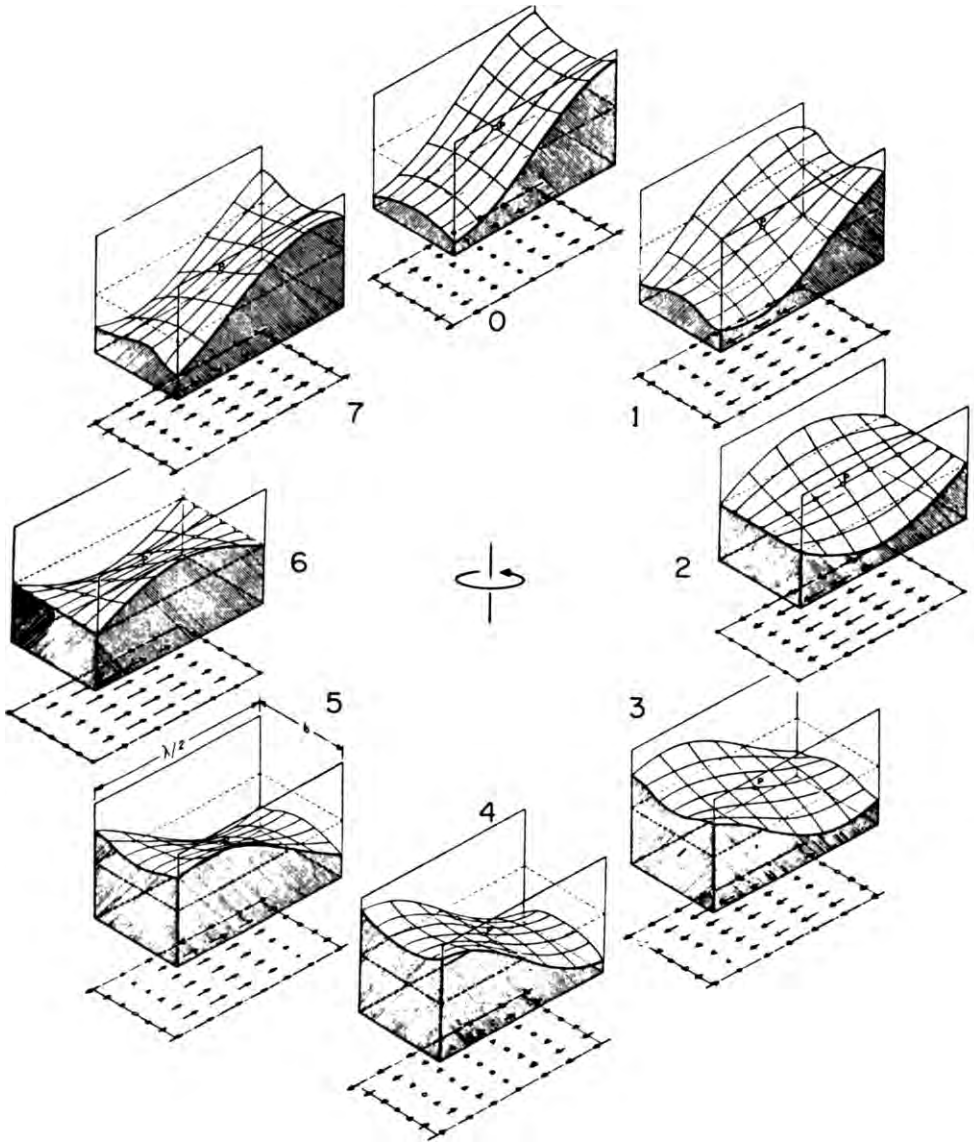

FIGURE 7-21 Successive phases (1/8 cycle) of the long standing wave resulting from combining the two Kelvin waves of Figure 7-20 traveling in opposite directions in a straight, rotating lake basin channel (width of 7 km) of rectangular cross section. The wave topography is at the metalimnion interface, with the upper layer omitted. Horizontal wave current components are projected as vectors onto the plane below the channel. The point of zero elevation change is shown at *P*, around which the wave rotates counterclockwise. (From Mortimer, C. H.: *Verhandlungen Int. Ver. Limnol. 19*:67, 1975.)

dominate the wave pattern, with upwellings and Kelvin-type wave responses restricted to nearshore bands of some 20 km width. This pattern in fact has been observed in Lake Michigan (Mortimer, 1974). One must visualize a transition in the wave-induced current patterns from the cellular, clockwise-rotating, near-inertial periodicity of the offshore Poincaré-type waves in very large lakes and the shore-parallel Kelvin-type currents that increase in amplitude as the shore is approached. This transition is sketched in Figure 7-23. In smaller basins of Lac Léman size, on the other hand, one can predict that the internal, Kelvin-type, long-standing-wave response will dominate. Metalimnetic oscillations with a counterclockwise rotation of the internal wave motion in Lac Léman can be interpreted as an internal Kelvin-type wave progressing counterclockwise around the basin in the manner illustrated in Figure 7-21, with a periodicity of a little over three days (Mortimer, 1963, 1974). As this usually coincides with the periodicity of storm passages, the oscillatory response of Lac Léman is strong. In Lake Michigan, by contrast, the internal Kelvin wave requires about four

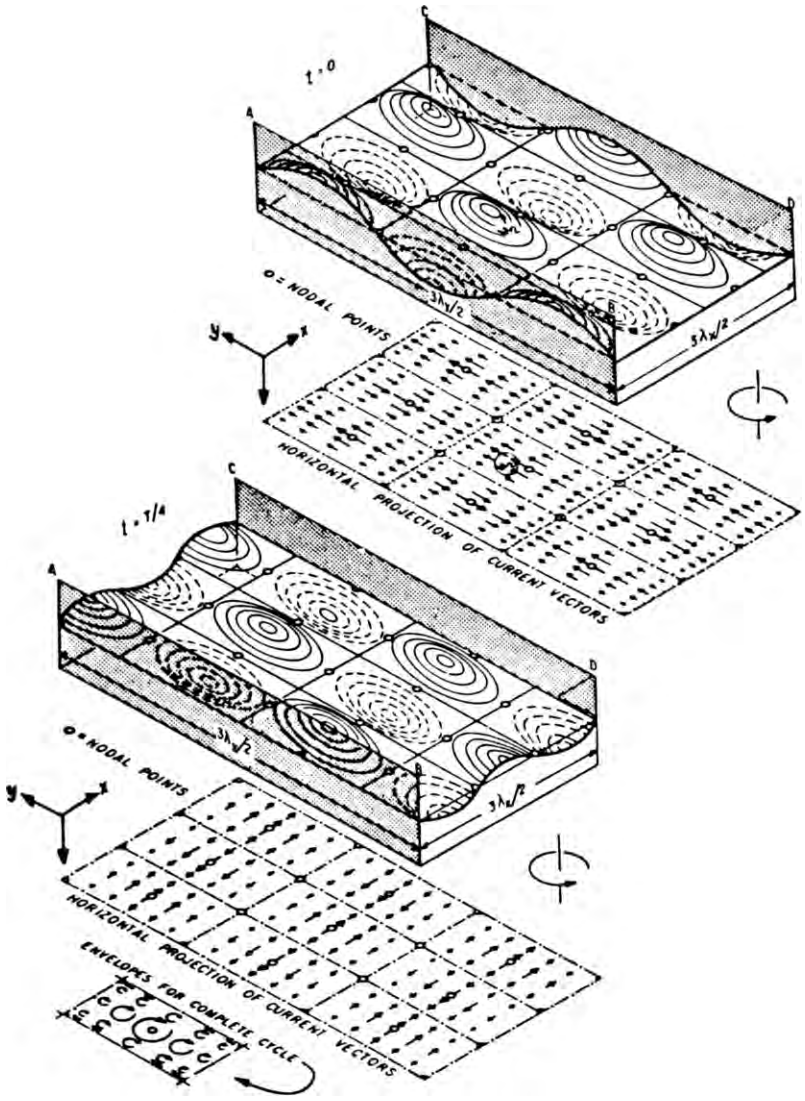

FIGURE 7-22 A standing Poincaré wave in which two phases separated by 1/4 cycle of the oscillation are shown for the cross-channel trinodal case, with a ratio of long-channel to cross-channel wavelengths of 2:1. Current vectors rotate clockwise and attain their maximum values in the center of the cells. The two phases of the figure show the oscillations separated by a quarter period in which, in addition to the clockwise rotation of the vectors, the current directions of one cell remain approximately parallel and opposite in direction to those in neighboring cells. (From Mortimer, C. H.: *Mitteilungen Int. Ver. Limnol. 20*:17, 1974.)

weeks to complete the circuit of the shores. This cycle is rarely completed before a new storm disturbs its progress.

VIII. CIRCULATION CAUSED BY THERMAL BARS

Another feature of large lakes is a steady circulation set in motion along the shore as a result of density gradients arising when shallow, nearshore waters heat more rapidly than the open water mass (Fig. 7-24). In the illustrated Lake Ontario example, the shallow waters develop stratification, while the main water mass remains in its isothermal (usually below 4°C) mixed winter condition. A narrow transition zone, called a ***thermal bar,*** consisting of a nearly vertical 4°C isotherm, develops between the open water mass and the littoral stratified water. Thermal density differences drive downward flowing currents along the vertical thermal bar into both the lower portions of the inshore and offshore water masses. The density-driven circulation is dependent on the bottom topography,

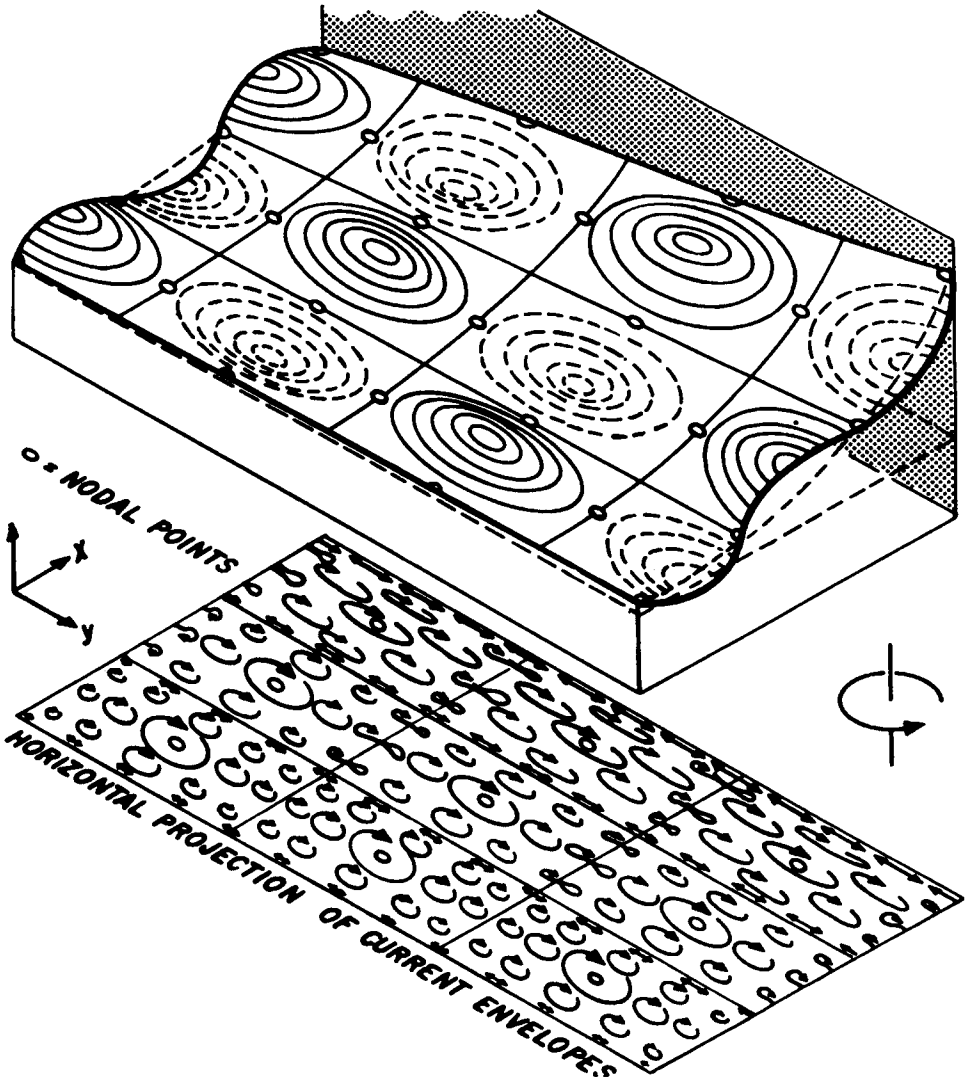

FIGURE 7-23 Combination of a multinodal standing Poincaré wave in a very wide channel model, of which only one side is shown, and a portion of a Kelvin wave traveling along the side. The elevation and current amplitudes associated with the Kelvin wave are at a maximum at the channel side (elevation amplitude, a), and decrease exponentially away from the side in the x-direction, falling to $1/e$ of the onshore value at a distance d_e from the side. The figure illustrates the transition, in current trajectories, from a nearshore pattern dominated by the Kelvin wave to a pattern dominated by the Poincaré wave at distances $> 2d_e$ offshore. (From Mortimer, C. H.: *Large-scale Oscillatory Motions and Seasonal Temperature Changes in Lake Michigan and Lake Ontario*. Special Report no. 12, Center for Great Lakes Studies, University of Wisconsin-Milwaukee, 1971.)

with a more pronounced circulation and considerable descending motions inside the thermal bar zone of convergence in lakes with steep slopes (Malm, 1995). The downward density-mediated currents outside the thermal bar can penetrate to very deep strata or bottom layers and cause appreciable convective mixing (e.g., Lake Baikal; Shimaraev *et al.*, 1993). The Earth's rotation combines with the density gradient to induce a counterclockwise coastal current inside the bar.

The thermal bar moves progressively further from shore as the heat influx continues to warm the larger open water mass. Little mixing occurs between inshore and offshore waters, and a significant portion of inshore water originates from runoff (Spain *et al.*, 1976). Finally, thermal differences between the inshore and offshore regions lessen to the point where stratification of the whole basin occurs (Rodgers, 1966). This mechanism results in temporary isolation of inshore waters

TABLE 7-4 Parameters of Single Kelvin Waves in Lac Léman and Lake Michigan Representative of Nearshore Conditions in Late Summer[a]

	Lac Léman		*Lake Michigan*	
Lake conditions	*Surface*	*Internal*	*Surface*	*Internal*
Inertial period (t_p) in hr	16.6		17.4	
Thickness of upper layer (m)		15.0		15.0
Thickness of lower layer (m)		85.0		60.0
Mean °C of upper layer		19°		20°
Mean °C of lower layer		6°		6°
Density difference $\times 10^{-3}$		1.54		1.74
Mean width (km)	7.9	7.4	102	100
Wave velocity (km hr^{-1})	113	1.59	104	1.60
Offshore distance intervals over which wave amplitude is successively halved	(207)	2.9	(190)	3.1
Percentage of wave amplitude still remaining at opposite shore	98%	17%	70%	$<1 \times 10^{-7}$%

[a] After data cited in Mortimer (1963).

where, when augmented by surface runoff and river discharge, chemical enrichment can occur. As a consequence, increased productivity can occur much earlier in the spring in the inshore regions than in the open water.

Thermal bars commonly occur to some extent in all lakes. In small lakes, the phenomenon is transitory, often lasting only a few days. In large lakes, however, the transition to stratification of the whole basin may take weeks, as seen in the example from Lake Ontario (see Fig. 7-24).

IX. CURRENTS GENERATED BY RIVER INFLUENTS

When a river enters a lake or reservoir, the incoming water will flow into a density layer in the lake that is most similar to its own density; this process is governed by temperature, dissolved material, and suspensoids. Depending on the density differences between the inflowing water and the lake water, three basic types of inflow water movements can result (Fig. 7-25). ***Overflow*** occurs when the inflow water density is less than the lake water density ($\rho_{in} < \rho$) and ***underflow*** results when the inflow water density is greater than the lake water density ($\rho_{in} > \rho$). If the density of inflow is greater than that of the epilimnion but less than that of the metalimnion or hypolimnion, flow enters in a plume at an intermediate depth, and ***interflow*** occurs ($\rho_1 < \rho_{in} < \rho_2$).

A certain amount of turbulent entrainment and mixing nearly always accompanies the flow of water into a lake, given adequate influx velocities. In many lakes, and especially in reservoirs, inflows enter through elongated bays, which tend to inhibit lateral mixing. As the water enters the basin, the depth of inflow increases and the velocity is gradually reduced until a critical section depth (d_0) is reached, characterized the densimetric Froude number (F_0) (Wunderlich, 1971), where mean velocity is divided by reduced gravity:

$$F_0 = \frac{(v/A_0)}{\sqrt{g(\Delta\rho/\rho)d_0}}$$

where

v = flow rate
A_0 = cross-sectional area at the critical section
ρ = density of inflow
$\Delta\rho$ = density difference between the incoming and receiving water

Overflow or underflow initiates at this critical section, with a reduction of flow velocity that may be accompanied by deposition of suspended materials. A critical analysis of density differences and distribution of inflowing water in Lake Biwa, Japan, showed that the inflowing river waters do not mix readily if density differences are reasonably large and flow occurs instead in complex overflow and interflow patterns (Morikawa *et al.*, 1959). Further detailed analyses of these mixing characteristics are given in Imberger and Hamlin (1982) and Imberger and Patterson (1990).

Variations in density differences between incoming water and those of the recipient water body are so great that generalizations are very difficult to make. Discharge also varies widely seasonally, not only in volume but in the accompanying load of dissolved and suspended materials. For example, in alpine situations, the density of river water is greater (cold, high dis-

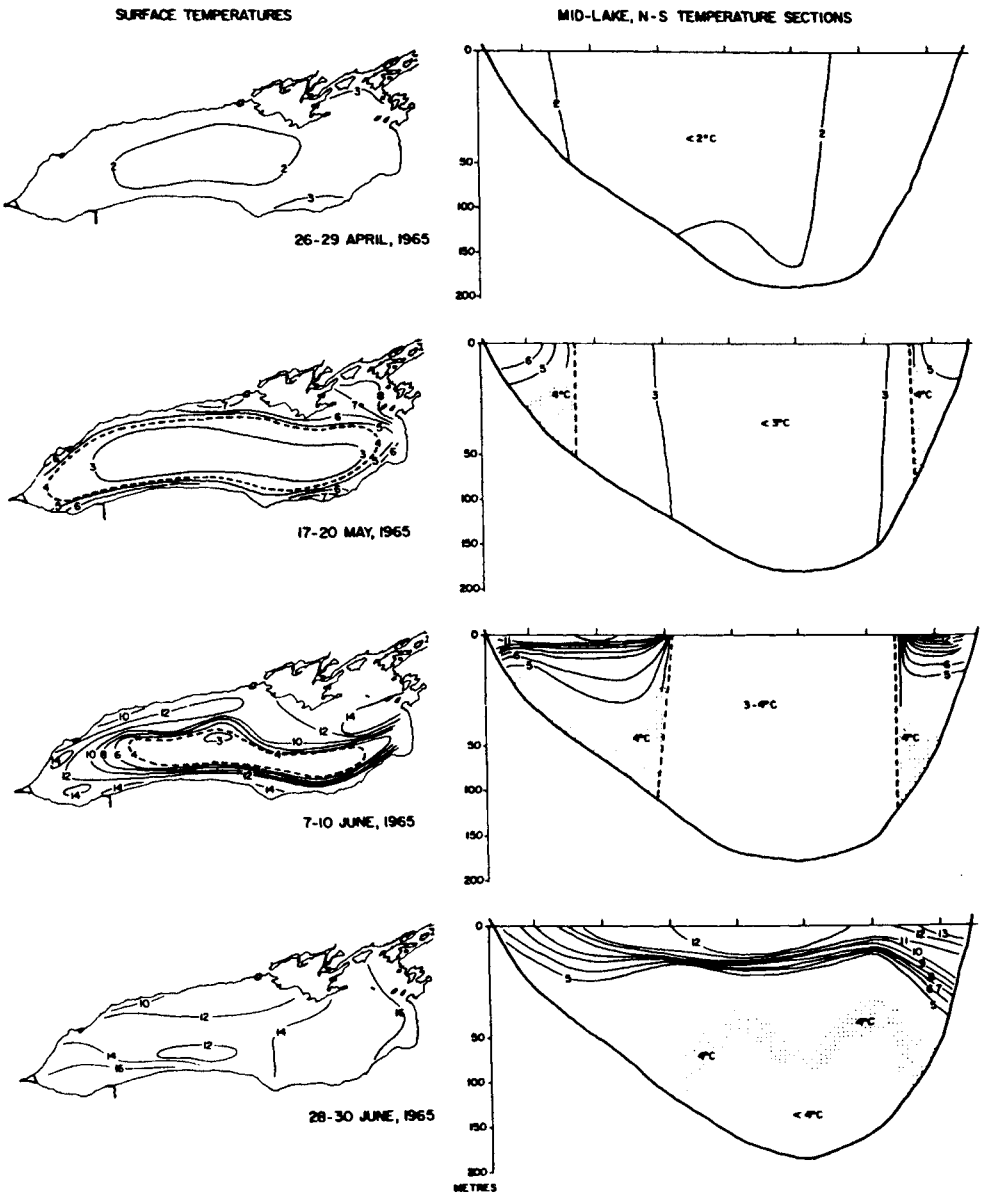

FIGURE 7-24 Formation and progress of a thermal bar in Lake Ontario from winter to full summer stratification. (From Rodgers, G. K.: *Publications Gt. Lakes Res. Div. Univ. Mich. 15*:372, 1966.)

solved and particulate load) than the recipient water and underflow is common, particularly if glacial erosion at the head of the river contributes to the suspended load. During the summer, although alpine river inflow water is still cold, its density is reduced by high-volume dilution with snow and icemelt runoff. In the summer, then, alpine rivers interflow into the metalimnion. This situation has been documented frequently (e.g., Chikita *et al.*, 1985). A particularly striking case is seen in the Bodensee, Germany, where light penetration is abruptly attenuated in the metalimnion over large areas of the lake by the intrusion of river water with a high suspended load (Lehn, 1965).

Geothermal fluids that are abnormally hot and contain high concentrations of dissolved salts create complex density-mediated currents. The hot (59°C) inflows to Lake Aratiatia, New Zealand, initially float on the surface waters (Johnstone *et al.*, 1988). As the influent water cools to a temperature ca. 10°C above that of the lake water, it sinks and forms density currents that rapidly mix with the lake water. Cooler saline or nutrient-rich inflows in other lakes can lead to under-

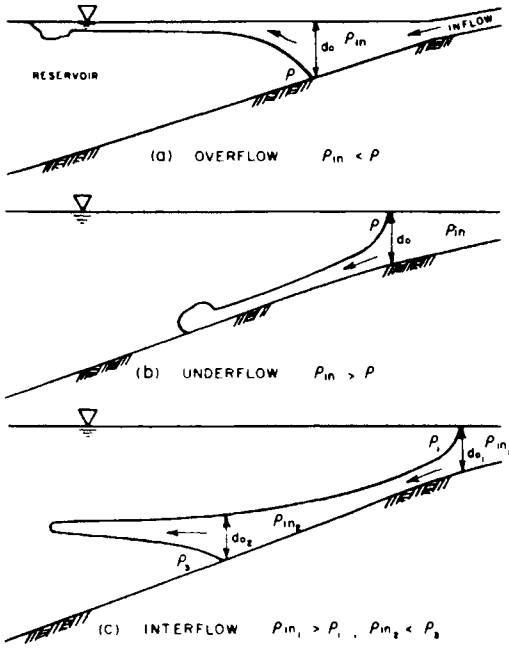

FIGURE 7-25 Types of inflow into lakes and reservoirs. (From Wunderlich, W. O.: The Dynamics of Density-Stratified Reservoirs. *In* Hall, G. E. (ed.), *Reservoir Fisheries and Limnology,* Washington, D.C., American Fisheries Society, 1971.)

flows, disruption of stratification, and alterations of chemical cycling with enhancement of interdependent biological productivity (see Vincent *et al.,* 1991; Gibbs, 1992).

The extent of intrusion and current generation in the receiving lake is also a function of the discharge volume of the river in relation to the volume of the lake. The theoretical retention time of a lake or reservoir, based on the relation of the total influent-outflow to the total volume of the lake, is realized only approximately in most lakes. Retention time varies with the dimensions and shape of the basin, seasonal rates of inflow, and stratification characteristics (Kajosaari, 1966; Englert and Stewart, 1983; Carmack *et al.,* 1986). At high discharge rates, overflow and interflow of rivers may channel across or through the water mass of the stratified basin, whereas at lower discharge rates, river water may penetrate more into the main water mass and may be mixed through more normal circulatory mechanisms. In larger lakes, geostrophic deflection of the incoming water intrusions, surface or interflows, is observed consistently.

X. CURRENTS UNDER ICE COVER

It is clear that the water of a lake under ice cover moves by currents, even in lakes of closed basins with no appreciable inflow and outflow. Much of the evidence for the existence of weak under-ice currents stems from careful direct measurements in which radioactive sodium (^{24}Na) was released at various points beneath the ice and its short-term distribution was measured for several days. Slow horizontal currents, with velocities too low to be measured by mechanical current meters, have been observed in a small ice-covered lake in Wisconsin (Likens and Hasler, 1962) and in a large, permanently ice-covered lake in Antarctica (Ragotzkie and Likens, 1964). Similarly, radioactive tracers have been used to measure slow horizontal movements in a small lake in Nova Scotia (McCarter *et al.,* 1952), in a meromictic lake in Washington (Hutchinson, 1957), and in the monimolimnion of a small meromictic lake in Wisconsin (Likens and Hasler, 1960).

Horizontal displacements of radiosodium were found to be generally asymmetrical in a small ice-covered, closed basin bog lake (Fig. 7-26). Horizontal velocities of at least 10 m day^{-1} (42 cm h^{-1}) were observed near the bottom at the deepest point of the basin, and maximum velocities of 15–20 m day^{-1}. Relatively constant horizontal eddy diffusivities indicated small mixing eddy lengths of < 1.6 m (Colman and Armstrong, 1983). The vertical component of this motion was between 1 and 3 orders of magnitude less than the horizontal component (Table 7-5). In further experiments, Likens and Ragotzkie (1966) also found a definite rotary movement of horizontal currents, which was cyclonic near the center of the lake and anticyclonic near the perimeter (Fig. 7-27).

These detailed studies and modeling analyses of the Tub Lake data (Rahm, 1983), as well as evidence from a larger lake in Swedish Lapland (Mortimer and Mackereth, 1958), several small Swedish lakes (Bengtsson, 1996), and small arctic lakes (Welch and Bergmann, 1985), all indicate that under-ice water movements are largely the result of convective cells of density currents generated primarily by relatively large quantities of heat flowing from the sediments. The thickness of the bottom current layer is small (ca. 1 dm), however, and the currents low, in the range of 0.1–1 mm s^{-1} (Malm, 1998, 1999). If the temperature of the water into which the heat flows is greater than 4°C, that flow will generate ascending buoyant currents. If, however, the lake has cooled to well below 4°C before the ice cover is established, the heat flux will increase the density of the water in contact with the sediments and cause it to flow as a density current down the sloping sides of the basin into the nearest depression. Chemical exchanges also occur between sediment and water; for example, oxygen is taken up by the sediments and associated microbes. If the lake basin

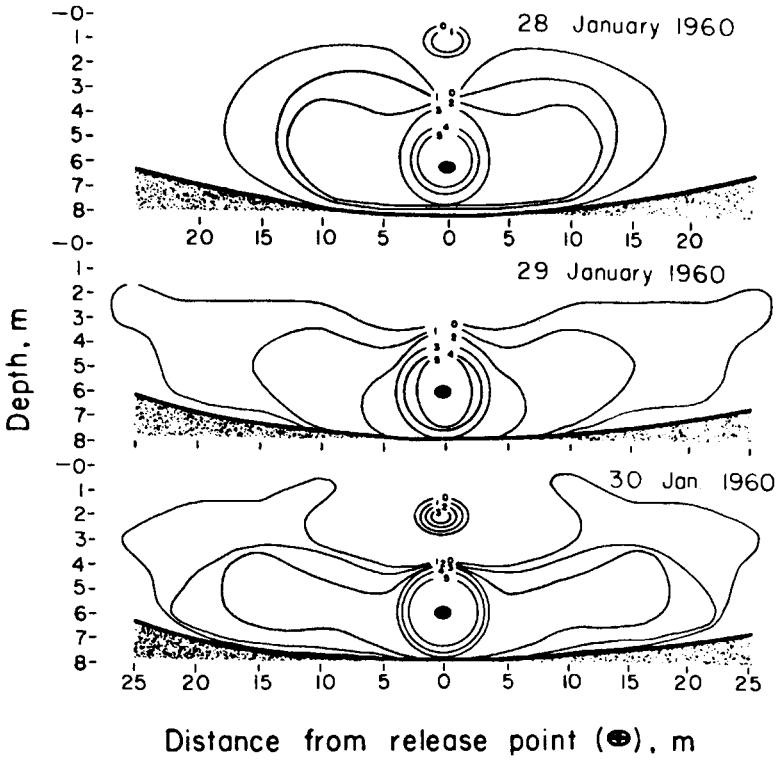

FIGURE 7-26 Diagram of the horizontal and vertical dispersal of ^{24}Na in Tub Lake, Wisconsin, under ice cover 24, 48, and 72 h after release. Integers indicate the logarithmic value of the radioactivity concentration in counts of min^{-1}. (From Likens, G. E., and Ragotzkie, R. A.: J. *Geophys. Res.* 70:2333, 1965. contains more than one topographically separated depression, the density flows may produce significantly different temperatures and chemical compositions in the bottom waters of these depressions (Mortimer and Mackereth, 1958).

Most of the heat of the sediments is gained during the previous summer period and fall turnover (cf. Chap. 5) and is dissipated slowly. Birge *et al.* (1927) found that about 650 cal cm^{-2} were conducted from the sediment to the water of Lake Mendota during the period of ice

[b] Negative values of w indicate downward motion and positive values indicate upward movement.

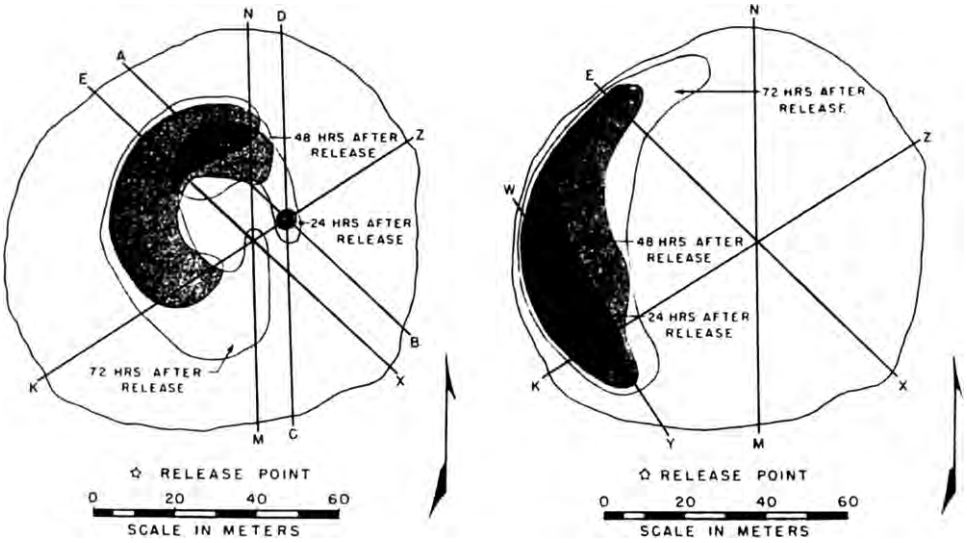

FIGURE 7-27 Maximum horizontal displacement of ^{24}Na following its release at a depth of 5 m (right) and of ^{131}I following its release at a depth of 3 m (left) in Tub Lake, Wisconsin, January, 1962. (From Likens, G. E., and Ragotzkie, R. A.: *Verhandlungen Int. Ver. Limnol. 16*:126, 1966.)

cover (110 days), a heat gain of 5.9 cal cm^{-2} day^{-1}. Thermal gains of 3–4 cal cm^{-2} day^{-1} are common in small temperate lakes during the winter. Tub Lake gained about 3 cal cm^{-2} day^{-1}, and larger Lake Torneträsk, Swedish Lapland, about 1 cal cm^{-2} day^{-1}. The sediment heat source is adequate to explain the observed currents. Biological oxidation during respiration in the sediments represents a caloric equivalent of about 0.04°C cm^{-3}, which is totally inadequate as a heat source.

Geothermal heat flow (approximately 1.23×10^{-6} cal cm^{-2} sec^{-1}) from the interior of the Earth represents only about 0.1 cal cm^{-2} day^{-1} through the sediments of the lake. Ground water that is relatively warm and circulating near the basin probably transmits some heat through the sediments to the lake water. In Wisconsin, this potential heat source was estimated to be about 1 cal cm^{-2} day^{-1}, a significant source of thermal conductivity in addition to that from heat storage from the previous summer. Thus, a major operator of thermally induced convection currents under winter conditions appears to be sediment heat that accumulated during summer.

In addition, oscillating currents can be generated in ice-covered lakes with little river inflow and outflow in proportion to total lake volume. Reciprocating water movements result from such surface seiches and have periodicities that are predicted theoretically from morphometric characteristics of the lake basins (Bengtsson, 1986; Malm *et al.*, 1998; Malm, 1999). The seiche-induced currents are geostrophic, and their magnitudes in Swedish and Russian lakes were in the range of < 1–4 mm s^{-1}.

An excess of solar radiation at the lake surface over heat losses is appreciable only at the surface and in late spring; it is absorbed primarily in melting ice and snow. Under certain conditions, some solar radiation penetrates ice cover and warms the water below the ice, which then moves downward in convection currents (0.5–2 mm s^{-1}) because of its higher density (Matthews and Heaney, 1987; Bengtsson and Svensson, 1996). Requirements include high solar radiation inputs, high extinction coefficients, as in dystrophic lakes, to absorb the entering energy, and low water-temperature-induced density differences that form the inverse stratification. Mixing under ice cover can also be induced by turbulent shear flows from river discharges or meltwater (Stigebrant, 1978; Bergmann and Welch, 1985; Kenney, 1991). In large lakes, wind-induced movements of the ice sheet can cause displacements and mixing beneath the ice (Stewart, 1973b).

XI. HYDRODYNAMICS AMONG AQUATIC ECOSYSTEMS

The water of streams and rivers usually moves continuously in a unidirectional flow, except where influenced by tides. Flows are highly irregular seasonally and with precipitation events, as well as with variations in runoff and groundwater inputs (Table 7-6). Current velocities are controlled by the channel morphology and elevational gradient, water volume, type of substratum, and obstructions such as woody debris

TABLE 7-6 Comparative Hydrodynamic Characteristics among River, Reservoir, and Natural Lake Ecosystems[a]

	Rivers	*Reservoirs*	*Natural lakes*
Water-level fluctuations	Large, rapid, irregular; flooding common	Large, irregular	Small, stable
Inflow	Overland and groundwater runoff; highly irregular and seasonal, less so with large groundwater inflows	Most runoff to reservoir via river tributaries (high stream orders); penetration into stratified strata complex (over- , inter- , and underflows); often flow is directed along old riverbed valley	Runoff to lake via tributaries and (often low stream orders) diffuse sources; penetration into stratified waters small and dispersive
Outflow (withdrawal)	Discharge highly irregular with inflows and precipitation event frequency	Highly irregular with water use; withdrawals from surface layers or from hypolimnion	Relatively stable; usually largely surface water via surface outflow or shallow ground water
Flushing rates	Rapid, unidirectional, horizontal	Short, variable (days to several weeks); increase with surface withdrawal; disruption of stratification with hypolimnetic withdrawal; three-dimensional	Long, relatively constant (one to many years); three-dimensional

[a] Assembled from many sources and the syntheses on rivers of Ryder and Pesendorfer (1980) and on reservoirs and lakes of Wetzel (1990b).

and ice. In reservoirs, inflows tend to follow the original river channel (thalweg) and distribute into the water strata on the basis of densities derived from differences in temperature and dissolved salts (Table 7-6). In natural lakes, inflows from surface or groundwater sources tend to be dispersive and small in comparison to the total volume.

Water-level fluctuations in river ecosystems are large, rapid, and irregular, and flooding is common. In reservoirs, water levels are influenced by both the dynamics of river inflows as well as the management of withdrawals from the surface or hypolimnetic strata (Table 7-6; Wetzel, 1990b; Tundisi and Straškraba, 1994). Water-level fluctuations in natural lakes tend to be small and relatively stable. These water-level differences between reservoirs and natural lakes are to a large extent related to the marked differences in the ratios of drainage basin area to lake area, which is very much larger in reservoir ecosystems (Chap. 3).

As a result of these differences in flow and water-level fluctuations, flushing rates in natural lakes are long (one to several years) and relatively constant. Flushing rates of reservoirs are short and variable (days to several weeks) in response to inflow and withdrawal/outflow regimes (Table 7-6). Flushing rates of river ecosystems are comparatively rapid and directional.

XII. SUMMARY

1. Water movements in lakes occur in response to forces, especially wind, that transfer energy to the water. Rhythmic motions (oscillations) result both at the surface of the water and internally, deep within the basin. These motions and their attendant currents may be in phase or in opposition. The ultimate fate of these movements is to degrade into arrhythmic turbulent motions, which disperse the water and the chemicals and organisms within it.
2. As water of a given density moves along an interface, such as the wall of a tube or water of a different density, frictional shearing stresses occur between them. Below a certain speed of flow, water movement is smooth and undisturbed at the interface. This ordered movement is called ***laminar flow.*** As the velocity of movement is increased, the damping effects of gravity are exceeded and vortices occur at the interface, with a decrease in stability. Water movement then becomes disordered in ***turbulent flow,*** in which the frictional increases result in mixing of the two fluids of different density perpendicular to the direction of the current movements. Since the velocities needed to induce turbulent flow are very low (only a few mm sec^{-1}) laminar flow is rarely found in aquatic systems.
3. The coefficient of eddy diffusion (K_z) measures the rate or intensity of mixing (turbulent exchange) across the plane of a density gradient, most often a thermal gradient. K_z decreases markedly in the transition from the turbulent epilimnion into the more stable metalimnion and as the thermal density gradient increases seasonally during sum-

mer stratification. K_z also decreases, that is, there is less turbulent mixing in the metalimnion and hypolimnion of smaller lakes of greater stability than in lakes of large area with longer fetch for wind exposure.

4. Water in streams and rivers flows directionally along decreasing elevational gradients. Frictional shear forces of the water against channel substrata result in turbulent flows. Current velocities are low near the substrata and increase toward the center of the channel. Resistance along the channel and banks results in a spiraling flow pattern that alternates scouring and deposition at relatively uniform distances along the stream channel and result in a meandering channel morphometry. Obstructions (fallen trees, aquatic plants) of any type can modify flow patterns and greatly increase habitat and flow complexity.
5. Flowing water can be forced by advection into the interstitial spaces of stream sediment material, particularly sands and gravel. The zone of sediments into which overlying stream water actively infiltrates by advection is termed the ***hyporheic zone*** and may extend for several centimeters to well over a meter in depth.
6. Movement of air over water sets the water surface into an oscillating motion, called ***progressive*** or ***traveling surface waves.***
   a. The water of surface waves moves in a ***circular*** path (Fig. 7-9). Water is displaced upward and returned to equilibrium by gravity along a circular path (therefore, they are sometimes called *gravity* waves).
   b. The height of the vertical oscillation is attenuated rapidly with depth and decreases by half of the cycloid diameter for every depth increase of 1/9 the wavelength (distance from crest to crest).
   c. While water entrained in surface waves oscillates considerably up and down, horizontal movement is small. The wavelength is much less than the water depth.
   d. When the wavelength of these short surface waves is less than 6.3 cm (2π), the surface waves are called ***ripples*** (capillary waves).
   e. The height of the highest surface waves on a lake is proportional to the square root of the ***fetch,*** that distance over which the wind has blown uninterrupted by land.
7. When surface waves occur near the shore in shallow water, their circular motions are transformed into a to-and-fro sloshing that extends to the bottom of the water column. The wavelength becomes more than 20 times the water depth. As deepwater surface waves enter shallower water, their velocity decreases proportional to the square root of depth. A reduction in wavelength occurs with a marked increase in wave height. With increased height, the waves become asymmetrical and unstable. The collapse or breaking of water over the front of the wave results in a ***breaker*** (Fig. 7-11).
   a. In a ***plunging*** breaker the forward face of the wave becomes convex and the crest curls over and collapses.
   b. The crest of a ***spilling breaker*** collapses forward, spilling water downward over the front of the wave.
   c. Shallowwater wave energy is effective in moving littoral sediments to deeper water and inhibiting the growth of many organisms not adapted to such turbulence.
8. Currents are nonperiodic water movements. Although many external forces contribute to the generation of currents, wind is dominant in driving ***surface currents*** of open water.
   a. The velocity of wind-driven water currents is about 2% of wind speed. The water velocity of surface layers increases in a linear way with wind velocity until a critical wind speed (approximately 6 m s^{-1}) is reached, beyond which the ratio becomes nonlinear.
   b. The Coriolis force from the Earth's rotation creates ***geostrophic effects*** by deflecting the direction of surface currents from that of the wind. Deflection is to the right of wind direction in the Northern Hemisphere and to the left in the Southern Hemisphere. The resulting geostrophic wind-drift deflection is 45° from the wind direction in very large lakes. The angle of declination decreases as the size and especially depth of lakes decrease.
9. ***Langmuir circulations*** are large currents of turbulent motion of the upper strata of lakes that are organized into vertical helices. Langmuir circulations move water and entrained particles in circular cells along cylindrical patterns both vertically and in a helical manner parallel to the wind direction and perpendicular to the lines of surface waves (Fig. 7-13).
   a. Downward movement velocities at cell convergences are about three times greater than upward current velocities at divergences.
   b. Aggregations of surface particles that occur at lines of divergence are called ***streaks.***
   c. Langmuir circulations are generated by surface waves at wind velocities above 2–3 m sec^{-1}. Wind energy is converted through surface wave energy into turbulence; surface instability is

then dispersed downward and drives the convection pattern.

d. Langmuir circulation is a primary way in which turbulent motion is transported downward and the upper layers of water are mixed.

10. Water movements in surface strata cause water to pile up at the downwind end of the lake basin. The epilimnetic water there flows downward by gravity until it encounters the more dense water of the metalimnion and then flows back (upwind) along the epilimnetic-metalimnetic interface.
    a. A portion of the metalimnetic water is entrained (incorporated by mixing) into that of the epilimnion. As a result, the epilimnion can become deeper than was previously the case as the upper portion of the metalimnion is eroded.
    b. If the shear at the thermocline is sufficiently great, resulting in low Richardson numbers ($R_i < 0.25$), turbulent flow and vortices occur in the upwind direction. Internal waves can form at the shear interface.
    c. As entrained water of the metalimnion reaches the upwind end of the basin, especially as the storm event producing the movement ends, some flow of the metalimnion is transferred downward to the hypolimnion. In a similar manner, although on a much smaller scale, movement occurs along the metalimnetic-hypolimnetic density-gradient interface in the windward direction.
11. Wind-induced tilting of the water surface and of the metalimnion (or barometric pressure on one part of a large lake) results in a displacement of more water to one end of the lake than is at the other. When the wind stops as the storm passes, the tilted water strata flow back toward equilibrium. The equilibrium point is overshot, however, by momentum. The resulting rocking motion of the entire water mass of the upper lake strata results in ***long standing waves*** termed ***seiches.***
    a. Seiches have the form of very long wave patterns with wavelengths approximating the dimensions of the basin of many lakes.
    b. The surface of the metalimnion oscillates up and down at the lake ends like a seesaw about a line, the ***node,*** of no vertical motion. Maximum vertical motion occurs at the ends, the ***antinodes,*** often at the ends of the lake basin. Horizontal movement is maximum at the nodal line and nil at the antinodes. The horizontal movements reverse direction with each long oscillation and can create currents of sufficient size to develop instability, vortices, and waves. The seiches return to equilibrium as a result of gravity and frictional damping, with a progressive reduction in the duration of the oscillation periodicity.
    c. ***Surface seiches*** affect the motion of the entire water mass of the lake, whether stratified or not, and have maximum amplitude at the surface.
        i. Horizontal oscillation at the nodal line is large when the basin is very long in relation to depth.
        ii. The amplitude of surface seiches is relatively small (to several meters, maximum) but is sufficient to cause significant flooding and erosion effects of shoreline areas in large lakes.
        iii. The periodicity of surface seiches increases with increasing basin dimensions (see Table 7-2).
    d. ***Internal seiches*** occur when lakes are stratified and the metalimnion is set into oscillation as an internal standing wave.
        i. Both the periodicity and the amplitude of internal seiches are much greater (nearly an order of magnitude) than those of surface seiches.
        ii. Most internal seiches are uninodal, although multinodal seiches occur in very large lakes.
        iii. Since the nodal horizontal oscillations of internal seiches are much larger than those of surface seiches, shearing flow at the metalimnetic interfaces can generate large ***internal progressive waves.*** These internal waves on the metalimnion are about 10 times larger than surface waves, but they propagate and break internally much as surface waves do.
        iv. The geostrophic effects of Coriolis force increase toward either pole north and south of the equator. The geostrophic effects deflect the oscillation patterns and flows associated with internal seiches and cause large-scale twisting undulations of the metalimnion (Fig. 7-18).
        v. The internal currents and waves cause considerable mixing of water, solutes, and organisms across the epilimnetic–metalimnetic interface.
    e. ***Long progressive waves*** of both the surface and metalimnion waters have wavelengths that are much greater than the water depth. Long progressive waves are nondispersive.
        i. As the long waves oscillate in lakes sufficiently large for Coriolis geostrophic effects

to influence motion and intersect the shore line, the rotational effects and decay of wave energy by gravity generate currents that are parallel to the shore and to the progression of the waves (Fig. 7-20). The wave amplitude of these ***Kelvin waves*** decreases exponentially away from the shore.

ii. In very large lakes, the long waves can travel in open water without the interference of shore boundaries. These ***long gravity waves*** (***Poincaré waves***) are influenced by Coriolis geostrophic forces and form a wave pattern of alternating hills and valleys with corresponding cellular patterns of currents (Fig. 7-22).

iii. The amplitude of Poincaré waves increases as the shore boundary is reached and these waves are dispersed into the Kelvin wave configuration (Fig. 7-23).

12. A narrow zone of warm water develops between the shore line and the open water mass in the spring. The shallow nearshore waters heat more rapidly than the open waters. A density-driven circulation perpendicular to the shore consists of two circulation cells, with a zone of convergence, termed a ***thermal bar,*** in between. Little mixing occurs between inshore and offshore waters until the whole lake is thermally stratified.
13. Incoming river water to a lake or reservoir flows into strata of density similar to its own. Inflow water movements are dependent on density differences from temperature, dissolved materials, and particulate suspensoids and vary greatly seasonally and among lake ecosystems.
14. Slow water currents occur in lakes even though the water is sealed from wind by ice cover and there is no appreciable inflow and outflow. Horizontal current velocities tend to be greater than vertical velocities. The currents are thermally induced by convection from heat flowing from the sediments. Most of the heat released from the sediments during winter was accumulated during the previous summer.
15. Comparative analyses of hydrodynamics among river, reservoir, and natural lake ecosystems emphasize the transition from rapid, gravity-mediated, unidirectional and horizontal flushing rates in rivers to long, wind-driven, relatively constant, three-dimensional movements in lakes. Water-level fluctuations shift from large and irregular among streams to relatively small and stable among natural lakes.

IX. Summary

Aquatic ecosystems are open and require a continual input of energy in the form of organic matter. This organic matter is produced almost totally by photosynthesis and is either used by consumers or stored in the ecosystem. Organic matter and energy driving the ecosystem are either produced within the river or lake or are imported from terrestrial or land–water interface communities to the river or lake. Within the aquatic ecosystem, organic matter is degraded physically, as in direct photolysis, utilized by decomposer organisms, or ingested by grazer (metazoan) organisms. Energy and nutrients must continually be replenished in such open systems in which available energy and other resources are constantly being utilized and respired to inorganic compounds and so lost or made unavailable.

Discussion so far has been directed to the basic physical aspects of water itself, how water is distributed to river and lake basins, and the origins of rivers and of lake basins, and how drainage basin morphology is modified with time. We then considered both the penetration of solar radiation and the distribution of heat in various fresh waters and explained how absorbed heat interacts with wind energy to influence water movements, particularly in standing waters.

Now the basic nutrient chemistry of aquatic ecosystems will be evaluated. The biota are inseparably coupled with the dynamics of many chemical elements, in particular the nutrient distribution and their biogeochemical regulation of nutrient fluxes and recycling. Before discussing the major chemical constituents in detail, however, a brief overview of the ecosystem components and how they interrelate is useful.

I. THE DRAINAGE BASIN CONCEPT

Terrestrial and aquatic ecosystems are linked by movements of water and materials through the drainage basin to recipient rivers and lakes. Chemical and biological processes modify the composition of the materials dissolved within and moved by the water. Geological features of the landscape govern the directions of movement and particularly the residence time

of water during movement in surface and ground waters toward rivers and lakes. The duration of contact with soil and associated microbiota influences the content of dissolved salts and organic products conveyed in the water. Terrestrial and wetland vegetation in the drainage basin influence the chemical content of both water falling through their leaf canopy as well as water in the soil by selective assimilation and storage within their tissues. The movements and fluxes of a number of these compounds will be treated separately in subsequent chapters.

From drainage basins that are vegetated, such as in forests, usually only about one-third of the incoming precipitation leaves as runoff and groundwater seepage to streams and rivers. Removal of vegetation greatly increases the amount and accelerates the rate of flow of runoff from the landscape. During periods of high precipitation, water in streams frequently exceeds the capacities of the river channels and inundates the flood plains, often for long periods of months. During this inundation, organic matter and many nutrients can be returned to the flooded land and result in highly productive adjacent aquatic habitats.

The drainage basin clearly regulates the characteristics of rivers and lakes within it (Hynes, 1975; Likens, 1984). The geomorphology of the land determines the soil and ionic composition, slope, and, in combination with climate, the vegetation cover. The vegetation and soil composition influence not only the amount of water runoff but both the composition and quantity of organic matter that enter streams and lakes. Finally, as will be reiterated constantly, one cannot study aquatic ecosystems without consideration of human influences. Human pollution and modifications of the environment and climate are now so pervasive that no aquatic environment of the biosphere is unaltered in some manner by these disturbances. Human influences vary greatly and change with time but nonetheless often dominate regulation of biotic productivity and biogeochemical cycling.

II. STREAMS AND RIVERS

The characteristics of stream and river ecosystems, each summarized and integrated in individual topical chapters, are extremely diverse. However, several characteristics distinguish running waters from other inland ecosystems (Hynes, 1970; Minshall, 1988; Calow and Petts, 1992; Allen, 1995; Giller and Malmqvist, 1998).

a. Flow is *unidirectional;* as a result, downstream reaches are influenced by upstream reaches.
b. Running waters are *linear in form* and occupy a very small portion of the total drainage basin area.
c. *Channel substrata and channel morphology tend to be unstable* and undergo constant change as a result of the erosive and molar action of flowing water.
d. *Much of the organic matter entering and supporting metabolism in streams on an annual basis originates from allochthonous sources.* Metabolism at nearly all levels is variably but usually dominantly dependent on organic matter imported from terrestrial sources, and that dependency usually increases with smaller, low-order streams.
e. *Spatial and temporal heterogeneity is high* among many parameters in river ecosystems. The heterogeneity within a river tends to be much more dynamic than in standing waters. Rivers generally possess much greater and more dynamic longitudinal changes in flow, chemical conditions, and biota, particularly in adjacent bank and floodplain areas, than is the case in standing waters. Because streams and rivers respond relatively rapidly to precipitation events within the drainage basin, rapid and large changes occur frequently in loading from the drainage basins and resulting physical and chemical conditions. Flow, dissolved oxygen, and water chemistry are primary regulators of life in flowing water (lotic) ecosystems. Extremes in cyclic variations of these and related parameters set the physiological and behavioral boundaries tolerated by biota.
f. *High variability of physical, chemical, and biological characteristics exists among different streams and rivers* and, as a result, generalizations are more difficult than is the case among many standing waters.
g. Although basic biological functions and growth are similar among biota of lakes and rivers, many of the *stream biota have specialized adaptations to conditions within flowing water.*

III. LAKE ECOSYSTEM CONCEPT

Several early investigators emphasized the functional relationships of organisms within lakes (e.g., Forbes, 1887; Lindeman, 1942). The innovative perceptions of these studies led to intensive evaluation of interrelationships among organisms and changes in specific organism populations in response to alterations

in physical, chemical, and biotic properties of the environment. Lakes were initially viewed, incorrectly, as microcosms, functionally isolated from the rest of the landscape and biosphere.

In their time, these analyses were perceptive and they led to extensive investigations of the interrelationships between biotic and physical components within lakes. These studies, which continue to the present time, are of fundamental importance; they have resulted in a comprehensive understanding that is unrivaled by any other area of ecology. Still, within a broad context, these in-lake analyses encompass but a small part of the lake ecosystem.

A number of early workers called attention to the importance of nutrients from the drainage basin in regulating metabolism in lakes. This insight recognized what is commonly accepted now—that the lake ecosystem consists of the lake and its entire drainage basin. Recognition of the importance of the drainage basin, however, is still largely limited to the loading of inorganic and organic nutrients. Comprehensive analyses of the manner in which the terrestrial biota regulate loading to streams and recipient lakes are much more rare (e.g., Likens *et al.*, 1977; Likens, 1985; Likens and Bormann, 1995).

The importance of the catchment area to inputs of both particulate and especially dissolved organic matter to lakes, and of the regulatory influences of this dissolved and colloidal organic matter once it reaches the lake, are finally gaining appreciation and understanding after some 30 years of championing and study by R. G. Wetzel and co-workers. Extremely heterogeneous and productive wetland–littoral areas often lie at the interface between the terrestrial drainage basin and the open-water zone of the lake (Fig. 8-1). These complex wetland–littoral areas are exceedingly important in regulating lake metabolism (Wetzel, 1979, 1990a, 1995). Since a majority of lakes of the biosphere are small and relatively shallow (cf. Fig. 3-2), the metabolically active wetland and littoral components dominate the productivity of most lakes of the world. These complex interface regions are the least understood lake ecosystem component, particularly of very shallow lakes; major aspects will be discussed later (cf. Chaps. 18, 19, 20, and 22).

The effects that terrestrial, wetland, and littoral biota have on the quality and quantity of inorganic and organic loading to a lake can be profound. Water laden with inorganic and organic substances flows from higher elevations to the recipient lake basin both in ground water and in surface streams. Chemical and biological reactions occur en route that selectively modify the quality and quantity of nutrients and organic substances entering the lake. Surface flows often pass through the wetland–littoral complex and can further selectively lose or gain inorganic and organic compounds before reaching the open water.

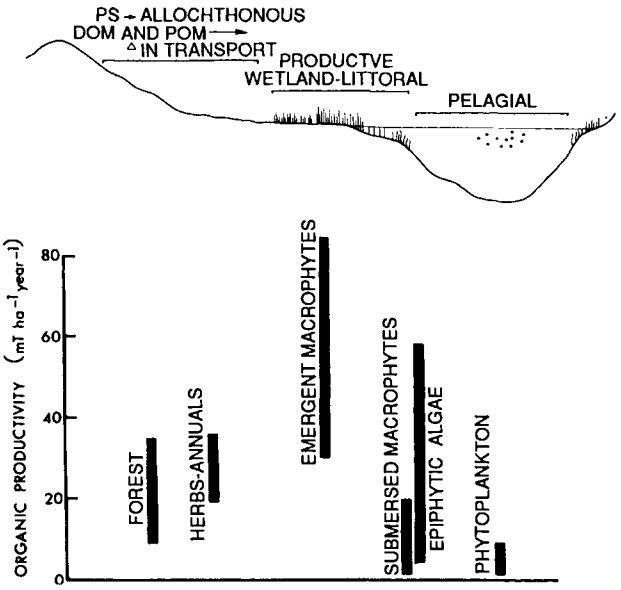

FIGURE 8-1 The lake ecosystem, showing the drainage basin with terrestrial photosynthesis (*PS*) of organic matter, movement of nutrients and dissolved (*DOM*) and particulate (*POM*) organic matter in surface and groundwater flows towards the lake basin and chemical and biotic alteration of these materials en route, especially as they pass through the highly productive and metabolically active wetland–littoral zone of the lake per se (net organic productivity in metric tons per hectare per year).

Finally, appreciable loading of inorganic and organic substances to the atmosphere is common from the industrial and agricultural activities of humans. These compounds reach the drainage basin and lake itself by dryfall and with wet and frozen precipitation. This source of loading is often a significant portion of the total nutrient and contaminant loading to a lake.

A. Lacustrine Zonation and Terminology

The bottom of a lake basin is separable from the free open water, the ***pelagic zone***, and is further divisible into a number of rather distinct transitional zones from the shore line to the deepest point (Fig. 8-2). The ***epilittoral zone*** lies entirely above the water level and is uninfluenced by spray; the ***supralittoral zone*** also lies entirely above the water level but is subject to spraying by waves. The ***eulittoral zone*** encompasses that shoreline region between the highest and lowest seasonal water levels and is often influenced by the disturbances of breaking waves. The eulittoral zone and the ***infralittoral zone*** collectively constitute the littoral zone. The infralittoral zone is subdivided into three zones in

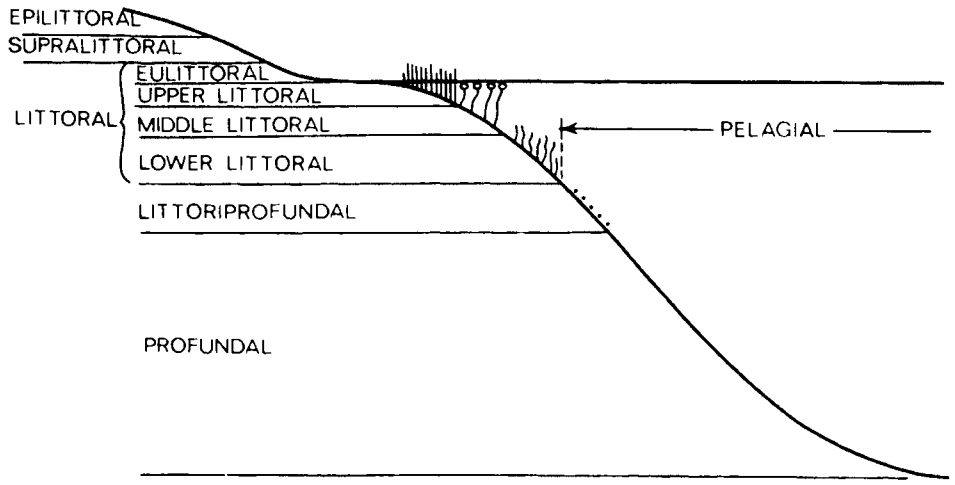

FIGURE 8-2 Lacustrine zonation (see text for discussion). (After Hutchinson, 1967.)

relation to the commonly observed distribution of macrophytic vegetation: *upper infralittoral* or zone of emergent rooted vegetation; *middle infralittoral* or zone of floating-leaved rooted vegetation; and *lower infralittoral* or zone of submersed rooted or adnate macrophytes.

Below the littoral is a transitional zone, the ***littoriprofundal,*** occupied by scattered photosynthetic algae and bacteria. The littoriprofundal zone is often adjacent to the metalimnion of stratified lakes. The upper boundary of the littoriprofundal zone at the lower edge of macrovegetation of the lower infralittoral is usually quite distinct. The lower boundary of the littoriprofundal consists of a gradient of benthic algae and especially cyanobacteria and other photosynthetic bacteria and is less sharply demarcated. The remainder of the sediments, which consists of exposed fine sediment free of vegetation, is referred to as the ***profundal zone.***

The philology associated with bacteria and algae variously attached to substrata in aquatic systems is involved (cf. reviews by Naumann, 1931; Cooke, 1956; Sládečková, 1962; Wetzel, 1964, 1996; Round, 1964a, 1965a; and Hutchinson, 1967). The number of terms is large and many are unnecessarily complex and quite confusing, especially when removed from their original definitions. The subject is rather unrewarding because of the great variation in microhabitats and association of organisms with substrata. A few widely used terms in limnology need to be discussed.

The term ***benthos,*** originating from the Greek word for "bottom," was initially defined broadly to include the assemblage of organisms associated with the bottom or, better, any solid–liquid interface in aquatic systems. Benthos is now nearly uniformly applied to animals associated with substrata.[1] The terms *Aufwuchs* (German: "growth upon"), and to a lesser extent *haptobenthos,* generally connote all organisms adnate to, but not penetrating, a solid surface. Since the term *Aufwuchs* is so broad and ambiguous, it is of little meaning and should be abandoned.

Periphyton, although variously used, usually refers to microbial growth upon substrata. It is a broad term that applies to microbiota living on any substratum, living or dead, plant, animal, or nonliving. Despite being etyomologically imprecise, the word is so entrenched in limnology that its use has been internationally accepted (cf. Wetzel, 1983b). In contrast, ***biofilm*** is a term more frequently used in engineering applications and often refers to predominantly attached heterotrophic bacterial communities. Biofilm, however, is essentially synonymous to periphyton. Reference to more specific subdivisions by complex phrases (e.g., epiphytic periphyton) results in involved and often redundant nomina. A much more explicit manner of expression, and one championed by F. E. Round, is to refer to the organisms with appropriate modifiers descriptive of the substrata upon which they grow in natural habitats. Hence, among the algal communities, one can readily differentiate the following (Fig. 8-3): (a) ***epipelic*** algae as the flora growing on sediments (fine, organic); (b) ***epilithic*** algae growing on rock or stone surfaces; (c) ***epiphytic*** algae growing on macrophytic surfaces; (d) ***epizooic*** algae growing on surfaces of animals; and (e) ***epipsammic*** algae as the rather specific organisms growing on or moving through sand.

[1] *Herpobenthos* as used by Hutchinson (1967) is synonymous with *benthos* when the term *benthos* is unqualified and means "growing on" or "moving through sediment."

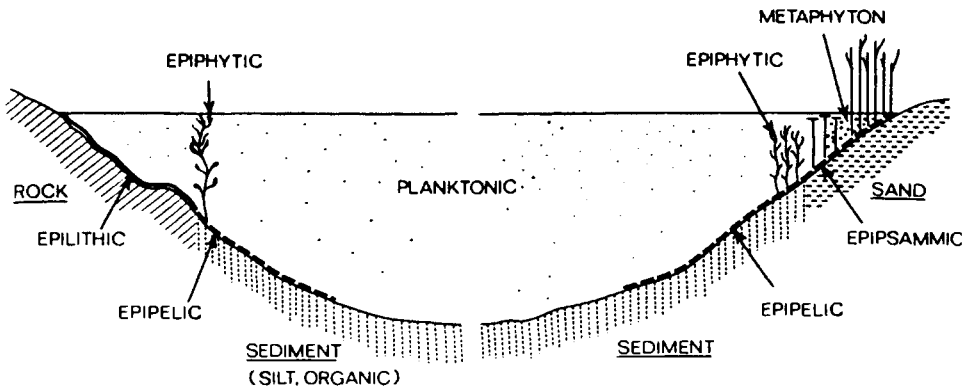

FIGURE 8-3 Major terms of microfloral communities associated with different substrata in inland waters.

The general word ***psammon*** refers to all organisms growing or moving through sand (cf. Cummins, 1962, for a detailed discussion of particle-size differentiation among sediments).

A group of algae found aggregated in the littoral zone is the ***metaphyton,***[2] which is neither strictly attached to substrata nor truly suspended. The metaphyton commonly originates from true floating algal populations that aggregate among macrophytes and debris of the littoral zone as a result of wind-induced water movements. In other situations, the metaphytonic algae can originate from fragmentation of dense epipelic and epiphytic microbial populations. A surprisingly large number of descriptions exist of the clustering of metaphytonic algae and macrophytes into "lake balls," which are densely packed aggregations of algae, plant parts, or both. These balls are formed by the alternating rolling movements of wave action in the littoral zone (Nakazawa, 1973).

The ***phytoplankton*** consist of the assemblage of small plants or photosynthetic bacteria having no or very limited powers of locomotion; they are therefore more or less subject to distribution by water movements. Certain planktonic[3] algae move by means of flagella or possess various mechanisms that alter their buoyancy. Most, however, are "freely floating," a term commonly used when referring to ***plankton*** in general, even though it is obviously somewhat of a misnomer, in that most algae do not float. Most algae are slightly denser than water and sink, or sediment from, the water. Phytoplankton are largely restricted to ***lentic*** (standing) waters and large rivers with relatively low current velocities (cf. Wetzel, 1975b; Wetzel and Ward, 1992). Phytoplankton in streams of moderate flow, which either break loose from the algal communities attached to substrata or enter a stream from the outflow of lakes, are commonly rapidly fragmented or killed by the abrasive action of turbulence and substrata (see, e.g., Chandler, 1937, and Chap. 15). Distinctly macroscopic algae with long filamentous forms usually inhabit parts of the littoral zone. The common groups of phytoplankton, their population and community dynamics, and their productivity have been studied extensively (cf. Chap. 15).

Animals of fresh waters are extremely diverse and include representatives of nearly all phyla. The ***zooplankton*** include animals suspended in water with limited powers of locomotion; they are subject to dispersal by turbulence and other water movements. Like phytoplankton, zooplankton are usually denser than water and constantly sink by gravity to lower depths. The planktonic protozoa and other protists have limited locomotion, but the rotifers, cladoceran and copepod microcrustaceans, and certain immature insect larvae often move extensively in quiescent lake water. These important zooplankton are treated in detail in subsequent chapters (Chaps. 16 and 19).

The distinction between suspended zooplankton having limited powers of locomotion and animals capable of swimming independently of turbulence—the latter referred to as ***nekton***—is often diffuse. Certain zooplankton and early larval stages of fish are initially planktonic but distinctly nektonic in later life stages (cf. Chap. 16).

A number of specialized organisms, the ***pleuston,*** are adapted to the interface habitat between air and water. Numerous macroscopic organisms, such as many of the duckweeds (Lemnaceae) and adult insects (e.g., gerrid hemipterans), are morphologically adapted to the air–water interface. Many species of bacteria and algae,

[2] *Metaphyton* (Behre, 1956) is essentially synonymous with the terms *tychoplankton* and *pseudoplankton* used much earlier by Naumann (1931) and the term *pseudoperiphyton* used by Sládečková (1960).

[3] The word *planktonic,* while etymologically incorrect (see discussion by Rodhe, 1974, and Hutchinson, 1974), is so ingrained in aquatic ecology that change is not desirable.

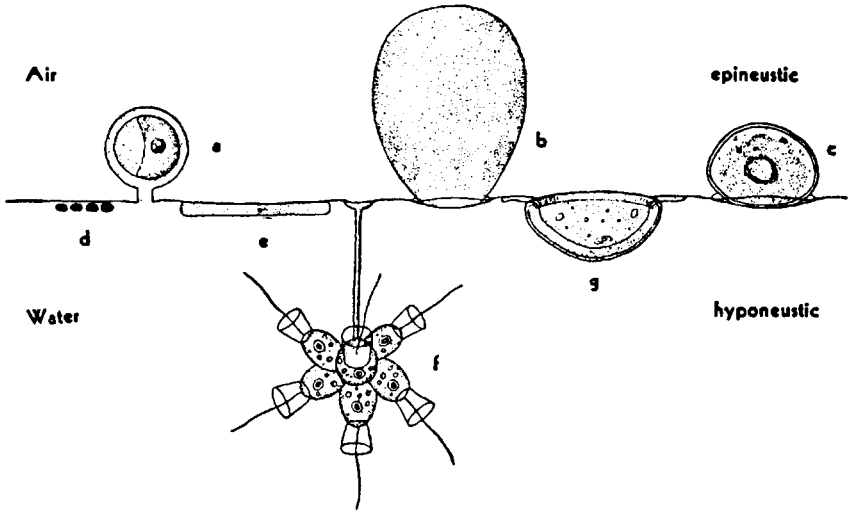

FIGURE 8-4 Exemplary organisms of the neuston at the surface film. Epineustonic: (a) *Chromatophyton* (Chrysophyceae); (b) *Botrydiopsis* (Xanthophyceae); (c) *Nautococcus* (Chlorococcaceae). Hyponeustonic: (d) *Lampropedia* (Coccaceae); (e) *Navicula* (Bacillariophyceae); (f) *Codonosiga* (Craspedomonadaceae); (g) *Arcella* (Rhizopoda). (From Ruttner, F.: *Fundamentals of Limnology*, 3rd ed., Toronto, University of Toronto Press, 1963.)

including some diatoms, chrysophytes, and xanthophytes, are specialized to live at the interface. The microscopic components of the pleuston are collectively termed ***neuston***, and are separated into those organisms adapted to living on the upper surface of the interface film (the *epineuston*) and those living on the underside of the surface film (*hyponeuston*) (Naumann, 1917; Gladyshev and Malyshevskiy, 1982). Most neustonic organisms live on the upper surface of the interface. A few examples of algal and protozoan neuston are illustrated in Figure 8-4.

The development of neuston is most extensive in sheltered, quiescent waters. In large bodies of water, neustonic algae develop in the pelagic zone during calm periods but are quite changeable and transitory (Nägeli and Schanz, 1990). The algal species of the neuston within the surface-film habitat differ considerably from those of the underlying bulk-water phytoplankton. Similar results have been observed in marine ecosystems (see Zaitsev, 1970; Wandschneider, 1979). Surface films maintain themselves only during periods of very calm conditions for periods of several hours (12–32 h) or days (Fott, 1954; Hühnerfuss *et al.*, 1977).

Conspicuous development of the neuston, particularly of the epineuston, is common in small, quiet waters in the littoral or along the margins and backwater areas of streams. Often, populations of epineustonic organisms become so large that light is reflected from cellular chromatophores, and the water appears to be covered with a dry film of varying coloration. Some neustonic algae, such as *Nautococcus*, release a buoyant, pigmented extracellular layer composed of a hydrophobic mixture of carboxylated polysaccharides and waxes (Pentecost, 1984). A few cladoceran zooplankton and insect larvae are adapted to feed on the neuston from the underside of the interface film.

Very little is known of the physiology and metabolism of the neuston of fresh waters in comparison with that of marine waters (cf. Zaitsev, 1970; Hardy, 1973; De Souza-Lima and Romano, 1983). Although the neustonic productivity and contributions to the total metabolism of fresh waters probably are small in most situations, their roles in shallow lake and wetland ecosystems deserve much further study.

IV. POPULATION GROWTH AND REGULATION

A ***population*** of organisms is a spatially defined assemblage of individuals of one species. A population of a species could broadly include all individuals of that species inhabiting the biosphere, but ecologists generally deal with individuals of a species that occupy, or populate, a more localized area, such as a particular lake or section of flowing water. If movement into and out of the defined area is small, relative to the number of births and deaths occurring within the area, population changes within the area can be studied with reasonable accuracy. The number of individuals per unit area or volume of water, the population ***density***, is an index of population size at any given time.

Growth among populations and their competitive interactions for available resources are fundamental to nearly all aspects of biological limnology. Analyses of

population growth have been the subject of intensive quantitative and theoretical study.[4] Although a detailed analysis is inappropriate here, several fundamental relationships and concepts are discussed, since reference is made to these basic parameters and characteristics in subsequent evaluations of freshwater population and community dynamics.

The growth of a population can be very rapid among smaller organisms. The rate of growth (g) is a geometric expression of the increase of the numbers (N) of the population. The time (t) that it takes a population number to double under ideal conditions is

$$t = \frac{\log_e 2}{\log_e g} = \frac{0.69}{\log_e g} \qquad (8\text{-}1)$$

Environmental and competitive restrictions quickly limit the size of the populations either by increasing death rate or by decreasing birth rate.

The geometric constant (g, Eq. 8-1) for rate of population change is difficult to use in comparative growth analyses among populations because of differences in population sizes. This problem is mathematically avoided by expressing population growth with an exponential constant, r, where $r = \log_e g$, or $g = e^r$. Calculation of r from population growth data is done by obtaining the difference between the logarithms of the population sizes at the beginning and the end of a period of growth and dividing by the length of the time period over which the observations are conducted:

$$r = \frac{\log_e N_t - \log_e N_0}{t} \qquad (8\text{-}2)$$

Factor r is an instantaneous, relative measure of population growth rate, in which the percentage rate of increase in a population is determined at every time interval.

The growth rate of a population can be characterized by the logistic equation, which incorporates a term for the intrinsic capacity of a population to grow and a term corresponding to density-dependent limitations upon that growth potential imposed by the competition of others in the population for available environmental resources. Among small, rapidly growing, asexual or parthenogenetic organisms, such as bacteria, many algae, and zooplankton, the differential form of the logistic:

$$\frac{dN}{dt} = rN\left(\frac{K - N}{K}\right) \qquad (8\text{-}3)$$

[4]The basic discussion of population analyses is presented in many texts on population biology (e.g., Wilson and Bossert, 1971; Hutchinson, 1978; Ricklefs, 1979; cf. also Kingsland, 1982).

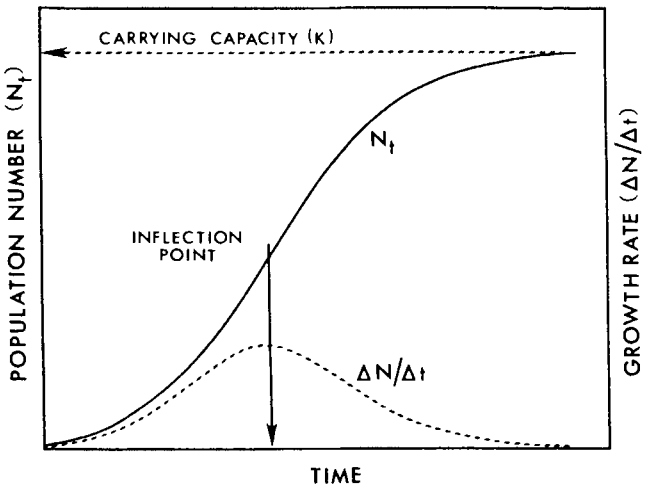

FIGURE 8-5 Common sigmoid growth curve of a population with time (N_t) as it approaches the environmental carrying capacity (K). The growth rate ($\Delta N/\Delta t$) denotes the difference in number of organisms over each time interval. (Modified from Ricklefs, 1979.)

or

$$\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right) \qquad (8\text{-}4)$$

can adequately model a population (N) growing from a small number of individuals to an upper-limiting population K, the latter being governed by nutrient supply, space, inhibitory metabolic products, and other density-dependent factors. As the population increases toward the carrying capacity (K), fewer resources are available for reproduction, and reproductive rates decline. As the population density approaches the carrying capacity, $(1 - N/K)$ approaches zero and population growth ceases. The resulting logistic growth curve has a sigmoid shape (Fig. 8-5) and is commonly observed among natural and experimental populations. The basic logistic model discussed here has been variously modified (cf. Hutchinson, 1978) but is commonly found among populations.

A ***life table*** and its resulting ***survivorship curve*** provide the parameters needed for determining the survival and reproductive performance of a population. When a large group (e.g., 1000) of individuals of the same age or nearly the same age, referred to as a ***cohort,*** are counted at time intervals, one can obtain an estimate of the number of survivors in each time interval. The fraction (l_x) of the original cohort surviving to time x is plotted logarithmically against x to yield a survivorship curve (Fig. 8-6). Such a survivorship curve, in which the population is followed as it changes with time, is age-specific, since all surviving individuals have similar ages at any time (Hutchinson, 1978). The ***specific death rate*** (q_x) over any time interval x to $x + 1$ is the number of

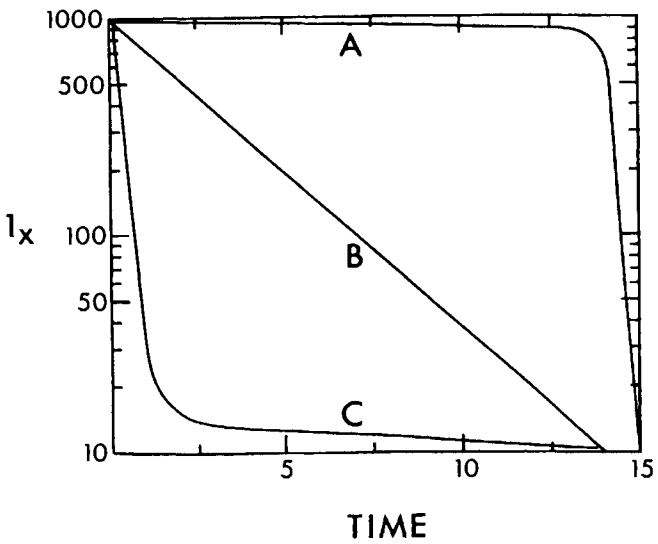

FIGURE 8-6 Idealized survivorship curves of a population (a) with a determined physiological life expectancy (negatively skewed rectangular curve), (b) with a constant death rate (diagonal), and (c) with high juvenile mortality (positively skewed rectangular). (Modified from Hutchinson, 1978.)

individuals dying during that interval ($l_x - l_{x+1}$) divided by l_x. The slope of the survivorship curve at any point corresponds to an instantaneous value of q_x.

Population size tends to oscillate about the equilibrium population level (K) that can be supported by the environment. The rate of increase per individual will decline steadily throughout time as the population grows following the logistic growth equation. The density-dependent decline can result either from a decrease in birth rate (b) or an increase in mortality (death rate, d) as N increases ($r = b - d$). In contrast, density-independent changes in population size can be caused by environmental factors that affect all individuals in a population with equal probability. Density-dependent changes in b or d are particularly important in the regulation of population sizes under uniform environmental conditions. When environmental conditions fluctuate, density-independent constraints to population growth can assume greater importance. Examples of these population changes are discussed in detail in subsequent chapters.

V. COMMUNITY STRUCTURE AND INTERRELATIONSHIPS

Although variously defined, a ***community*** usually refers to a group of interacting populations. Some practical spatial boundaries are most often applied to studies of communities (e.g., planktonic communities) because habitats are diverse and often organisms move from one habitat to another. Throughout subsequent discussions of freshwater biota, the effects of density-dependent and dynamic environmental factors on population and community changes will be evaluated. It is useful to summarize the basic concepts of these relationships and competition among populations of a community in a general way before evaluating specific cases.

A. Ecological Niche

The concept of the ecological niche has had a long history of development and interpretation in ecology. A given habitat consists of a number of interacting environmental gradients. The gradients include both physical and biotic factors, many of which are dynamic and change constantly at differing rates.

In seminal analyses, Hutchinson (1944a, 1957, 1978) formally defined the ***niche*** concept as a certain biological activity space in which an organism exists in a particular habitat. This space is influenced by the physiological and behavioral limits of a species and by the effects of environmental parameters (physical and biotic, such as temperature and predation) acting upon it. Each of these parameters can be ordinated on an axis and can be thought of as a dimension in space. *The fundamental niche, then, can be viewed as an* n*-dimensional space or hypervolume,* with each of its n-axes or dimensions corresponding to the range of an environmental parameter over which the organism can exist. Since many physical and biotic factors interact, each species occupies only a portion of its fundamental niche; this portion can be referred to as the species' realized niche.

Exact quantitative definition of a species' niche, realized or fundamental, is impossible because of its infinitely large number of axes or dimensions. In addition, while it is mathematically and statistically possible to describe multidimensional spaces, we can readily understand physical or graphical explanations in only three or fewer dimensions. In many cases, however, only a few dimensions are needed to adequately describe specific niche interactions (cf. Hutchinson, 1978; Morowitz, 1980).

B. Competition

For each species and each resource requirement, a range of possible existence is bounded by extremes of tolerance and bracketing an optimal growth zone. Species differ in resource requirements for optimal growth and reproductive success, but rarely does a species occupy only optimal zones within its requirements. Certain

variables (e.g., temperature) are continuous, whereas others (e.g., prey availability) are discrete or discontinuous. Some species have similar requirements along one or more resource axes. When two or more species overlap in terms of resource utilization, competition occurs.

The logistic growth equation can be extended to gain insight into interspecific competition and coexistence of populations in a given habitat over a period of time. In the logistic growth equation (Eq. 8-4), rN is the growth potential of the population in the absence of interspecific competition. The term $1 - N/K$ indicates the change in growth, usually a decrease, caused by competition among individuals of the population (N) with respect to the carrying capacity (K) of the environment. As population growth approaches the capacity (K) of the environment to support it, N/K approaches 1, and the resulting growth potential ($1 - N/K$) approaches zero.

When two species occur in the same habitat, competition for limiting resources may occur that reduces growth potential and influences the population levels attained. The Volterra equations describe competition between two species:

$$\frac{dN_1}{dt} = r_1N_1\left(1 - \frac{N_1}{K_1} - \frac{\alpha_{12}N_2}{K_1}\right)$$

$$\frac{dN_2}{dt} = r_2N_2\left(1 - \frac{N_2}{K_2} - \frac{\alpha_{21}N_1}{K_2}\right) \qquad (8\text{-}5)$$

The ***competition coefficients*** (α_{12} and α_{21}) indicate the intensity of the effect that each species has on the population growth of the other. The growth rate of each population consequently becomes dependent upon the number of individuals in the populations of both species.

An increase in population size of one species will result in displacement of the other. Numerous combinations of competitive effects have been found. Often, individuals of one species have a greater effect on individuals of a second species than on members of their own (the first) species, and the competitive effect of individuals of the second species on the first is less than the effects on its own (the second) species ($\alpha_{12} > K_1/K_2$ and $\alpha_{21} < K_2/K_1$). When each species has a greater effect on the other species than it does upon its own growth ($\alpha_{12} > K_1/K_2$ and $\alpha_{21} > K_2/K_1$), which species survives will depend upon the initial proportion of the two species in the growing mixed populations (cf. detailed treatment in Hutchinson, 1978).

If each species has a greater effect on its own members than it does on individuals of the other species (i.e., $\alpha_{12} < K_1/K_2$ and $\alpha_{21} < K_2/K_1$), coexistence of the two species can occur. For competitive exclusion of one or more species by a dominant competing species to occur, the environmental medium must be homogeneous, and sufficient time in relation to reproduction must be available. Often, particularly in planktonic environments, conditions change too rapidly for competitive effects to drive a species to extinction. As a result, a number of apparently competing species with similar environmental requirements coexist. Such interactions will be discussed repeatedly in subsequent chapters.

VI. ECOSYSTEM INTERRELATIONSHIPS

In most cases, energy required for growth and maintenance of organisms enters ecosystems as light and is converted to chemical energy by plant photosynthesis (***autotrophy***). Biological communities are supported by and based on the photosynthetic production of organic matter, produced either within a community (autochthonous production) or derived from an external source (allochthonous production) and transported in a dead or decomposing state to a community for utilization (***heterotrophy***).

A. Trophic Structure of Food Cycles

In self-sustaining biological communities, functionally similar organisms can be grouped into a series of operational levels. Each level, which usually consists of many species competing with each other for available resources, forms a ***trophic level.*** The ***trophic structure*** of a community refers to the pathways by which energy is transferred and nutrients are cycled through the community trophic levels.

Photosynthetic organisms are primary producers, and they represent the first level (Λ_1) of the trophic structure.[5] The Λ_1 organisms are eaten by primary consumers or herbivores (Λ_2), which in turn are successively consumed by secondary (Λ_3), tertiary (Λ_4), et cetera, consumers (carnivores). Since energy is lost in each transfer, more than six trophic levels can rarely be sustained. Organisms exist in complex food webs, in which nutrients and energy of one trophic level are utilized by organisms from several different trophic levels. Although greatly oversimplified, Lindeman's (1942) conceptualization is useful for understanding the general patterns of ecosystem structure and energy flow.

The productivity of each trophic level (Λ_n) was considered to be the rate of energy content entering

[5]The notations, which were initially introduced by Hutchinson (unpublished), were later formalized by Lindeman (1942).

(λ_n) the trophic level from the lower one (Λ_{n-1}):

$$\frac{d\Lambda_n}{dt} = \lambda_n + \lambda'_n \tag{8-6}$$

where λ'_n is the rate of energy leaving the trophic level by metabolic dissipation (respiration with dispersion as heat), returned to the environment as excrement or dead organisms, or being passed on to the next trophic level (Λ_{n+1}) as food.

The amount of energy available for metabolism decreases with each increase in trophic level because energy is lost with each transformation. Since organisms expend a considerable amount of energy for maintenance, only a portion of the energy of one trophic level is available for transfer and use by higher trophic levels. Therefore, at equilibrium (Hutchinson, 1978):

$$\lambda_n = -\lambda'_n \tag{8-7}$$

and

$$\cdots \lambda_{n-1} > \lambda_n > \lambda_{n+1} \cdots \tag{8-8}$$

Total biomass and numbers of individuals at each successively higher trophic level also usually decrease, although some exceptions will be discussed later.

Efficiency of energy or material transfer through a trophic level is simply the ratio, expressed as a percentage, of energy or material leaving a level or system to the quantity of energy or material entering the level or system. In the case just discussed, efficiency would equal the ratio of these productivities, λ_n/λ_{n-1} (critically discussed by Kozlovsky, 1968). The ***ecological-efficiency*** is this percentage of transfer of energy from one trophic level to the next. The rate of conversion of solar energy (Λ_0) into chemical energy by photosynthesis (λ_1) by the first trophic level (Λ_1) of primary producers is small, usually less than 1%, because of the great losses of light energy by nonbiological scattering and absorption and dissipation as heat (Chap. 5). The expenditures of energy for maintenance and the losses to the detrital dynamic structure (see Chap. 22) increase with higher trophic levels. As a result, the efficiencies of energy transfer are low from one trophic level to the next (5–15%) and usually decrease as Λ_n increases.

The general trophic-level conceptual view of feeding interactions in aquatic ecosystems has received appreciable criticism because omnivory is so prevalent. In most ecological communities, individuals of a species feed from several trophic levels (cf. review by Persson, 1999). Life-history omnivory is a result of individuals using different resources during different parts of their life cycle. Many of these differences in feeding, particularly during the different stages and sizes of the life cycle of a species, will be detailed in the discussions that follow in this work. Life-history omnivory does not mean that consumer–resource dynamics that are delineated in the trophic level concept become decoupled, but rather that consumer–resource dynamics become coupled in more complex ways.

The presence of size/stage structure means that the utility of the trophic level concept is much less functional in reality, because size-structured interactions cause both horizontal and vertical heterogeneity in food-web interactions (Fig. 8-7). In the simple case of horizontal heterogeneity of food-web feeding interactions (Fig. 8-7, *left,*), several species at each trophic level may lead to covariation among adjacent trophic levels. In the case of vertical heterogeneity (Fig. 8-7, *middle,*), species A is feeding from several trophic levels (omnivory). In the case of both horizontal and vertical

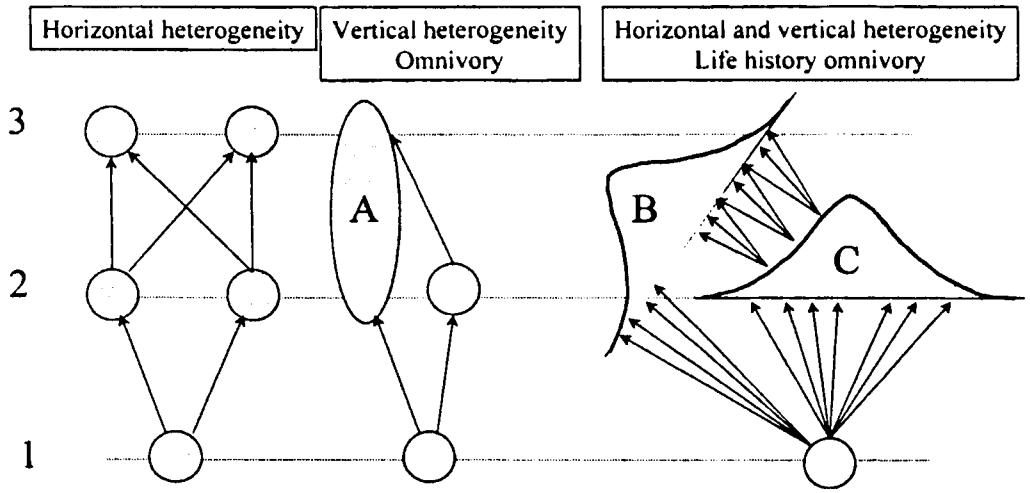

FIGURE 8-7 Three types of heterogeneities in food webs that will give rise to community patterns not expected (see text) from a simple trophic level conceptual approach. (From Persson, 1999.)

heterogeneity (Fig. 8-7, *right,*), species B is feeding from different trophic levels in different parts of its life cycle (life-history omnivory). The distributions in the right-hand figure denote size distributions. Horizontal heterogeneity is present in species C, because individuals of different sizes have different interaction coefficients with the resource being used. Horizontal heterogeneity is present for species B for the same reason as for species C, and, in addition, vertical heterogeneity is present because species B shifts from feeding on the basal resource to feeding on species C with increasing size. Simple linear food-chain models based on direct trophic levels are not realistic.

Another important facet of these trophic structure and energy relationships was that they were developed based almost solely on the ingestion of particulate organic matter (POM) (Wetzel, 1995). Nearly all evaluations of flows of energy within the trophic structures and their variants were specifically orientated along ingestion by animals of particles of organic matter. Excellent understanding was gained from research directed toward the size of POM, morphological aspects of ingestion (e.g., mouth gape, filtration) and avoidance of ingestion (e.g., transparency/visibility, interference by cellular or body projections), behavioral capabilities of organisms for movements within the pelagic zone in relation to refuges and/or escape from predators, nutritional differences in particulate food, and others. Although many of these studies concede that many organisms consume variable amounts of particulate detritus (dead particulate organic matter) and that particulate detritus nearly always dominates over living POM (e.g., Saunders, 1972), quantitative measures of consumption, assimilation, and egestion of detrital POM and its associated attached bacteria are practically unknown.

VII. DETRITUS: DEAD ORGANIC MATTER AND DETRITAL DYNAMIC STRUCTURE

The living biota of lakes constitute only a very small portion of the total organic matter of ecosystems, even in the most productive of freshwater habitats. Most of the organic matter in aquatic ecosystems is nonliving and is collectively referred to as ***detritus.***

The functioning of aquatic ecosystems centers on the cycling of organic carbon between living and nonliving components. Because of the pivotal relationships between the productivity of the living components and the massive amounts of nonliving organic matter, the subject will be discussed in detail later (Chap. 23). Two aspects, however, should be emphasized at this point.

Detritus consists of all nonliving organic matter, in both dissolved and particulate forms. In aquatic ecosystems in general, nearly all of the organic matter consists of dissolved organic carbon compounds (DOC) and particulate organic carbon compounds (POC). The ratio of DOC to POC is usually between 6:1 and 10:1 in both lake and running water ecosystems (Wetzel, 1984). Although living POC of the biota constitutes a very small portion of the total POC, particularly in the pelagic region, the microbial components are important in mediating the fluxes of carbon between the dissolved and particulate phases of detrital organic carbon.

Organic matter originates from photosynthesis within the lake or river ecosystem per se or from the drainage basin. Particulate organic carbon loadings from the drainage basin are relatively small; most organic carbon is transported and imported in dissolved form. Similarly, much of the very high net primary productivity of the wetlands and littoral land–water interface regions of lakes and river ecosystems enters the open–water regions as dissolved organic matter (Wetzel, 1990a; Wetzel and Ward, 1992). This pool of dissolved organic matter is supplemented by the low phytoplanktonic primary production to varying degrees in proportion to the size and geomorphology of the lake and river basins. Clearly, most lakes are small and shallow, and the ratios of organic carbon loadings from allochthonous and littoral sources to those of the pelagic are large (cf. Fig. 3-2; Wetzel, 1990a). The pool of organic matter is variously metabolized, sedimented, or exported.

Very little of either the particulate or the dissolved organic matter emanating from new photosynthetic production is consumed by animals or enters the consumer food chain but instead enters nonpredatory pools of dissolved and particulate detritus (Wetzel *et al.,* 1972; Rich and Wetzel, 1978; Wetzel, 1983, 1995). Because little of this organic carbon does enter the consumer food chain, however, does not mean it is neither metabolized nor important. Not only is this organic carbon the dominant energetic pathway but these microbial and chemical fluxes are essential to the maintenance of nutrient recycling and the metabolic stability of the ecosystem.

Metabolism of particulate and especially dissolved organic detritus from both allochthonous and many pelagic and nonpelagic autochthonous sources dominates both material and energy fluxes. The amount of detrital organic matter is very large, and it is chemically more recalcitrant to biological degradation than is living organic matter. As a result, metabolism of detritus is slow, but the quantity is large and much greater than that resulting from living organic matter that is ingested by anaimals. This slow decomposition provides an inherent ecosystem stability that energetically dampens the ephemeral, volatile fluctuations of higher-trophic-level species populations as they respond to rapidly oscillating factors governing their growth and reproduction (Chap. 23).

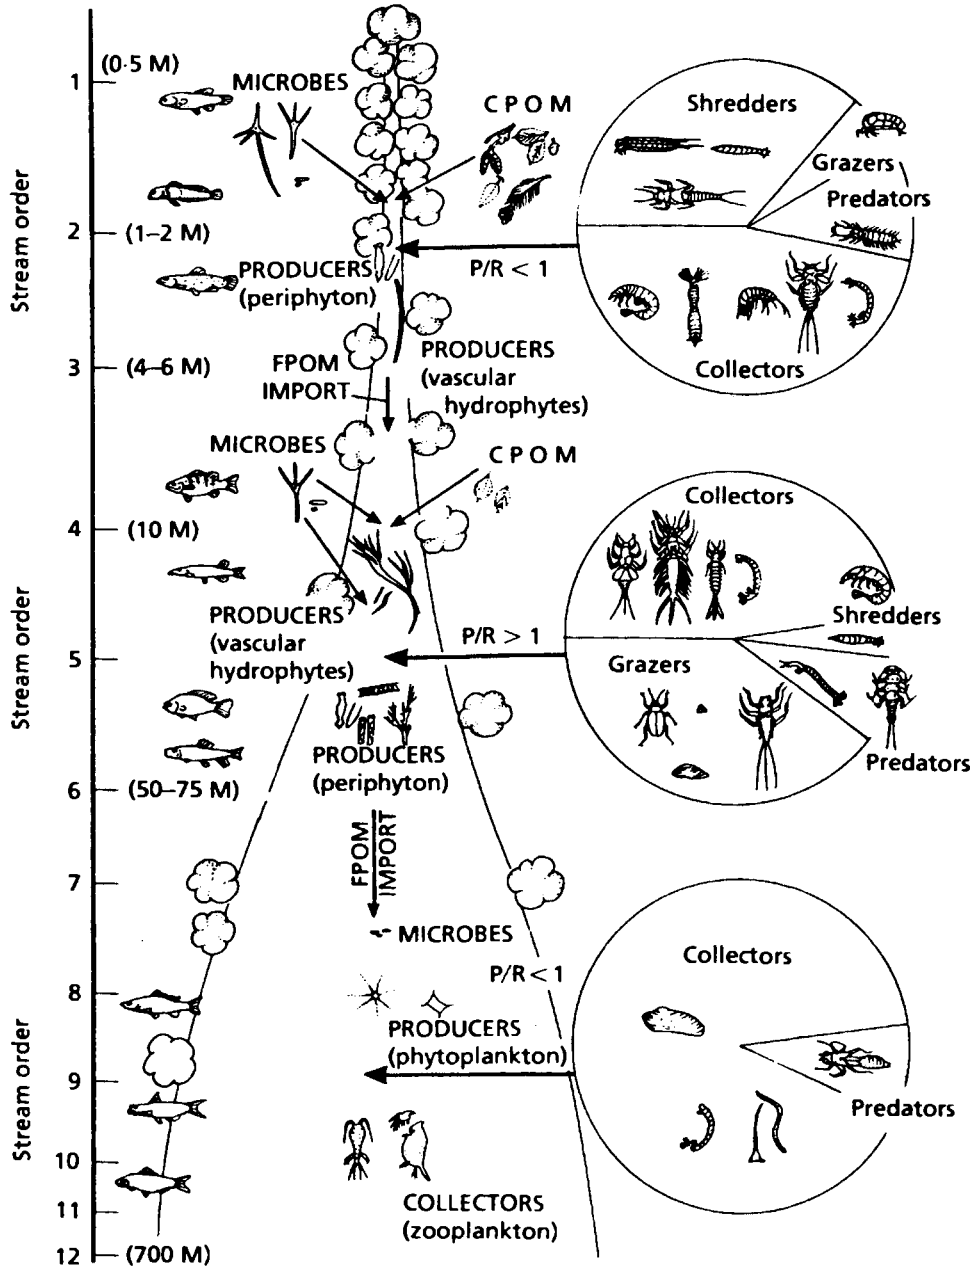

FIGURE 8-8 A generalized model of the shifts in the relative changes in organisms along a river tributary system from headwaters to mouth as predicted by the river continuum concept (RCC; modified from Vannote *et al.*, 1980, and Cummins, 1992). The river system is shown as a single stem of increasing stream order and width. Headwaters (orders 1–3) are depicted as dominated by riparian shading and litter inputs that result in a heterotrophic ratio of community photosynthetic production to community respiration of less than one ($P/R<1$). The midreaches (orders 4–6) are less dependent upon direct riparian plant litter input and, with increased width and reduced canopy shading, often have a net autotrophic metabolism ($P/R>1$). Larger rivers are dominated by fine particulate organic matter but the increased transport load and increased depth results in reduced light penetration, and the ecosystem is again characterized by a $P/R<1$.

A. River Continuum Concept (RCC)

Recognition that the drainage basin was a basic unit for streams and rivers led to the development of the ***river continuum concept*** (**RCC**). The RCC views the entire river ecosystem as longitudinally changing physical templates overlain by biological adaptations along these gradients (Vannote *et al.*, 1980; Cushing *et al.*, 1983; Minshall *et al.*, 1985; Cummins *et al.*, 1995). Geomorphological and hydrological characteristics form the fundamental template along drainage basins upon

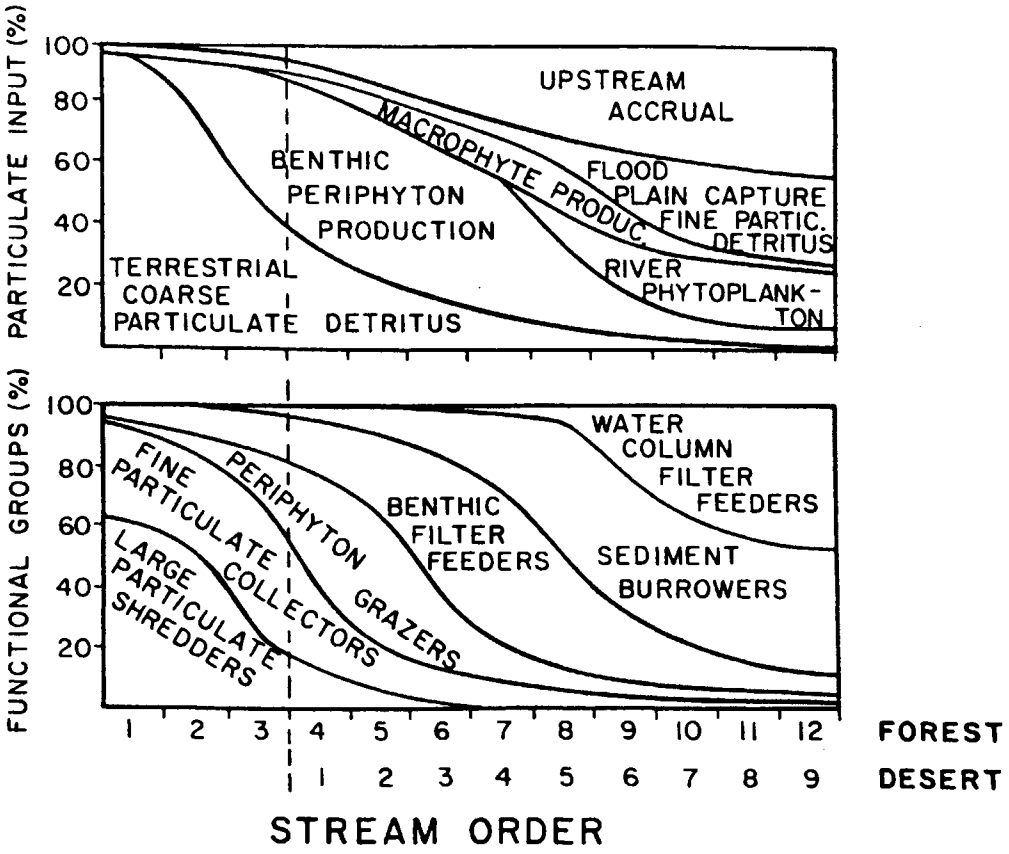

FIGURE 8-9 Commonly anticipated changes in *particulate* organic matter inputs (*upper*) and functional feeding group relationships among invertebrates (*lower*) along a river continuum (after Minshall *et al.*, 1985). The different scales on the abscissa emphasize that different streams enter the continuum at different points. For example, forest streams begin with a strong terrestrial influence with a predominance of allochthonous dissolved and particulate organic matter and detrital macroinvertebrates. In contrast, desert streams, with little if any shading and reduced inputs of allochthonous particulate organic matter, enter the sequence at a position more downstream in the forested stream sequence.

which biological communities become adapted. Both this template and biological communities change along drainage basins from headwaters to river mouth in a reasonably predictable manner (Figs. 8-8 and 8-9).

Generalizations of the RCC focus on seasonal variations of organic matter supply along the continuum (photosynthetic within the stream vs. allochthonous inputs), structure and feeding types of the invertebrate communities, and resource partitioning along the length of the river drainage basin. Heavily forested headwater streams have a leaf canopy that restricts light availability and a very low primary productivity. As a result, these streams exhibit very low primary production: community respiration ratios (P/R) and imports (I) of external organic matter exceed exports (E); thus $E/I < 1$. Such streams are strongly heterotrophic and dependent on imported production of organic matter. Larger rivers less influenced by a canopy of riparian vegetation or streams from desert regions have greater primary production within the river channel. As a result the P/R ratios can be >1, at least at certain times of the year, during which time exports downstream can exceed imports of organic matter from external sources.

The RCC has been modified variously during the past two decades and functions well in a general sense among a variety of river ecosystems. Many of these modifications will be treated in greater detail in subsequent topical chapters. The predictability effectiveness of the RCC varies with changes in physical factors, particularly current velocity, over time. Biological communities have adapted to long-term physical conditions; when human interference alters these properties, particularly over short periods, predictability decreases.

As indicated earlier, materials are displaced downstream, and as a result nutrients are also utilized, stored, released and displaced downstream as they cycle (cf. Chaps. 12 and 13). Recycling of materials within and between water and sediments of streams is controlled by many interacting abiotic and biotic factors, all superimposed on the overall pattern deter-

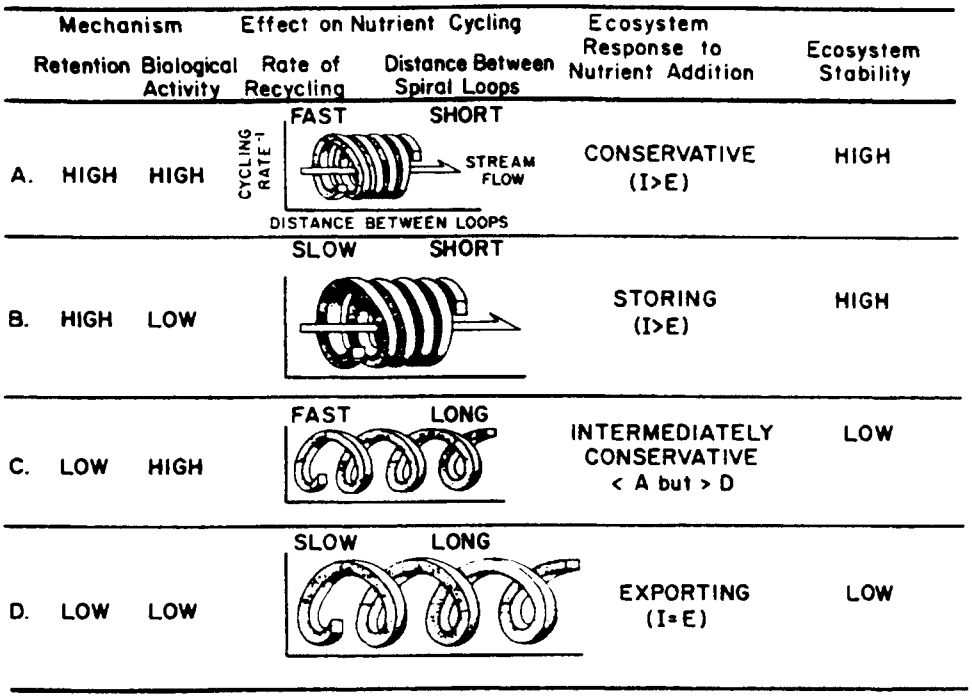

FIGURE 8-10 Hypothetical effects of interactions between distance of downstream movement (velocity × time) and measures of biological activity, such as bacterial metabolism, on organic matter or nutrient cycling in streams of low order (1–4). I = import; E = export. The spiraling rate of recycling reflects biological activity, in which the smaller the diameter of the loop, the faster the rate. Distance between spiral loops represents the extent of downstream displacement of a cycle by the flow of water. The effect of flow can be offset by retention mechanisms so that the higher the retention, the shorter the stream distance between cycles. The quantity of material being cycled is represented by the thickness of the spiraling line. (Modified from Minshall *et al.*, 1983.)

mined largely by flow. The length (openness) of the nutrient cycling along the stream is determined largely by flow and physical retention structures and is modified (size and tightness of loops) by rates of biotic activity in each reach of the stream (Fig. 8-10). The vegetation of the land–water interface along streams greatly influences and modifies productivity within streams and rivers. This vegetation functions in regulation of runoff, nutrient and dissolved and particulate organic matter loadings, as well as the chemical composition of organic matter entering the rivers ecosystems both in dissolved and particulate forms.

B. Diversity

The number of species in a community (species richness, S) increases with the complexity of food webs and with the extent of niche overlap or species packing (i.e., the number of species-niche hypervolumes that a given habitat can contain), especially in the lower trophic levels of food chains. Evaluations of species diversity within a community are complicated by dominant species and an abundance of rare species (Pielou, 1977; Sugihara, 1980). Various indices of diversity have been used, the most common of which account for both relative abundance as well as the number of species. The Shannon diversity index (H') is based on information theory (Shannon and Weaver, 1949):

$$H' = -\sum_{i=1}^{s} p_i \log_2 p_i \qquad (8\text{-}9)$$

in units per individual per unit volume or area, where p_i is estimated from n_i/N as the proportion of the total population of individuals (N) belonging to the ith species (n_i) and using logarithms to the base 2. In an ecological context, H' measures the diversity in a many-species community.

VIII. PRODUCTIVITY

In any analysis of ecosystem or community productivity, it is important that the values obtained be comparable among different ecosystems, among different community components of the same system, or among different responses of populations to environmental

dynamics. The conceptual framework behind productivity historically has been characterized by numerous definitions largely based on agriculture and economics. Perhaps more so than in any other field, in aquatic ecology the questions of productivity have been addressed in detail, and arrays of often incongruous terms and definitions have been proposed. These definitions, many of which are unnecessarily complex, have caused much confusion that has led to ambiguous thinking and expression.

The basic terminology and definitions of the concepts of productivity have been discussed in detail by MacFadyen (1948, 1950), Elster (1954a), Balogh (1958), Davis (1963), Westlake (1963, 1965a), Wetzel (1983, 1995), Benke (1993), and Lucas (1996). Much of the confusion emanates from early concepts that considered productivity as the maximum growth and development of organisms under optimal conditions (Thienemann, 1931); that is, the potential production of organisms or organic matter per unit volume or surface area per unit time (Dussart, 1966). Although the potential of organisms to produce and increase towards infinity may be a useful conceptual framework, in the real world environmental constraints regulate these increases. Optimal conditions for an organism, population, community, or ecosystem can, at best, only be approximated after extensive investigation. Even when the detailed physiological optima for an organism are determined, their applicability to theoretical maximum growth under the dynamics of a nearly infinite number of competitive interactions in natural systems is relegated to the abstract. Such information is much more useful in the interpretation of abiotic and biotic environmental growth controls under *in situ* natural or disturbed conditions.

It is much more meaningful to define the term ***production*** in relation to realized or actual production of organisms, a functional group of organisms in a community, or an ecosystem. Changes in production are related to time and the dynamics of environmental regulatory parameters. However, to generate separate terms for productivity under arbitrarily defined "natural conditions" and under perturbed conditions, as has been variously done, has introduced anthropocentricity and unnecessary complexity. The following definitions of terms represent common usage, and all are in basic agreement with the long history of theoretical discussions (cf. Westlake, 1963; 1965a; Benke, 1993; Lucas, 1996).

A. Terminology and Definitions

Standing crop (also referred to as *standing stock*) is the weight of organic material that can be sampled or harvested at any one time from a given area. Standing crop does not necessarily include the whole population, because certain species or inaccessible parts of the sampled species may be omitted by the sampling procedure. The term derives from agricultural usage of the word *crop,* which is the total weight of organic material removed from a given area over a period of time in the course of normal harvesting practice (usually maximum above-ground foliage or below-ground rooting tissues). The crop is a much less variable measurement than the standing crop, which depends on the time of measurement. For example, a wheat crop is the annual maximum standing crop of above-ground foliage, an alfalfa crop is often the annual total of several standing crops of plant tops, and a sugar cane crop may be a standing crop of tops after nearly two years. Underground organs can constitute a large portion of the total plant mass, and there may be great differences in the standing crop according to the time of sampling.

1. ***Biomass*** is the mass or weight of all living material in a unit area at a given instant in time and is often calculated as the product of mean individual weight (W) and density (N). Biomass has the dimensions of ***mass per unit area or volume*** (e.g., ash-free dry mass m^{-2}). Complications have resulted from the wide usage of standing crop in limnology. When applied to plankton, *standing crop* (or stock) is synonymous with *biomass.* Ambiguities arise when *standing crop,* which refers only to the upper above-ground portions, is applied to aquatic macrophytes; *biomass* includes the entire plant. Biomass evaluations are essential in any analyses of an aquatic plant population or of production dynamics. Because of such inherent differences between the terms, *the measurement of standing crop and use of the term should be abandoned in limnology and only biomass should be used.* If, for some reason, for example, in herbivory, the foliage above ground is specifically of interest, it should be labeled as such: *above-ground biomass.*

2. ***Yield*** is the crop expressed as a rate.

3. Life in ecosystems depends on the flow of energy through the system. ***Production is a flow or flux of mass or energy over time; its dimensions are mass area^{-1} time^{-1} (e.g., g m^{-2} yr^{-1}).*** *Production* thus refers to the increase in biomass of new organic material formed over a period and includes any losses attributable to respiration, excretion, secretion, injury, death, or grazing. Thus, primary production is the quantity of new organic matter created by photosynthesis or the stored energy this material represents. If a photosynthetic organism also uses organic substrates (i.e., is mixotrophic) to supplement photosynthetic metabolism, this additional energy flow is secondary production, even though new organic material may be produced by transformation.

Daily production, weekly production, and annual production are all flows differing only in their specific time units. Natural systems have so many factors causing rapid, frequent, and irregular changes in the instantaneous rates that only average rates can be determined in normal study. It is imperative, as we will stress repeatedly, that the evaluations be done with consideration of the generation times of the organisms under consideration. Weekly evaluations of the productivity of bacteria, for example, are of limited meaning because much of their population dynamics will be excluded; a weekly sampling regimen may be adequate for certain animal components.

In some situations, production may be treated as an integrated accumulation of flows for some time interval. Many secondary production methods are based on first estimating such flow accumulations (Benke, 1993). For example, interval or integrated production (IP) = $N\ \Delta W$, where N = mean density and ΔW = mean increase in weight of an individual over the interval (Table 8-1). Dividing IP by the interval length in days yields daily production (P_d, a flow for the interval), and adding all the IP values for the year gives annual production (P, also a flow). The IP value is an estimate of cohort production of little value in itself, except to serve as an intermediate step in estimating the true flow as annual production. *The annual time period is the only meaningful interval in comparative quantitative analyses of material and energy fluxes at population, community, and ecosystem levels* (Wetzel, 1995).

Losses of production at any ecosystem level occur as a result of nonpredatory losses (respiratory generation of CO_2 and heat, excretion and secretion of dissolved organic materials, and death or injury) and predatory losses (grazing by herbivores or by carnivores). ***Gross production*** (sometimes termed *real production*) refers to the observed change in biomass, plus all predatory and nonpredatory losses, divided by the time interval. Thus, *gross primary production* is the rate of production of new organic matter, or fixation of energy, including that subsequently used and lost during that time interval. ***Net production*** (occasionally termed *apparent production*) is the gross accumulation or production of new organic matter, or stored energy, less losses, divided by the time interval. Sometimes only respiratory losses are subtracted, particularly among evaluations of plant productivity in which losses from processes other than respiration are small. However, all

TABLE 8-1 Terminology and Units Used in Secondary Production Evaluations[a]

Symbol	*Definition*	*Units*	*Type of unit*	*Comments*
W	Individual weight	mg	Mass	Individual weight of an animal at a given time (W_t); often presented as the mean ($\overline{W}$) or difference (ΔW) between sampling dates
N	Density	No. m^{-2}	Storage	Density at a given time (N_t); often presented as the mean ($\overline{N}$) or difference (ΔN) between two sampling dates
B	Biomass	$g \cdot m^{-2}$	Storage	Biomass at a given time (B_t); often presented as a mean over period for which production is calculated (e.g., annual or cohort)
P	Annual production	$g \cdot m^{-2} \cdot yr^{-1}$	Flow	A flow (flux) with time units of per year
P_d	Daily production	$g \cdot m^{-2} \cdot d^{-1}$	Flow	A flow (flux) with time units of per day calculated as $P_d = gB$
IP	Interval production	$g \cdot m^{-2}$	Accumulation (integration)	Integration of production over an arbitrary time period (Δt) (e.g., $IP = gB\ \Delta t$ or $\overline{N}\ \Delta W$); $P = \Sigma IP$ for a year and $P_d = IP/\Delta t$
IP_c	Cohort production	$g \cdot m^{-2}$	Accumulation (integration)	Integration of production over developmental time of cohort (CPI—see below); usually equals annual P when ≤ 1 gen/yr
P/B	Annual P/B	yr^{-1}	Rate	Fraction of biomass which flows per year. Can vary from 0.1 to >200 for aquatic invertebrates
P_d/B	Daily P/B	d^{-1}	Rate	Fraction of biomass that flows per day. Equals daily growth rate, g (see below)
IP_c/B	Cohort P/B	Unitless	Ratio	A true ratio (not a rate) with values usually ranging from 2 to 8
CPI	Cohort production interval	d, yr	Time interval	Time interval from hatching to final size class or emergence
G	Instantaneous biomass growth rate	Unitless	Log of a ratio	$\ln(W_{t+\Delta t}/W_t)$—not a true rate until divided by Δt (see below)
g	Daily instantaneous biomass growth rate	d^{-1}	Rate	Generally computed as G divided by Δt in days

[a] Modified from Benke (1993).

losses should be considered in a true evaluation of net production.

B. Evaluation of Biomass and Production

Numerous parameters have been used in evaluations of the biomass and production of aquatic organisms, including enumeration, volume, wet (fresh) weight, dry weight, organic weight, content of carbon, pigments, energy as heat on combustion, and ATP, and the rates of metabolism of oxygen and carbon dioxide. Often these criteria have been used uncritically, which makes comparability and interpretation difficult (cf. reviews of Lund and Talling, 1957; Strickland, 1960; Westlake, 1965b; Vollenweider, 1969b; Edmondson and Winberg, 1971; Stein, 1973; Wetzel and Likens, 1991; Benke, 1993; among others).

1. Enumeration and Biovolume

Enumeration of organisms per unit volume of water or area is a commonly used method to evaluate microorganisms. Although numbers afford great advantages in permitting qualitative differentiation between species and differentiation of organisms from detrital particles, numbers do not give a true evaluation of biomass because organisms differ greatly in size (cf. Table 8-2). The abundance of each species is better expressed as the biovolume of all individuals (numbers times average cell volume determined from mean dimensions of the cells) per unit volume of water or area of substratum. Among larger organisms, such as zooplankton, benthic fauna, and fish, biomass can be determined using allometric relationships specific to the organisms under study. Volume is a poor measure of aquatic macrophytes because of great variability of internal gas spaces (cf. Chap. 18); thus the relationship between volume and biomass can be extremely variable.

2. Weight (Mass)

Fresh weight, the weight of the organism without any adherent water is, with appropriate precautions, essentially equivalent to wet weight. Owing to the highly variable water content of nearly all organisms, however, wet weight should be avoided. If elaborate precautions are taken, wet-weight analyses can be converted to dry weight on a species basis from a particular environment. Dry weight is variable at temperatures below 100°C; hence, dry weight at 105°C is the international standard. If the very small percentage (usually much less than 1%) of volatile organic constituents lost at 105°C is germane to the analyses, lyophilization (freeze-drying) is the preferred method.

Although dry weight is employed widely in production analyses, organic (ash-free) dry weight, reasonably determined in most situations by the loss in dry weight after ignition at 550°C, is the preferred measure of biomass for larger organisms. The difficulty of separating bacteria, algae, and other small microorganisms from detrital particulate organic matter restricts the application of ash-free dry-weight measurements to larger organisms.

3. Cellular Constituents

Perhaps the most satisfactory means of measuring the biomass of photosynthetic organisms is to oxidize the organic plant material back to carbon dioxide, from which it originated in photosynthetic reduction. The organic carbon content of plants is one of the least variable constituents and falls nearly without exception within the range of 40–60% of ash-free dry weight. The average carbon content among algae is 53 ± 5%, and among aquatic macrophytes, 47% of ash-free dry weight. Exclusion of extraneous organic detritus is not practical at present, and analyses of particulate organic carbon in pelagic samples (cf. Chap. 23) include a very high percentage (usually $\gg$50%) of nonliving organic material. Algal carbon content usually is estimated from average species content and is extrapolated to natural populations by biovolume measurements of the populations, since the carbon-to-volume relationships are allometric (Mullin *et al.*, 1966; Wetzel and Likens, 2000).

A number of other cellular constituents have been variously employed to estimate changes in population biomass. Except for carbon, however, measurement of biomass by other elements is so complicated, owing to the extreme variability of cellular composition in response to environmental changes, that their use is limited to specific physiological analyses. Although pigment content also varies appreciably with environmental parameters, being able to correct accurately for pigment degradation products in order to measure only the functional pigment content of plants (separate from particulate detritus) permits approximate analyses of composite population dynamics among algae (Wetzel and Likens, 2000).

Several conversion factors have appeared in the literature that allow biomass estimates of one cellular component to be made from another. Even under the most favorable conditions, such factors must be used with utmost caution; under most conditions their use cannot be justified and is best not attempted.

4. Production

Rates of production have been estimated by numerous techniques, most of which are discussed in ensuing treatments of specific groups of organisms. Among aquatic macrophytes, and to a certain extent

[a] After Nauwerck (1963), Findenegg (unpublished in Vollenweider *et al.*, 1969) and Wetzel and Allen (unpublished). Numerous values for tropical and other species are given in Lewis (1977) and Hillebrand *et al.* (1999).

[b] Formerly *Melosira*.

attached algae, primary production can be estimated from changes in biomass over time (Chap. 18). Estimates of production rates by planktonic microflora from changes in biomass are much more difficult (Vollenweider, 1969b). A temporal set of biomass measurements results in minimal estimates or underestimations of net production because of losses attributable to grazing, transport, sedimentation, death, and decomposition. Rarely are these parameters sufficiently evaluated to permit analyses of production rates from changes in biomass; exceptions include the investigations by Lund (1949, 1950, 1954), Grim (1952), and Crumpton and Wetzel (1982), among others.

The primary production of phytoplankton has received an extraordinary amount of attention in limnology and has been measured in great detail in a number of aquatic ecosystems. The reasons for the abundance of information on rates of primary production are manifold.

First, phytoplanktonic production represents a major synthesis of organic matter of aquatic systems and can be summarized in the universal equation:

$$6CO_2 + 12H_2O \xrightarrow[\substack{\text{pigment}\\\text{receptor}}]{\text{light}} C_6H_{12}O_6 + 6H_2O + 6O_2$$

This equation is a gross oversimplification of the complex Calvin–Benson metabolic pathway of photosynthesis of the basic redox reaction:

$$CO_2 + 2AH_2 \xrightarrow{h \cdot \nu} (HCOH) + 2A + H_2O,$$

in which AH_2 represents a hydrogen donor. Normally, the hydrogen donor is water but, as discussed later, types of donors can include an array of reduced sulfur (e.g., H_2S) or organic carbon compounds among autotrophic and certain other bacteria. In large lakes, phytoplanktonic production can represents a major input of new organic matter and potential energy that drives the ecosystem.

Secondly, as is often the case in ecology, the development of reasonably accurate techniques for the measurement of *in situ* rates of community production has led to their wide application, unfortunately often without any sound rationale as to why the measurements were being made. Only now, after many years of experimentation, is there an adequate understanding of the methodology. The appeal of these techniques lies in being able to measure directly rates of metabolism *in situ;* most other evaluations of production are forced to use indirect methods. A similar plethora of *in situ* measurements of heterotrophic bacterial production is emerging with the employment of direct estimates of rates of synthesis of DNA and other proteins by use of specifically radiolabelled precursors of proteins.

In practice, changes in oxygen production or rates of carbon uptake are usually measured on isolated samples of the natural communities that are incubated for brief periods at the points of collection or under simulated natural conditions aboard ship (cf. Wetzel and Likens, 2000). Certain environmental factors (e.g., temperature and light) are simulated closely; other factors, such as turbulence, nutrient replenishment, and grazing, can differ to varying degrees in the isolated samples. Alternatively, productivity estimates can be made from measurements of changes in oxygen, pH, carbon, or conductivity over short intervals in the natural environment on nonisolated communities. This approach, in addition to possessing numerous complications, yields composite estimates of community microbial metabolism rather than that specifically of the algae or submersed macrophytes.

The light- and dark-bottle techniques for estimating primary production have received wide application. In the oxygen method, samples of phytoplankton populations are incubated at the depths from which they were collected in clear and opaqued bottles. The initial concentration of dissolved oxygen (c_1) can be expected to decline to a lower value (c_2) by respiration in the darkened bottles and increase to a higher concentration (c_3) in the clear bottles, according to the difference between photosynthetic production and respiratory consumption. The difference ($c_1 - c_2$) represents the respiratory activity per unit volume over the time interval of incubation. The difference ($c_3 - c_1$) is equal to the net photosynthetic activity, and the sum $(c_3 - c_1) + (c_1 - c_2) = (c_3 - c_2)$ corresponds to the gross photosynthetic activity. Numerous assumptions are made in the method that can alter the photosynthetic measurements appreciably; for example, respiration rates are not necessarily the same in light and dark, since photorespiration clearly occurs in algae, other processes such as photo-oxidative consumption utilize oxygen separately from apparent respiratory uptake, nonphotolysis of water by bacterial photosynthesis, et cetera. Under many circumstances, these errors are small, but the technique can be considered only as a reasonable estimate. It is probable, however, that these and analytical errors in determination of oxygen concentrations are appreciably less than sampling errors in the analyses of heterogeneous plankton populations in the lake. Large portions of recent methodological works are devoted to detailed discussions of this and the following ^{14}C techniques (see especially Strickland, 1960; Vinberg, 1960; Vollenweider *et al.,* 1969b; Strickland and Parsons, 1972; Westlake *et al.,* 1980; Wetzel and Likens, 2000).

The incorporation of ^{14}C tracer into the organic matter of phytoplankton during photosynthesis has been used as a sensitive measure of the rate of primary

production. If the total CO_2 content of the experimental water is known, and if a known amount of $^{14}CO_2$ is added to the water, then determination of the content of labeled carbon in the phytoplankton after incubation permits estimation of the total amount of carbon assimilated. Numerous methodological and physiological problems confront application of the ^{14}C light-and-dark technique; however, with care, most technical problems can be overcome and errors evaluated, for example, respiratory losses of CO_2 and secretion rates of soluble organic products of photosynthesis. Rates of respiration are difficult to evaluate directly with this technique. In many situations, the ^{14}C method yields a measure close to net photosynthetic rates. Comparison of the oxygen and ^{14}C methods under optimal conditions shows close agreement, with a photosynthetic quotient ($PQ = \Delta O_2 / -\Delta CO_2$, by volume) somewhat greater than unity (Fogg, 1963). The photosynthetic quotient varies from near unity when carbohydrates are the principal photosynthetic products, to as high as 3.0 during synthesis of lipids. Assuming a photosynthetic quotient of 1.2 and a statistical significance level of $p < .05$, the smallest amount of photosynthesis that the oxygen light-and-dark technique can measure under ideal conditions is about 10 mg cm^{-3} hr^{-1} (Strickland, 1960). The limit of sensitivity of the ^{14}C method is some 3 orders of magnitude lower, on the order of 0.01 mg cm^{-3} hr^{-1} (Wetzel and Likens, 2000).

Secondary production in fresh waters by invertebrates and vertebrates is much more difficult to estimate accurately than is primary production. Trophic relationships are complex and often change during the life cycle of a species or from one ecosystem to another. The size of animals varies greatly from immature to adult stages, and the diet can also vary greatly throughout the life history. Because most animals are mobile, they actively distribute themselves in response to environmental stimuli, which results in heterogeneous distributions and makes accurate sampling more difficult.

Production measurements of animals are based on estimation of numbers, biomass, and growth rates. The sampling accuracy of changes in population size decreases from zooplankton to benthic organisms to fish. In contrast, growth rates are easier to evaluate in many temperate fishes and in long-lived invertebrates than they are in small, rapidly reproducing zooplankton, other invertebrates, and protists. The basic methods of estimating production of each of these main animal groups will be discussed in subsequent chapters.

When evaluating the population dynamics and production of any animal, estimating food incorporation or ingestion and the utilization of ingested food is imperative. Assimilation means the absorption of food from the digestive system, and the efficiency of assimilation refers to the percentage fraction of ingested food that is digested and absorbed into the body. Assimilation efficiency is not constant and varies greatly with the food quality and rates of food ingestion. Measurements of assimilation are based on the simple relation:

$$\text{Assimilation} = \text{ingestion} - \text{egestion},$$

or

$$\text{Assimilation} = \text{growth} + \text{respiration}$$

Although these relationships are simple, their accurate measurement among natural populations of zooplankton and larger organisms is problematic. The methods employed are discussed critically in Edmondson and Winberg (1971), Winberg (1971), Downing and Rigler (1984), Wetzel and Likens (2000), and Benke (1993). Although ingestion can be measured *in situ* with reasonable sophistication, accurate measurements of egestion rates are often beyond the capacity of contemporary technology. *Growth* is used in a general sense in that it includes the production of eggs or young, much in the same way that respiration includes excretion and other losses as well as normal biochemical respiration.

Assimilation and its efficiency can be approximated with the first of the preceding equations by measuring changes in the radioactivity of the animal after allowing it to feed first on radioactive food and then on nonradioactive food (cf. Sorokin, 1968; Saunders, 1969; Edmondson and Winberg, 1971). Growth and respiration can be estimated by the second equation by measuring the feeding rate (e.g., in calories per time), the growth rate, and respiration. Respiration measured as oxygen consumption can be converted to energy units if the respiratory quotient (CO_2 produced/O_2 consumed) is known.

C. Production/Biomass (*P/B*) Ratios

Biomass (*B*) is a measurement of mass for a population present at one point in time in units of mass per unit area (e.g., g m^{-2}) or volume and is therefore a temporary storage of mass or energy. Production (*P*) is a flow or flux of mass (or energy) per area per time (e.g., g m^{-2} yr^{-1}). The ratio (*P/B*) of production (*P*) divided by mean biomass (*B*) is a rate with units of inverse time (e.g., 1/year). *P/B* is essentially a weighted mean value of biomass growth rates of all individuals in a population (Benke, 1993). The *P/B* ratios can be used to estimate the turnover rate of organisms and for an entire trophic level to give a general index of the rate of energy flow relative to the biomass. Determination of *P/B* values is useful in making comparisons among different trophic levels, as well as among similar trophic levels under different environmental conditions.

Average annual *P/B* ratios generally decrease with increasing trophic level (Table 8-3) and range over 2

TABLE 8-3 Mean and Range of *P/B* Ratios among Trophic Groups of Freshwater Ecosystems[a]

	Mean	*Range*
Bacteria	141.0	73–237
Phytoplankton	113.0	9–359
Herbivorous Zooplankton	15.9	0.5–44.0
Carnivorous Zooplankton	11.6	1.5–30.4
Herbivorous Benthic Invertebrates	3.7	0.6–200
Carnivorous Benthic Invertebrates	4.8	1.0–80

[a] After data of Saunders *et al.* (1980), Brylinsky (1980), and Benke (1993).

orders of magnitude (Brylinsky, 1980; Benke, 1993). As would be expected, (a) annual production is higher in short-lived species than in long-lived species, and (b) annual production of a species decreases proportionally as its biomass increases. Therefore, smaller organisms tend to have greater *P/B* values, and *P/B* ratios decrease with increasing organism size and biomass. Production per unit biomass generally increases with decreasing latitude of the aquatic ecosystem since the active growing season is longer, which allows increased numbers of generations per growing season at lower latitudes. Organisms of oligotrophic lakes tend to have lower *P/B* values than those in eutrophic lakes (Brylinsky, 1980; Saunders *et al.*, 1980).

IX. SUMMARY

1. Aquatic ecosystems are open and require a continual input of energy in the form of organic matter.
2. Aquatic ecosystems consist of entire drainage basins. The geomorphology of the land, vegetation and soil composition, and biota, including humans, determine the characteristics of rivers and lakes within the drainage basin.
3. The nutrient and organic-matter content of drainage water from the catchment area is modified in each of the terrestrial, stream, and wetland–littoral components, as well as in the lake or reservoir per se.
4. Productivity is generally low to intermediate in the terrestrial components, highest in the wetland interface region between land and water, and lowest in the open-water portion of the lake.
5. Stream and river ecosystems are distinguished from other inland ecosystems by
   a. Unidirectinal flow
   b. Linear form that occupies little of the total drainage basin area
   c. Unstable and constantly changing channel substrata and morphology
   d. Having most of biotic metabolism supported by organic matter originating from external allochthonous sources that is imported to the stream or river
   e. High spatial heterogeneity that changes rapidly and frequently
   f. High variability and individuality of physical, chemical, and biological characteristics
6. The lake is separated into the open-water *pelagic zone* and the *littoral zone,* the latter consisting of the bottom of the lake basin colonized by macrovegetation. The sediments free of vegetation that lie below the pelagic zone are referred to as the *profundal zone* (Fig. 8-2). The *littoriprofundal zone* is the transitional area of the sediments between the littoral and profundal zones occupied by scattered benthic algae.
7. Various terms have been applied to groups of organisms living within these zones. *Plankton* are small organisms with no or limited powers of locomotion that are suspended in the water; they are subject to dispersal by turbulence and other water movements. Both the small plant plankton, the *phytoplankton,* and animal plankton, the *zooplankton,* are usually denser than water and sink by gravity to lower depths. Organisms with relatively good swimming powers of locomotion are termed *nekton.*
   a. Bacteria and algae growing attached to substrata are collectively called *periphyton* and have been further named in relation to the type of substrata (sediments, rock, plant, animal, sand) upon which they grow (Fig. 8-3).
   b. *Benthos* refers to nonplanktonic animals associated with substrata at the sediment–water interface.
   c. Specialized organisms adapted to living at the air–water interface are called *pleuston.* The pleuston is dominated by microflora collectively termed *neuston.*
8. *A population* is a defined assemblage of individuals of one species. The growth rate of a population is characterized by both its intrinsic capacity to grow and reproduce and the limitations imposed upon that growth potential by the environment and competition of others in the population.
   a. The population growth of many small organisms can be accurately described with the logistic growth equation. As a growing population approaches its environmental carrying capacity, reproduction usually declines because resources become limiting. Under idealized conditions, when a population attains its carrying capacity, reproductive rates decline to zero.

   b. Survivorship curves permit an analysis of the survival and reproductive performance of a population at different time intervals.
9. A group of interacting populations forms a *community.*
10. The success of organisms is governed by individual physiologic and behavioral limits and by physical and biotic environmental parameters acting upon them. Each of the regulating parameters forms a dimension; the *niche* refers to an *n*-dimensional resource space, or hypervolume. Each species occupies only a portion of its niche hypervolume.
    a. Species niches can overlap, and overlap in resource utilization can lead to *competition.* The logistic growth equation can be extended to include intra- and interspecific competition and predation and allow more realistic mathematical descriptions of population growth.
    b. In multispecies systems, better differential growth of one species will result in exclusion or displacement of another. Coexistence of competing species can occur where intraspecific competitive effects are greater than interspecific effects, through selective predation, or in cases where the environment changes faster than the time required for competitive exclusion.
11. In biological communities, functionally similar organisms can be grouped into *trophic levels* based on similarities in patterns of food production and consumption. Energy is transferred and nutrients are cycled within an overall ecosystem trophic structure.
    a. The productivity of each trophic level (Λ_n) is the rate at which energy enters the trophic level (λ_n) from the next lower level (Λ_{n-1}).
    b. Since organisms expend considerable energy for maintenance, and because death of an organism routes energy and nutrients into the detrital pool, only a portion of the energy of one trophic level is available for transfer and use by higher trophic levels. Available energy decreases progressively at higher trophic levels, so that rarely can more than five or six trophic levels be supported.
    c. The efficiency of energy transfer from one level to the next is low (5–15%) and often decreases as Λ_n increases.
    d. Life-cycle omnivory, where a species uses different resources during different parts of its life cycle, causes consumer–resource dynamics to be coupled in very complex pathways. These feeding heterogeneities decrease the value of the simple trophic level concept.
12. Living organisms constitute only a very small portion of the total organic matter of ecosystems. Most organic matter is nonliving and is collectively called *detritus.*
    a. Detritus consists of all dead particulate and dissolved organic matter. Dissolved organic matter is about 10 times more abundant than particulate organic matter.
    b. Much of the newly synthesized organic matter of photosynthesis is not consumed by animals, but instead enters the detrital pool and is decomposed.
13. Geomorphological and hydrological characteristics of streams form a longitudinally changing gradient within the drainage basin upon which biological communities of different types become adapted.
    a. This template, referred to as the river continuum concept (RCC), changes in a moderately predictable manner from the headwaters to the river mouth.
    b. As materials are displaced downstream, nutrients and other materials cycle as they are utilized, stored, released, and moved downstream. The rates and distance of nutrient cycling in a spiraling pattern change with different biotic and physical conditions.
14. Biomass is the mass (weight) of living material in a unit area at a given instant of time and has the dimensions of mass per unit area or volume.
15. *Production* is a flow or flux of mass or energy over time and has the dimensions of mass per area formed over a period of time and includes any losses from respiration, excretion, secretion, injury, death, and grazing.
    a. Estimates of primary production by photosynthesis can be obtained directly by following changes in oxygen production or rates of inorganic carbon assimilation.
    b. Secondary productivity by invertebrates and vertebrates is difficult to estimate because of complex trophic relationships, changes in diet during the organism's life history, and animal mobility. Productivity measurements of animals are based on changes in numbers, biomass, and growth rates.
    c. The annual time period is the only meaningful interval in comparative quantitative analyses of material and energy fluxes at population, community, and ecosystem levels.
    d. The ratio of production to biomass (P/B ratio) is a weighted mean value of biomass growth rates of all individuals in a population. The P/B ratio estimates the turnover rates of energy flow relative to biomass; P/B values generally decrease with increasing trophic level.

VII. Summary

I. THE OXYGEN CONTENT OF INLAND WATERS

Oxygen is the most fundamental parameter of lakes and streams, aside from water itself. Oxygen dissolved in water is obviously essential to the metabolism of all aerobic aquatic organisms. As a result, the solubility and particularly the dynamics of oxygen distribution in inland waters are basic to the understanding of the distribution, behavior, and growth of aquatic organisms.

The rates of supply of dissolved oxygen from the atmosphere and from photosynthetic inputs, and the hydro-mechanical distribution of oxygen, are counterbalanced by consumptive metabolism by biota and nonbiotic chemical reactions. The rate of oxygen utilization in relation to photosynthesis permits an approximate evaluation of the metabolism of a section of stream or of the lake as a whole.

The resulting distribution of oxygen affects strongly the solubility of many inorganic nutrients. Changes in nutrient availability are governed by shifts from aerobic to anaerobic environments in regions of lakes and of streams. The changes in distribution of nutrients result in rapid growth of many organisms capable of taking advantage of this altered nutrient availability. Population responses may be temporary and transient. If, however, long-term changes in oxygen-regulated nutrient availability are sustained, the productivity of the entire lake or stream can be radically altered. Although oxygen content and dynamics are discussed here largely as a separate entity, its integration with all facets of biotic metabolism will become more apparent in subsequent discussions.

II. SOLUBILITY OF OXYGEN IN WATER

Air contains about 20.95% oxygen by volume, and the remainder is nitrogen, except for a very small percentage of other gases. Because oxygen is more soluble in water than is nitrogen, the amount of oxygen dissolved in water equilibrated with air is greater than nitrogen. The solubility of oxygen is affected nonlinearly by temperature and increases considerably in cold water. The general relationship of oxygen solubility as a function of temperature is given in Table 9-1, although these values are subject to minor modifications as analytical assays improve (extensively discussed in Ohle, 1952; Mortimer, 1956, 1975, 1981; Hutchinson, 1957; Weiss, 1970; and Benson and Krause, 1980). More detailed data are given in the references cited.

The solubility of gases in water is affected by pressure as well as by temperature. Therefore, the

TABLE 9-1 Solubility of Oxygen in Pure Water in Relation to Temperature in Equilibrium with Air at Standard Pressure Saturated with Water Vapor[a]

[a] From Mortimer (1981) after data of Benson and Krause (1980). Unit standard concentrations (C^* by volume in mg liter^{-1} or mg cm^{-3} and $C^\dagger$ by weight in $\mu gat\ kg^{-1}$) of oxygen (1 mole = 31.9988 g) in pure water in equilibrium with air at standard pressure (1 atm = 760 mm Hg = 101.325 Pa) saturated with water vapor and with the dry air mole fraction for oxygen taken as 0.20946. To convert mg to cm^3 (ideal gas S.T.P.) or to μgat, multiply mg by 0.70046 or 62.502, respectively. To convert gat to mol, divide by 2. To convert C^* to $C^\dagger$, at temperature $(t)°$ and with the accuracy of this table, multiply C^* by the density of pure water at $t°$.

equilibrium of oxygen of the atmosphere with the oxygen concentration in the water depends on the atmospheric partial pressure of oxygen. Hence, the elevation of the inland water body also influences the concentrations of oxygen. Saturation is usually considered in relation to the pressure at the surface of the lake or river. The percentage saturation of oxygen in water has been treated extensively by Ricker (1934) and Mortimer (1956, 1975, 1981), both of whom have prepared nomograms to aid in such computations. The latter, from Mortimer, is based upon recent data and is recommended for use (cf. Wetzel and Likens, 2000).

The amount of a gas that will remain in dissolved phase is influenced by the atmospheric pressure to which the lake is exposed, by meteorological conditions, and also by hydrostatic pressure exerted by the stratum of water overlying a particular depth. The amount of gas that can be held in water by the combined atmospheric and hydrostatic pressures at a particular depth is called the *absolute saturation* (Ricker, 1934). The actual pressure, P_z, in atmospheres at a given depth is equal to that at the surface, P_0, + 0.0967 times the depth, z, in meters, or

$$P_z = P_0 + 0.0967z$$

The importance of this relationship lies in the amount of pressure required to prevent the formation of bubbles, which rise and escape to the surface. Such bubbles are a composite of many gases, the most common of which are oxygen derived from photosynthesis and methane resulting from anaerobic decomposition under certain conditions. The degree of supersaturation of oxygen necessary for bubble growth increases with depth and hydrostatic pressure. In still water, bubble growth may occur as a result of oxygen tension at depths greater than about 1 m (Ramsey, 1962a). At greater depth, an unusually high degree of supersaturation is required, as well as an absence of turbulence or internal waves that may induce a depth displacement and change in pressure. Very small bubbles can be stabilized by an adsorbed organic film. Such bubbles, on rising to the surface, either rupture or accumulate on the surface as foam (Ramsey, 1962b). Such small bubbles that are coated with adsorbed organic films can also be transported to the surface by turbulent water movements in streams and accumulate as foam on the surface waters of streams. Depending upon turbulence patterns in lakes, oxygen produced at depths greater than 1–4 m can remain dissolved because of the hydrostatic pressure. Oxygen can accumulate to several hundred percent supersaturation relative to the pressure at the surface of the lake and still be below absolute saturation for this gas at depth.

Salinity also reduces the solubility of oxygen in water and must be considered in analyses of oxygen dissolved in inland saline and brackish waters. Gas influx rates are reduced markedly in saline waters by as much as an order of magnitude to water as saline as that of the Dead Sea (Gat and Shatkay, 1991). Bubble entrapment in turbulence from wave action becomes a dominant mode of gas transport in very saline waters. Oxygen solubility declines exponentially with increases in salt content and is reduced by about 20% in normal sea water and much more in hypersaline waters as compared to the amount in fresh water. Tables and a nomogram for oxygen saturation in saline water are given in Green and Carritt (1967) and Weiss (1970) and for hypersaline waters in Sherwood *et al.* (1991, 1992).

The methodology for oxygen analyses is treated elsewhere in great detail (e.g., Welch, 1948, Golterman, 1969; Wetzel and Likens, 2000; Standard Methods, APHA, 1998). The mainstay of oxygen analysis is the Winkler method, based on chemical fixation of the dissolved oxygen and colorimetric titration against reagents of known reaction with changing concentration. Numerous compounds, such as iron, nitrates, and organic matter, significant in polluted waters, can interfere and modifications are needed. In inland saline waters, other chemical methods must be used (Walker et al., 1970; Ellis and Kanamori, 1973). Recent advances in electrode technology now allow reasonably accurate direct measures of oxygen, particularly with microelectrodes, with which nearly instantaneous, continuous measurements are possible (e.g., Revsbech and Jørgensen, 1986).

III. DISTRIBUTION OF DISSOLVED OXYGEN IN RUNNING WATERS

The oxygen content within small, turbulent streams in approximately at, or somewhat above, saturation. Concentrations decline during summer months, as equilibrium solubility declines with increasing temperatures. However, as described later for lake ecosystems, the oxygen content of running waters is modified markedly by chemical and biological processes. Among larger rivers, marked variations in oxygen concentrations occur both spatially and temporally and are often coupled directly to discharge and loadings of organic matter. For example, in backwater areas of reduced current velocities and turbulence, residence times of water are longer and allow for greater alterations of oxygen content from either photosynthetic enrichment or respiratory reductions. Oxygen consumption can be large from direct chemical reactions with dissolved organic compounds of natural or human-related sources or from aerobic respiration of microbial degradation of these compounds. Oxygen demand increases in sites and during times of increased loading of organic matter. For example, during periods of increased leaf fall into heavily canopied streams, increased dissolved organic matter leaching from the leaves can enhance chemical and microbial utilization of dissolved oxygen. Dissolved organic matter leached from soils following precipitation events, or from marsh or swamp areas or loaded from organic sewage sources can similarly cause increased microbially mediated consumption of oxygen (Schneller, 1955; Hynes, 1960; Slack, 1964). In very productive wetland flood plains, as in the Pantanal wetland of the Paraguay River, high rates of organic matter decomposition can lead to high bacterial production of methane (see Chap. 21) (Hamilton et al., 1995, 1997). Bacterial methane oxidation can result in dissolved oxygen reduction or even depletion in backwater areas.

Ground water is often largely or completely devoid of oxygen as a result of chemical oxidations, bacterial respiration, and organic matter as water passes through soils toward stream channels. Groundwater influents are often totally deoxygenated. As anoxic or depleted water passes through hyporheic sediments, reaeration occurs from the stream water. Often, however, only a few millimeters of the upper sediment are well oxygenated.

Photosynthetic activities of algae and macrophytes can increase oxygen concentrations on a diurnal basis, particularly in relatively sluggish streams and rivers (Müller and Weise, 1987; Livingstone, 1991). In nutritionally enriched and productive streams, the magnitude of diurnal oscillations in dissolved oxygen concentrations can increase (Fig. 9-1). Bacterial and plant respiration can be most effective in reducing oxygen concentrations at night. Quantification of the diurnal changes in rates of oxygen production and consumption in a defined section of river has been used as a measure of photosynthetic production (cf. Wetzel and Likens, 2000, and APHA, 1998, for methodology). Oxygen consumption can also occur in lighted reaches of streams and rivers by photochemical oxidation of dissolved organic compounds (cf. review of Brezonik, 1994). Dissolved humic and other organic substances can function as sensitizers of photochemical reactions but also can absorb light and photolyze directly with the consumption of oxygen (e.g., Laane, *et al.*, 1985).

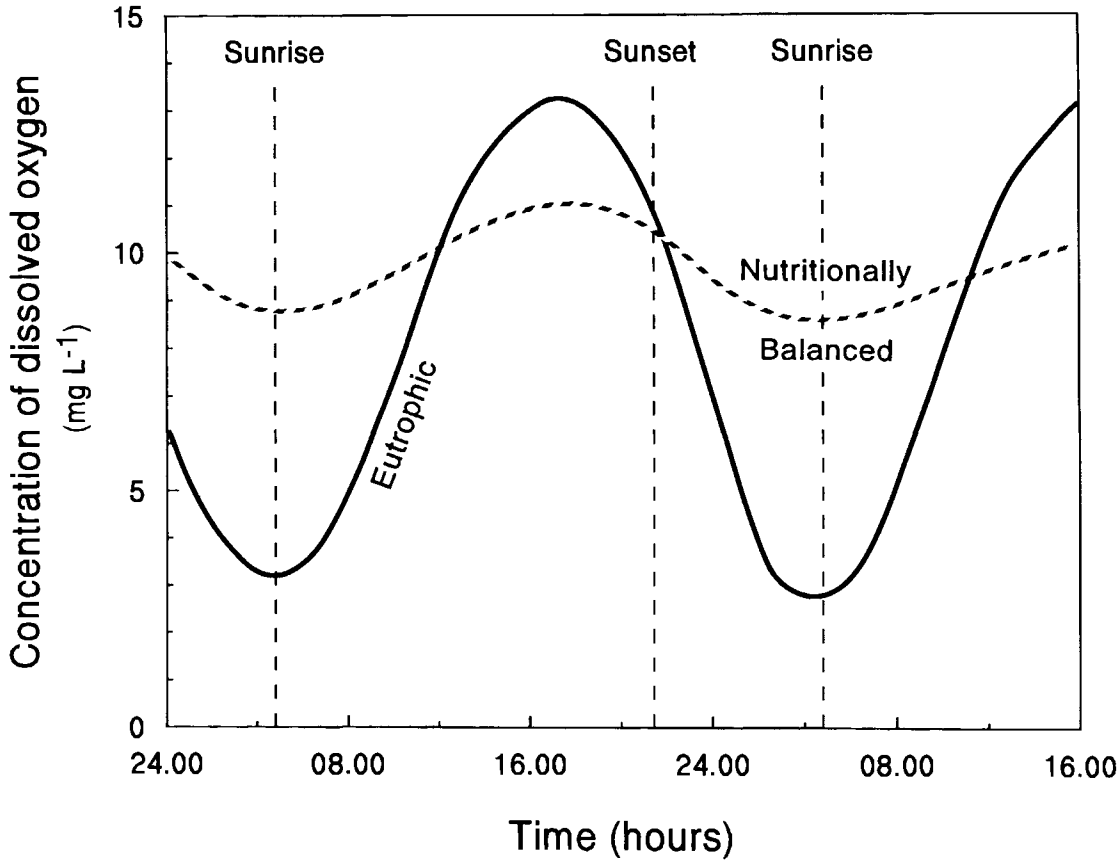

FIGURE 9-1 Diurnal cycle of dissolved oxygen concentrations in a nutritionally balanced and eutrophic stream. (From Walling and Webb, 1994, after data of Gower, 1980.)

IV. DISTRIBUTION OF DISSOLVED OXYGEN IN LAKES

Diffusion of gases into water is a very slow process. To establish an equilibrium between the atmosphere and dissolved oxygen within a reasonable period of time, the water must circulate, as it does during periods of turnover or in the epilimnion of stratified lakes. If the dissolved oxygen concentrations at depth are near saturation, equilibrium at prevailing temperatures and altitudinal pressure is established relatively quickly, usually in a matter of a few days. Very deep lakes, however, require longer periods for complete equilibrium saturation, and saturation may or may not be achieved before thermal stratification effectively terminates circulation for a seasonal interval.

In an idealized lake, the oxygen concentration at spring circulation is at or near 100% saturation, which would be between 12 to 13 mg O_2 liter^{-1} if occurring at about 4°C and at an altitude near sea level (Fig. 9-2). This ideal concentration at 100% saturation is based on physical control of diffusion, mixing, and saturation. Deviations are common, most frequently in the form of a slight supersaturation from photosynthetic activity in which dissolved oxygen is in excess of evasion to the atmosphere. Alternatively, biochemical oxidations can result in undersaturation during conditions where oxygen consumption slightly exceeds inputs from circulation equilibrium mechanisms. The near-surface waters of lakes containing large amounts of dissolved organic matter, such as dystrophic bog lakes or standing waters of wetlands, are often appreciably undersaturated with dissolved oxygen.

A. Orthograde Oxygen Profile

Where the lake is ***oligotrophic*** (low in nutrient inputs with low organic production), oxygen concentrations with depth are regulated largely by physical processes during summer stratification. The oxygen concentration in the circulating epilimnion decreases as the temperatures gradually increase (Fig. 9-2). Accompanying decreasing temperatures in the metalimnion and hypolimnion, the oxygen concentrations increase,

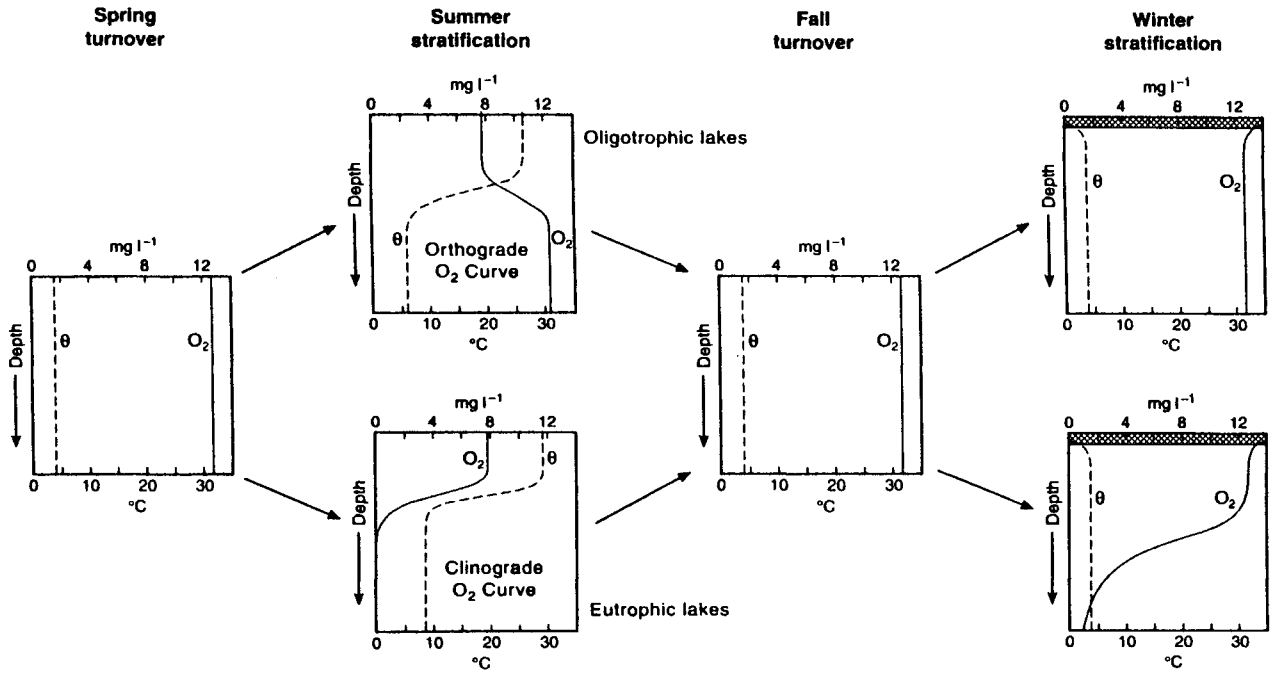

FIGURE 9-2 Idealized vertical distribution of oxygen concentrations and temperature (Θ) during the four main seasonal phases of an oligotrophic and a eutrophic dimictic lake.

that is, they have remained in the hypolimnion essentially at saturation from the period of cold spring turnover just before the summer stratification began. This oxygen profile has been termed (Åberg and Rodhe, 1942) ***orthograde.*** The important characteristic to note is that the percentage of saturation is more or less 100% with increasing depth.

B. Clinograde Oxygen Profile

An idealized orthograde curve is found only in a few extremely unproductive lakes or in moderately oligotrophic lakes during the very early stages of summer stratification. Oxidative processes occur constantly in the hypolimnion, and their intensity is proportional to the amount of organic matter reaching the hypolimnion from the upper zones of the lake. As a result, the oxygen concentrations of the hypolimnion become progressively more reduced and undersaturated. The oxygen content of the hypolimnion of ***eutrophic*** (high in nutrient loading with high organic production) lakes is depleted rapidly by oxidative processes. The resulting profile, in which the hypolimnion is often anaerobic, is termed ***clinograde*** (Fig. 9-2). The hypolimnetic oxygen content of highly eutrophic lakes is often depleted after only a few weeks of summer stratification. The hypolimnion remains anaerobic throughout this stratification period.

Loss of oxygen from the hypolimnion results primarily from biological oxidation of organic matter, both in the water and especially at the sediment–water interface, where bacterial decomposition is greater. Although plant and animal respiration can consume large, often biologically catastrophic, amounts of dissolved oxygen, major consumption from the lake is associated with bacterial decomposition of dissolved and of sedimenting particulate organic matter (Seto *et al.*, 1982). Oxygen consumption in the free water by bacterial respiration is intensive at all depths but in the hypolimnion is rarely offset by the oxygen renewal mechanisms of circulation and photosynthesis that occur in the epilimnion and metalimnion. Oxygen consumption is most intense at the sediment–water interface, where the accumulation of organic matter and bacterial metabolism are greatest. The interface region very rapidly becomes anaerobic during summer stratification, and the hypolimnetic depletion is usually observed first at the lowermost stratum of the hypolimnion. Diffusion of oxygen into this depleted zone from overlying layers occurs slowly. The horizontal distribution of the oxygen profile in the hypolimnion can be modified by vertical turbulence, horizontal translocations, and density currents that move along the basin sediments.

In addition to oxygen consumption by animals, plants, and particularly by bacterial respiration in the open water, chemical oxidation of dissolved organic

matter occurs. Lakes highly stained with humic organic compounds are frequently undersaturated even in epilimnetic strata. Although many mechanisms can be involved, at least some of the oxygen uptake results from purely chemical oxidations and from photochemical oxidations induced by ultraviolet light (e.g., Gjessing and Gjerdahl, 1970; Laane *et al.*, 1985; Brezonik, 1994; Wetzel *et al.*, 1995). These chemical oxidation processes are likely masked in very productive waters by the intense bacterial biochemical demands for oxygen.

The relative importance of different mechanisms of hypolimnetic oxygen depletion varies from lake to lake. In large, deep lakes, bacterial respiration of organic matter of phytoplanktonic origin may dominate, and benthic decomposition then will play a minor role. In shallow lakes with relatively large inputs of organic matter from terrestrial, stream, wetland, and littoral sources, decomposition of allochthonously derived dissolved organic matter and benthic particulate organic matter dominate (e.g., Melack and Fisher, 1983). And in highly stained bog lakes that receive large inputs of dissolved humic compounds, chemical oxidations may assume greater significance. Accompanying the shift from an aerobic to an anaerobic hypolimnion, a large, often major volume of the lake is excluded from habitation by most animals and many plants. Another major change is the shift from aerobic to anaerobic bacterial metabolism, which reduces the overall efficiency of the decomposition of organic matter.

Fall overturn begins with the complete loss of summer stratification. During the terminal stages of stratification, with progressive deepening of the epilimnion, the circulation of approximately oxygen-saturated water extends deeper into the hypolimnion. When circulation is complete, oxygen concentrations remain at saturation in accordance with solubilities at existing temperatures (Fig. 9-2).

As ice forms, the exchange of oxygen with the atmosphere ceases for all practical purposes. Based on solubility relationships, one would expect an oxygen concentration profile essentially at saturation in relation to temperature at any given depth. Such would be the case in an ultra-oligotrophic lake where biotic influences are minor. These profiles are very rarely found in

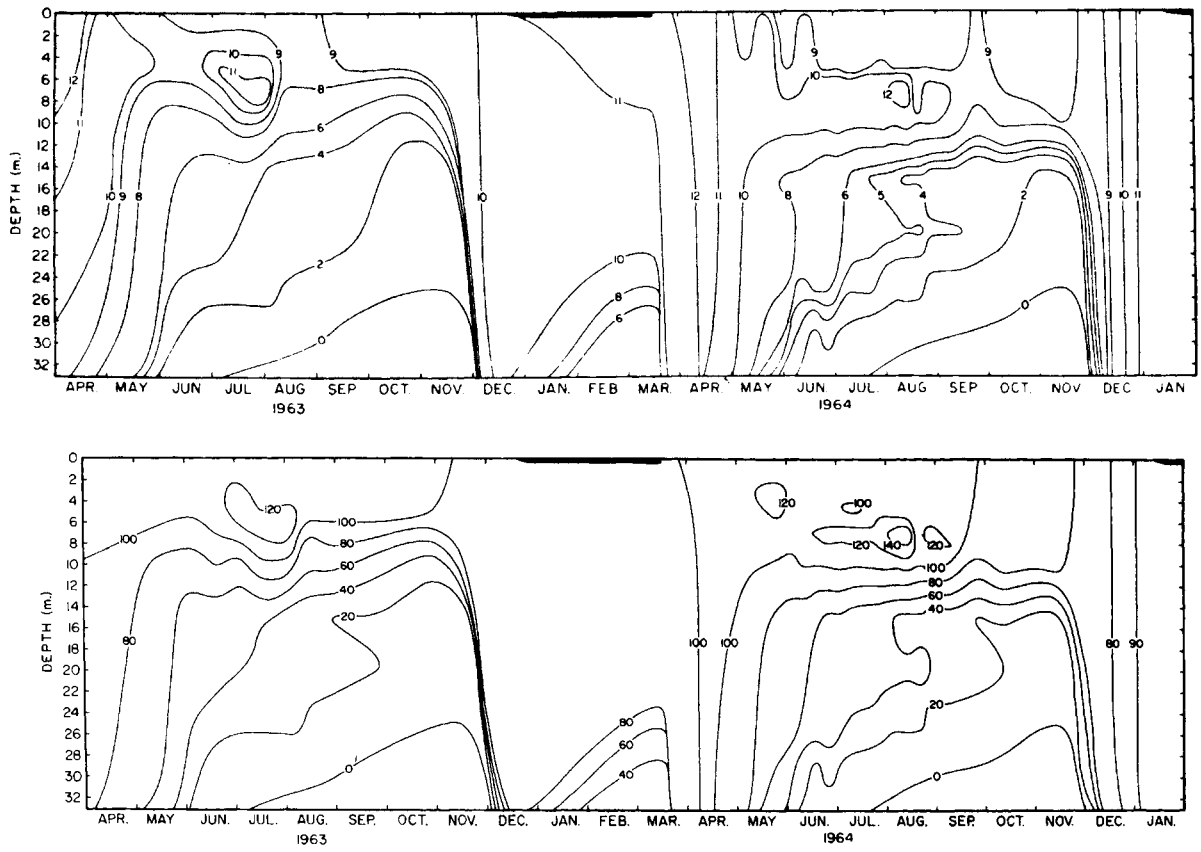

FIGURE 9-3 Depth–time diagram of isopleths of dissolved oxygen concentrations in mg liter^{-1} (*upper*) and percentage oxygen saturation (*lower*), Crooked Lake, Whitley County, northeastern Indiana. Ice cover drawn to scale. (From Wetzel, unpublished data.)

dimictic lakes. Much more frequently observed is a reduction in oxygen concentration with depth, which becomes particularly acute near the sediment.

In eutrophic lakes, photosynthetic production of organic matter, although less than in other seasons, continues throughout the winter and is often vigorous during the later stages of winter ice cover. Light penetration is variable with changing conditions of ice and snow cover, but the photic zone generally is confined to the upper layers. Respiratory utilization and chemical oxidations increase with depth as during summer stratification, although at a lower rate because of the lower temperatures. During winter, the water of the main water mass under ice is commonly colder than 4°C. Water in the littoral areas can be heated slightly through the ice by solar radiation. This warmer, slightly denser water will sink and flow in profile-bound density currents along the sediments to the deeper portions of the basin. Generally, water movement is sufficiently slow so that en route, the oxygen of this water is reduced or depleted as it passes over the sediment–water interface. At the bottom of depressions it displaces water upward and results in a conspicuous depletion at the sediment–water interface, accentuating the decompositional utilization already occurring there.

The stages of the annual cycle just discussed can be illustrated by isopleths of oxygen concentration and percentage saturation for an atypical dimictic lake of moderate productivity (Fig. 9-3). Noteworthy are the high concentrations (near 100% saturation) during the colder periods of spring and fall circulation. Epilimnetic concentrations of oxygen were reduced but, because of reduced solubility in the warmer water, were still at saturation. The high concentrations in the metalimnion were the result of photosynthesis and will be discussed in detail later. The slow, progressive reduction and final depletion of oxygen in the lower hypolimnion is seen in mid- and late summer. The same reduction, but not depletion, is seen under ice cover at the greater depths in Crooked Lake. More extreme changes are seen in the oxygen concentrations of smaller eutrophic Little Crooked Lake (Fig. 9-4), in which the changes were similar to those of Crooked Lake but were greater and more accelerated.

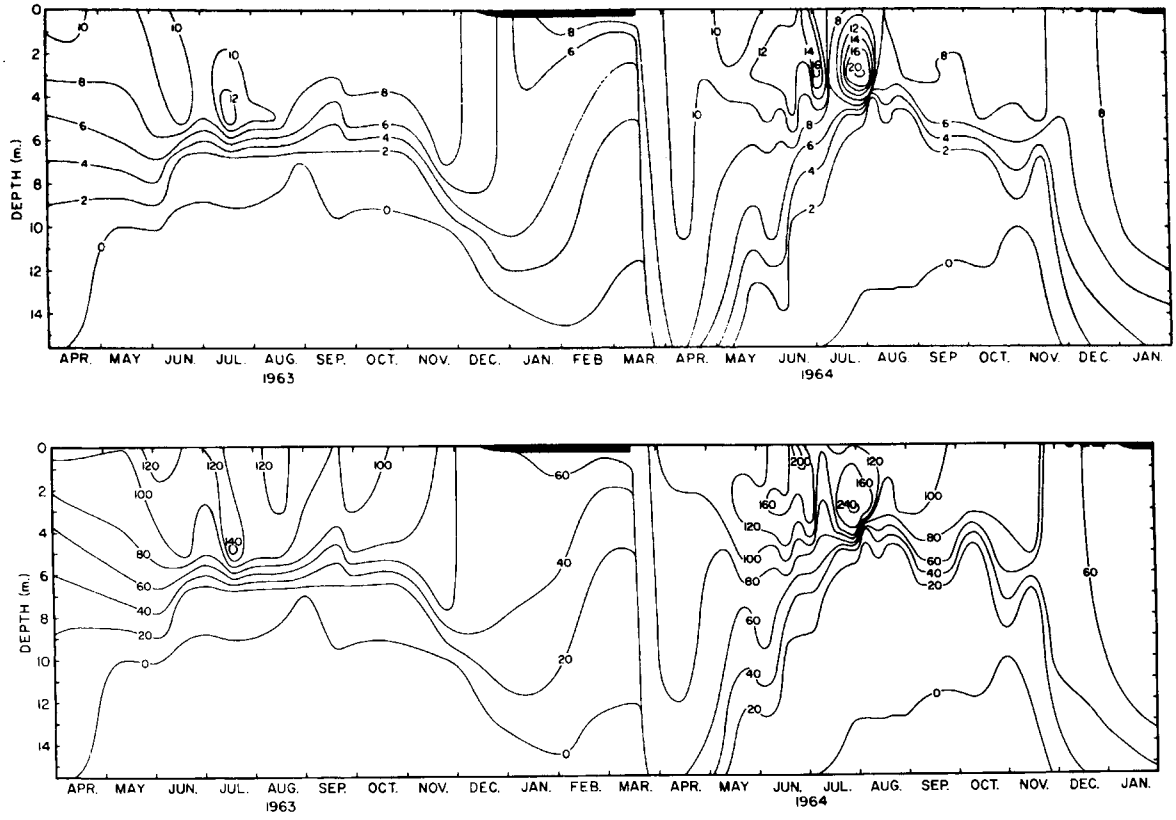

FIGURE 9-4 Depth–time diagram of isopleths of dissolved oxygen concentrations in mg liter^{-1} (*upper*) and percentage oxygen saturation (*lower*), Little Crooked Lake, Whitley County, northeastern Indiana. Ice cover drawn to scale. (From Wetzel, unpublished data.) Isopleth lines appear to merge where gradients are extremely steep; in reality, the lines are separated by small depth–time intervals.

V. VARIATIONS IN OXYGEN DISTRIBUTIONS

A. Metalimnetic Oxygen Maxima

Variations in the vertical and horizontal distributions of dissolved oxygen from the general conditions just discussed are often observed. The most common variation is an increase in oxygen in the metalimnion during stratification (Figs. 9-3, 9-4, 9-5, and 9-6); the metalimnetic maximum is referred to as a ***positive heterograde curve*** (Åberg and Rodhe, 1942). As the solubility of the epilimnetic water decreases with increasing summer temperatures, and oxygen consumption in the hypolimnion results in the typical clinograde reduction with depth, the result is an absolute oxygen maximum in the metalimnion, which may be at or above saturation.

Metalimnetic oxygen maxima often are extremely pronounced, with supersaturated values above 200% (Fig. 9-4). Concentrations of nearly 36 mg O_2 liter^{-1} (400% saturation) have been recorded (Birge and Juday, 1911). It is clear that the maxima are nearly always the result of oxygen produced by algal populations that develop more rapidly than they sink out of the lower water strata (Fig. 9-5a). The algae are commonly stenothermal,

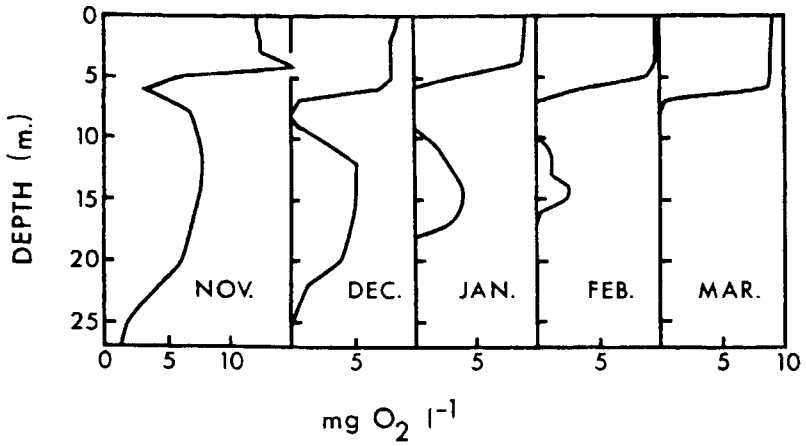

FIGURE 9-6 Depth profiles of dissolved oxygen concentrations during the summer (Southern Hemisphere) in hypereutrophic Lake Johnson, New Zealand, 1970–1971. Similar distributions were observed in the summers of 1969–1970, 1971–1972, and 1974. (Modified from Mitchell and Burns, 1979.)

adapted to growing well at low temperatures and low light intensities but having access to nutrient concentrations that are usually higher in the lower metalimnion than in the epilimnion. Cyanobacteria, especially *Oscillatoria*, are often major contributors to this phenomenon (Eberly, 1959, 1963, 1964; Wetzel, 1966a, 1966b). The depth at which metalimnetic oxygen maxima occur is correlated directly with the transparency of the water (Thienemann, 1928; Yoshimura, 1935). In most lakes metalimnetic maxima are found between 3 to 10 m, but in very clear lakes at depths as great as 50 m.

Extreme metalimnetic oxygen maxima are observed much more frequently in lakes that are strongly stratified. Such lakes commonly have high relative depths,[1] that is, their surface area is small relative to their maximum depth, and they are protected from intense wind action by surrounding topography and vegetation. The average peak in oxygen concentration and relative depth of over 50 lakes that exhibited extreme metalimnetic maxima was 17.2 mg liter^{-1} and 4.30% respectively (Eberly, 1964). Most lakes have a relative depth of <2%.

Metalimnetic oxygen maxima occur in many lakes. When characteristics of morphometry and biota are suitable for their development, the maxima occur consistently from year to year at approximately the same time and depth. For example, in Lawrence Lake, Michigan, the metalimnetic maximum occurred between 4 and 6 m, July through August, for 20 consecutive years of observation (Wetzel, unpublished). The oxygen maxima were superimposed exactly over maxima of photosynthesis by phytoplankton and summer growth maxima of dense beds of rooted aquatic plants on the steep slopes of the littoral zone (Rich *et al.*, 1971). It is likely that water in the littoral zone, enriched with oxygen, dissipates into the metalimnion layer of equal density and contributes to the observed oxygen peak. Ruttner (1963) and Dubay and Simmons (1979) reported a similar situation in small, clear lakes with precipitous slopes, in which the metalimnetic oxygen maximum coincided seasonally with zones of maximum production of submersed macrophytes.

B. Metalimnetic Oxygen Minima

The converse condition, a ***metalimnetic oxygen minimum*** exhibiting a ***negative heterograde curve*** (Fig. 9-5b), is much less frequently observed. Numerous causal mechanisms have been associated with such metalimnetic reductions, and most or all are likely to be in effect simultaneously in situations where such oxygen minima are observed. To single out one mechanism as operational to the exclusion of others (as, e.g., Czeczuga, 1959) can be misleading.

Oxidizable material produced in the epilimnion or brought into the lake from outside the basin continuously sinks. Sinking rates slow when it encounters denser metalimnetic water, which allows more time for decomposition (Birge and Juday, 1911; Thienemann, 1928). Organic matter introduced into reservoirs from storm water can flow, depending on water temperatures and densities, in the metalimnion, as interflow, and contribute to accelerated oxygen reduction in the metalimnion (Nix, 1981). Moreover, decomposition rates are usually higher in the metalimnion, where temperatures are greater than in the colder hypolimnion. As a result, more readily oxidizable organic matter is decomposed at this level, with concomitant consumption of oxygen by bacterial respiration; more resistant organic matter settles slowly into the hypolimnion (Kuznetsov and Karsinken, 1931; Vinberg, 1934; Åberg and Rodhe, 1942). In a review of the subject, Czeczuga (1959) presented some evidence from a lake in which, conversely, decomposition rates were greater in the epilimnion. However, renewal of epilimnetic oxygen and time of residence of sedimenting organic matter in the metalimnion were not clearly delineated. It is clear that a balance between the transparency of the trophogenic zone and the depth of the metalimnion is important in relation to the depth at which photosynthetic maxima occur and in relation to whether oxygen inputs are sufficient to offset decompositional consumption (Ruttner, 1933). It is easy to conceive of a situation in which a pronounced metalimnetic maximum could shift to a minimum within a summer season (Fig. 9-6).

In certain situations, concentrations of massive numbers of zooplanktonic microcrustacea in the metalimnion can contribute to a severe reduction of oxygen. Such respiratory consumption was most likely a major cause of the metalimnetic minima observed in Zürichsee, Switzerland (Minder, 1923), and the same condition can prevail in Lake Washington (Fig. 9-5b), where nonmigrating copepods often develop profusely in late summer (Shapiro, 1960). In the extreme case shown in Figure 9-6, less than 10 percent of the metalimnetic oxygen minimum was accounted for by zooplankton respiration (Mitchell and Burns, 1979). The metalimnetic anoxia was apparently caused mainly by intensive bacterial decomposition.

The basin morphometry of a lake can also contribute to metalimnetic oxygen minima. In cases

[1] Relative depth, or z_r, is an expression of the maximum depth (z_m) as a percentage of the mean diameter and is determined by

$$Z_r = \frac{50 z_m \sqrt{\pi}}{\sqrt{A_0}}$$

where A_0 is the surface area.

where the slope of the basin is gentle and where it coincides with the prevailing metalimnion, a greater area of the sediments with high bacterial utilization of oxygen will be in contact with metalimnetic water than is the case of sediments adjacent to the lower strata. Horizontal mixing and streaming of water from internal water movements is greatest in the metalimnion, where vertical density stability is greatest. As a result, reduction in oxygen content at the sediment–water interface is greater where the slope of the sediments is less. The oxygen reduction in the metalimnion may be sufficient to extend laterally over the entire lake, or, as in the case of Skärshultsjön, Sweden (Alsterberg, 1927), it may occur more strongly in the metalimnion closer to the sediment–metalimnion interface.

Biogenic oxidation of methane by methane-oxidizing bacteria can result in metalimnetic oxygen minima in certain productive lakes (Kuznetsov, 1935, 1970; Ohle, 1958). Methane from anaerobic fermentation in sediments rises from the sediments and is carried to water strata such as the metalimnion, where, with warmer temperatures and greater oxygen, methane oxidation can occur rapidly. In such cases, severe oxygen reduction can occur in a few days if adequate dissolved inorganic nitrogen is available (Rudd *et al.*, 1975, 1976).

C. Distribution in Meromictic Lakes

Extreme clinograde oxygen profiles occur in permanently stratified meromictic lakes (Fig. 9-5c). The permanent monimolimnion receives constant inputs of organic matter or sulfates from saline water, which rapidly deplete any oxygen intrusions.

Temporary (partial) meromixis, discussed in Chap. 6, can lead to highly variable, anomalous oxygen distributions. If a normally dimictic lake is quite productive, a strongly developed clinograde oxygen distribution during both summer and winter stratification would be anticipated, often with anaerobic deeper layers in both seasons. If spring or fall circulation and renewal of oxygen is incomplete before stratification is imposed, the reduced or anaerobic conditions of the lower strata will be carried over to the next stratified period and be further reinforced. Such was clearly the case in Little Crooked Lake in the autumn of 1963 (Fig. 9-4). Mixing was incomplete in Lawrence Lake in the spring of 1968 (Fig. 9-7), which resulted in an accentuated reduction of the hypolimnetic oxygen the following summer and anoxia below 11 m for three months. In normal years with complete spring circulation, as in the following four years (cf. Wetzel *et al.*, 1972), the hypolimnion did not become anaerobic—or only very briefly—just before fall turnover in a half-meter stratum immediately overlying the sediments. In 1973, incomplete mixing occurred again in the spring and resulted in an oxygen distribution pattern similar to that of 1968. Over a 19-year period of study, Lawrence Lake experienced temporary meromixis and enhanced hypolimnetic oxygen reductions every 3–4 years. The chemical nutrient and biotic implications of aerobic and anoxic hypolimnia are very important for the productivity of lakes and will be pursued in detail subsequently.

Oxygen concentrations of many perennially ice-covered lakes of Antarctica are persistently supersaturated. Oxygen carried into the lakes in glacial meltstreams is concentrated as water is removed as ice by ablation and sublimation (Wharton *et al.*, 1986).

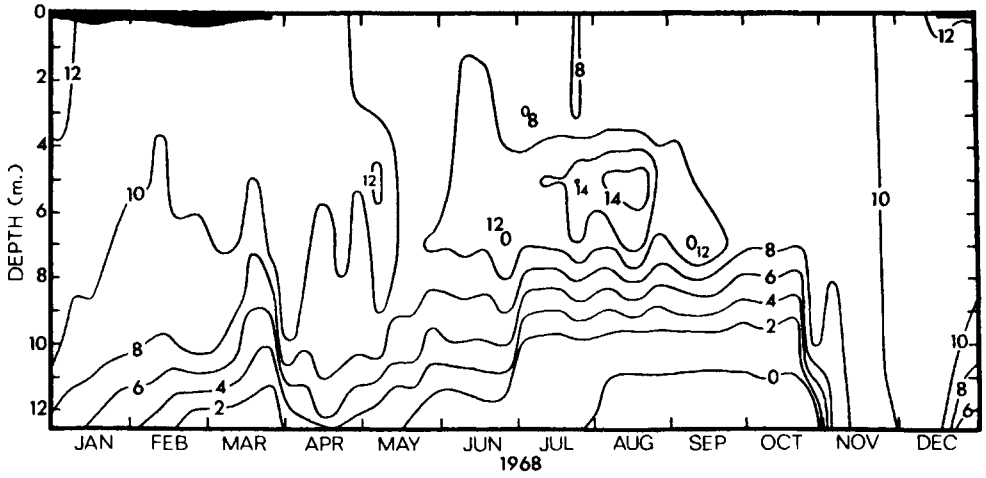

FIGURE 9-7 Depth–time diagram of isopleths of dissolved oxygen concentrations in mg liter $^{-1}$ of Lawrence Lake, Michigan, 1968. Ice cover drawn to scale. (From Wetzel *et al.*, 1972.)

D. Horizontal Variations and Diurnal Cycles

Horizontal spatial variations in the distribution of dissolved oxygen of the open-water pelagic zone of natural lakes are generally small during periods of spring and fall circulation. This situation can change during the productive summer periods and under ice-cover. Littoral aquatic plants often inhabit large areas of more productive lakes, to a depth of 3 to as much as 10 m. Photosynthesis of these macrophytes and of sessile algae growing attached to them and to the sediments can generate large amounts of oxygen. Similarly, large quantities of oxygen are utilized in respiration at night and by littoral bacteria in a zone rich in dissolved and particulate organic matter. The oxygen regime of the littoral zone is usually totally different from that of the open water and experiences marked diurnal cycles (Fig. 9-8). Moreover, the vertical distribution within the vascular plant beds can be highly stratified in accordance with the macrophyte portions that are actively photosynthesizing (often the upper foliage) or those lower parts that are predominately respiring (Fig. 9-8).

The oxygen content of the littoral zone is periodically severely reduced (e.g., Pokorný *et al.*, 1987). Such is the case when large populations of macrophytes (vascular hydrophytes and macroalgae) senesce and die at the end of their growing season. Severe oxygen deficits caused by intense decomposition can persist for several months and may extend from the littoral zone into the open water for some distance (Thomas, 1960). In shallow lakes where submersed hydrophytes grow over the entire basin, decomposition of the macrophytes and attached microflora at the end of the growing season, in late summer when temperatures are still high, can be so intense that the oxygen content of the entire lake may be severely reduced to near anoxia. Such a catastrophic event can result in massive die-offs of many animals; occasionally entire fish populations are lost in such a ***summerkill.***

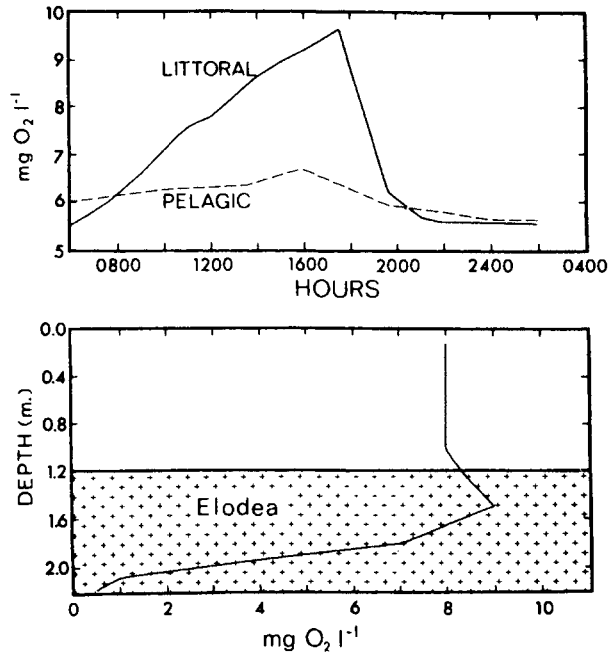

FIGURE 9-8 Upper: Changes in dissolved oxygen in the littoral and open-water areas over a diurnal period in eutrophic Winona Lake, Indiana, 9 August 1922. (From data of Scott, 1924.) *Lower*: Vertical stratification of oxygen within the littoral zone of Parvin Lake, Colorado, 9 July 1955, in a luxuriant stand of the submersed macrophyte *Elodea*. (Generated from data of Buscemi, 1958.)

Where lakes are extremely eutrophic, phytoplankton and attached algae often occur in such profusion that they severely attenuate light, and submersed macrophytes are limited to very shallow areas. Under such conditions, diurnal fluctuations in oxygen concentrations of the epilimnion are often just as marked as those of the littoral zone, as shown in Figure 9-8. Changes of 4 to as much as 6 mg O_2 liter^{-1} are seen commonly between early morning darkness and midafternoon (e.g., Lingeman *et al.*, 1975; Pokorný, *et al.*, 1987). Under clear ice cover in such productive waters, oxygen can accumulate and commonly result in diurnal supersaturation. Oxygen analyses in surface waters of productive waters undergoing rapid diurnal changes, when taken only at one time of day, show only one stage of a much more complex situation.

Large horizontal variations in oxygen content are also found in lakes of complex basin morphometry. When a lake consists of many bays or multidepressions, oxygen concentrations are very different in these areas, and each embayment may operate essentially as an individual lake (Welch and Eggleton, 1932; Wetzel, 1966a; Lind, 1987).

In reservoirs, oxygen distribution becomes highly variable horizontally, vertically, and seasonally (Straškraba *et al.*, 1973; and the detailed review of Cole and Hannon, 1990). The complex hydrodynamics of reservoirs are unique in relation to variations in influents, morphometry, draw-down and discharge, and other factors. In addition, seasonal variations in influxes of organic matter from inflowing streams can place varying oxidative demands on the oxygen content of reservoirs.

As a result of the interactions of natural and regulated flow dynamics, temperature, morphology, and community metabolism, a hypolimnetic anoxic zone often develops following the vernal stratification that is common in deep-storage reservoirs. The hypolimnetic anoxic zone develops first in the thalweg of the transition zone during summer stratification and then

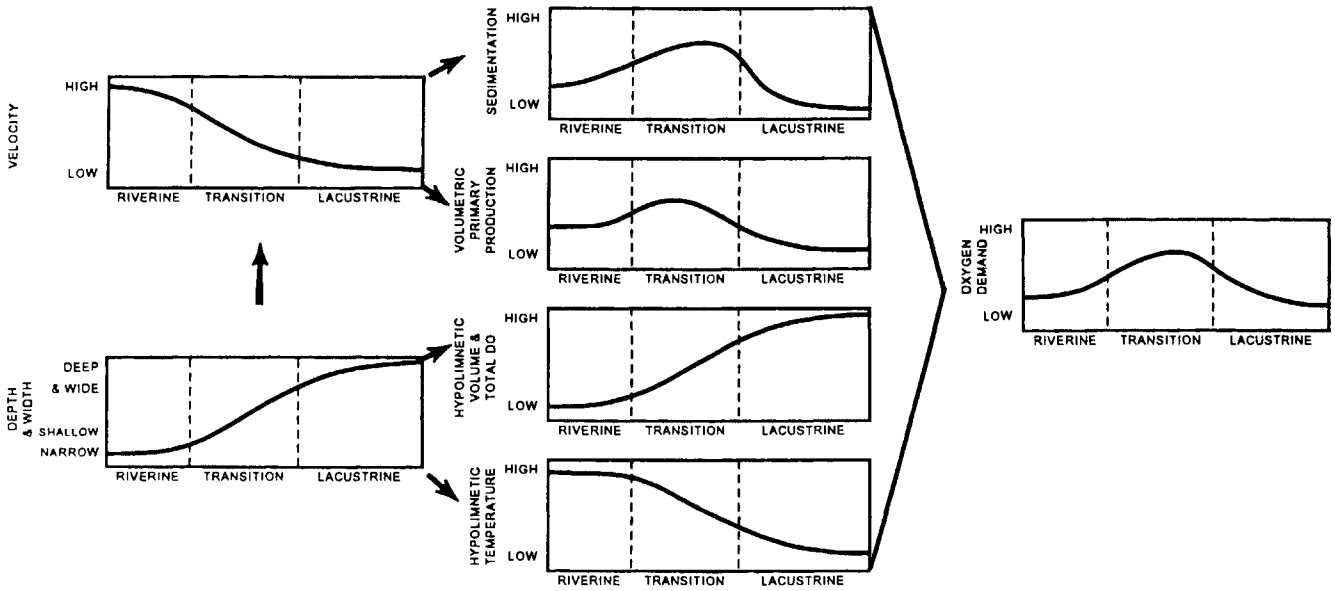

FIGURE 9-9 Relationships of velocity and depth to sedimentation, areal primary production of phytoplankton, hypolimnetic volume and total dissolved oxygen (DO), and hypolimnetic temperature in determining oxygen demand along the length of a reservoir. (Modified from Cole and Hannon, 1990.)

expands horizontally and vertically (Fig. 9-9). The time of onset of hypolimnetic anoxia is regulated largely by meteorological conditions that vary over the year in relation to geographic location. As in natural lakes, the distribution of oxygen and rates of loss are governed by a balance among mixing, inflow intrusions, photosynthesis, and losses by oxidative consumption. The processes are similar among all freshwater ecosystems, but the rates of change in reservoirs are generally much more variable and dynamic than in lakes (Table 9-2).

Horizontal variations in oxygen are particularly conspicuous in the winter under ice cover, especially in the near-surface strata. Fluctuations were noted earlier in response to seasonal changes in photosynthesis (Figs. 9-3, and 9-4). Photosynthesis by algae is strongly suppressed by snow cover on ice, but often accumulated snow cover is very patchy on the surface of windswept ice (Chap. 5, pp. 63ff). The result is variegated photosynthesis and oxygen production below the ice. Heavy snow cover can plunge the lake into virtual darkness; if sustained for several weeks, heavy respiratory demands by decomposition can reduce the oxygen content to very low levels or to anoxia (Greenbank, 1945). The resulting conditions are intolerable to many animals. For example, most fish cannot survive, even at low

TABLE 9-2 Comparison of Dissolved Oxygen Dynamics among Running and Standing Waters[a]

Parameter	*Rivers*	*Reservoirs*	*Lakes*
Dissolved Oxygen	Usually high	Somewhat lower solubilities (higher temperatures); greater horizontal variability with inflow, withdrawal, and POM loading patterns; metalimnetic oxygen minima more common than maxima	Somewhat higher solubilities (lower temperatures); small horizontal variability except in littoral zones; metalimnetic oxygen maxima more common than minima
Oxygen uptake from atmosphere	High	Moderate	Variable to low
Diurnal variations of dissolved oxygen	High, coupled to photosynthesis, respiration, and decomposition	Modest in eutrophic reservoirs	Usually low, can be large in littoral areas

[a] Modified from Ryder and Pesendorfer (1989) and Wetzel (1990a).

temperatures, at less than 2 mg O_2 liter^{-1}. Low oxygen concentrations can lead to selective fish mortality with profound effects on intraspecific population structure (Casselman and Harvey, 1975) and community relationships in subsequent years. Alterations of food-web structure by selective fish mortality in which planktivorous predation is altered can lead to marked differences in zooplanktonic community composition, size structure, and grazing impacts. For example, winterkills eliminated carnivorous fishes of a small eutrophic lake of southern Michigan, which led to domination of the fish community by a small, planktivorous cyprinid minnow (Hall and Ehlinger, 1989). The zooplankton, previously consisting of two large *Daphnia* species, concomitantly shifted to a community of smaller species. Such ***winterkill*** conditions of low winter oxygen concentrations are common in shallow eutrophic lakes and becomes particularly acute at mean depths of < 3 m (e.g., Barica and Mathias, 1979).

Empirical models have been developed for shallow eutrophic lakes that allow estimations of the probable risk of rapid oxygen reductions, based on maximum midwinter ammonia–nitrogen and maximum summer phytoplankton development by chlorophyll *a* concentrations, that can lead to summerkill of fishes (Barica, 1984). A model was also prepared to estimate the probability, based on oxygen depletion rates under ice cover, mean depth of the lake, and length of ice cover, of winterkill of fishes. Risk increases greatly in shallow lakes with a mean depth < 4 m.

An example of the rapid seasonal changes in oxygen concentrations that can occur can be seen in Green Lake, a small reservoir lake in southern Michigan (Fig. 9-10). In early February, heavy ice and snow cover had severely reduced photosynthesis and the oxygen content of the lake, except in the area immediately adjacent to the small inlet. Three days later, following late winter rains on deteriorating ice, conditions had improved, although horizontal variations in oxygen concentrations still were conspicuous. A week later, oxygen brought in primarily from increased flow of the inlet had virtually obliterated the former distribution.

Methane and hydrogen can be formed in anaerobic sediments of productive lakes in sufficient quantities to bubble up and rise to the surface. Rossolimo (1935) and Kuznetsov (1935) have shown that the methane (CH_4) and hydrogen (H_2) are effectively oxidized by bacteria in water. Under ice cover, this oxidation can cause severe reductions in oxygen content (Fig. 9-11). Generation of these two gases, and oxygen utilization,

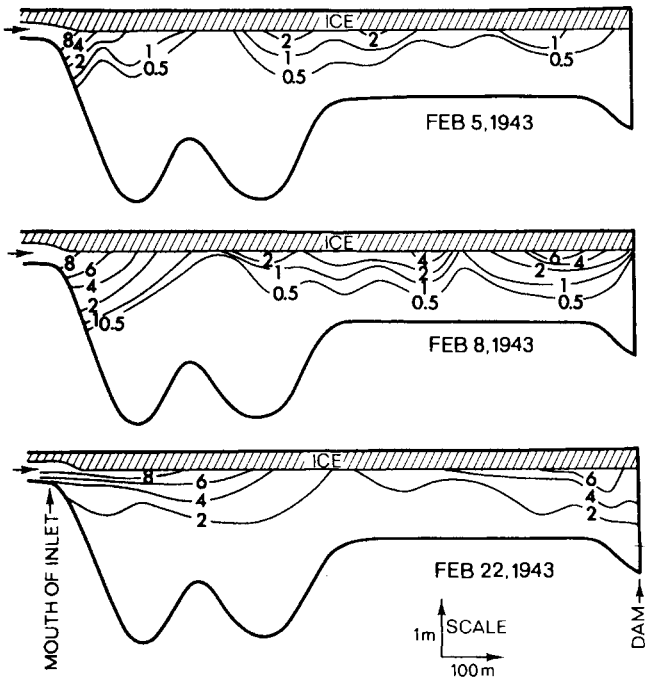

FIGURE 9-10 Horizontal isopleths of oxygen concentrations (mg liter^{-1}) during a two-week period in Green Lake, Michigan, winter 1943. (Modified from Greenbank, 1945.)

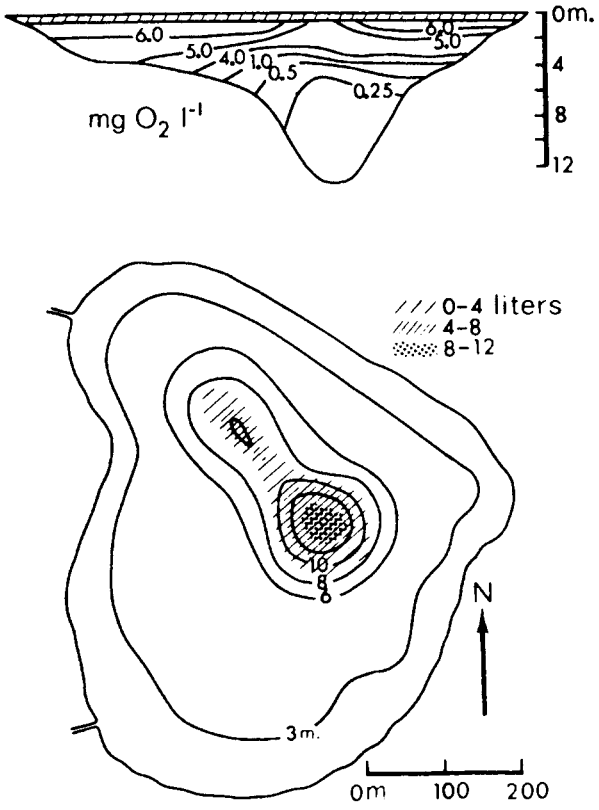

FIGURE 9-11 *Upper*: Isopleths of oxygen concentration in Lake Beloie, Russia, 15 March 1928; *lower*: quantity (liter m^{-2}) of gas, containing 20–24% CH_4, permeating the underside of the thawing ice in late winter. (Modified from Rossolimo, 1935.)

is particularly great over the deeper depressions of the lake basin. The central oxygen depletion is probably accelerated by profile-bound density currents that slowly accumulate in the depression and force overlying water upward. Oxygen concentration in these currents is reduced as they flow along the sediments to the deepest area.

Therefore, the oxygen régime of most dimictic lakes of the temperate zone is governed to a large extent by the quantities of oxidizable matter received during periods of stratification. In lakes that tend toward permanent stratification (either meromictic variants or oligomictic lakes of low elevation in equatorial regions), the oxygen distribution is clinograde and is determined by the duration of the stratification in relation to the inputs of oxidizable organic matter. Lakes containing large quantities of dissolved organic matter, such as bogs and bog lakes, have oxygen concentrations that are appreciably below saturation.

From the numerous examples of oxygen distribution and its control in natural water bodies, the effects of artificial loading of inland waters with pollutional sources of organic matter and other oxidizable materials should be readily apparent. Organic effluents from agricultural activities, sewage, and industry can effectively and rapidly exceed the degradative capacities of lakes and rivers. The resulting effects on aerobic organisms are direct and immediate. Indirect effects on the entire biogeochemical cycling and productivity are more gradual but, as we will see, are more effective in producing generally undesirable conditions.

VI. HYPOLIMNETIC OXYGEN DEPLETION RATES

The rate of loss of oxygen from the hypolimnion during summer stratification increases not only with depth, and hence with decreasing volume of the hypolimnion, but also with time during the stratification period. The difference in amount of oxygen present at the beginning, during, and at the end of stratification below a given depth is referred to as the ***oxygen deficit.*** In its simplest form, the oxygen deficit quantifies a metabolic relationship of the ***trophogenic zone***, the superficial stratum of a lake in which photosynthetic production predominates, with that in the underlying ***tropholytic zone,*** the aphotic deep stratum where decomposition of organic matter predominates. Hence, the amount of organic matter synthesized in the trophogenic zone that rains into and decomposes in the tropholytic zone is reflected in the rate of utilization of hypolimnetic oxygen. Although the dynamics of oxygen utilization are not that simple, the volumetric rate of oxygen consumption in the hypolimnion during summer stratification (oxygen deficit) provides an approximate estimate of the productivity of the lake.

The development of the theory of oxygen deficits as an approximation of lake productivity has a long history since its foundations in the fundamental work of Birge and Juday (1911), Thienemann (1928), and Juday and Birge (1932). Older means of estimating oxygen deficit have serious shortcomings and are only briefly discussed here. All deficit measurements must be used cautiously and only in a general way.

A. Actual, Absolute, and Relative Deficits

The ***actual oxygen deficit*** of the water refers to the difference between the observed oxygen content and the saturation value of a similar quantity of water at its observed temperature, salinity, and atmospheric pressure at the lake surface. A deficiency of this measurement is that it assumes that the water was saturated at the observed temperature during spring turnover and that oxygen intrusions from the trophogenic zone during stratification by currents was negligible. The same criticism can be leveled at the ***absolute oxygen deficit***, the difference between the observed oxygen concentration and the saturation value at 4°C at the pressure of the lake surface (Alsterberg, 1929). The assumption that the oxygen content during spring circulation is at saturation at 4°C is not always so; indeed, more often this is not the case. Therefore, Strøm (1931) proposed and used the ***relative oxygen deficit***, which is the difference between the oxygen content of the hypolimnion during summer stratification and that empirically determined at the end of spring turnover.

Use of the relative oxygen deficit improved estimations of rates of consumption because it took account of different oxygen deficits in layers below the hypolimnetic surface. Thus, consideration was given to the basic property of changing volumes of the strata with depth and to the importance of different hypolimnetic volumes among lakes. Thienemann (1926, 1928) emphasized this point clearly (Fig. 9-12). In comparing two lakes having identical volumes and identical

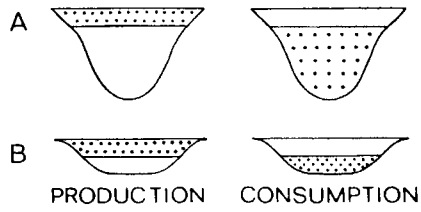

FIGURE 9-12 Diagrammatic representation of two lakes of equal production in the trophogenic zone but of differing volumes of their tropholytic zones, in which oxidative consumption occurs. (Modified from Thienemann, 1926, 1928.)

TABLE 9-3 Sample Computation of the Relative Areal Oxygen Deficit of Gull Lake, Summer 1972[a]

Calculations for 7 June 1972:

Strata (m)	*Volume (m^3)*	*Mean O_2 (mg liter^{-1})*	*Total O_2 in Strata (metric t)[b]*
15–20	12.910×10^6	9.42	121.612
20–25	5.221×10^6	8.90	46.464
25–30	0.203×10^6	8.68	1.762
30–33.5	0.0428×10^6	8.35	0.358
			170.196

Calculations for 1 August 1972: 76.719 metric t in hypolimnion

Difference: 93.477 t or 93.477×10^9 mg

The area of the surface of the hypolimnion at 15 m is $3.4980 \times 10^6 m^2$, or 34.98×10^9 cm^2.

By division, the difference in oxygen or areal oxygen deficit was 2.67 mg cm^{-2} 55 days^{-1} or 0.0486 mg cm^{-2} day^{-1}, or 1.46 mg cm^{-2} month^{-1}

[a] Unpublished data of Tague, Lauff, and Wetzel.
[b] 1 mg liter^{-1} = 1000 metric tons km^{-3} = 1 metric t $(10^6 m^3)^{-1}$.

trophic status in the trophogenic zones, it would be assumed that the production and influx of organic matter in the trophogenic zone of each would be the same and that similar amounts of oxidizable organic matter would sediment from the trophogenic layer into the tropholytic zones. However the volume of the first lake (*a*) is much larger than that of the second lake (*b*), and the first lake contains a much larger amount of oxygen to be utilized in decomposition. As a result, during a similar interval of time, the oxygen content of the hypolimnion of the shallow lake (*b*) would be reduced more rapidly than the oxygen in the hypolimnion of the deep lake (*a*). One might anticipate a clinograde oxygen curve in the former case and a more or less orthograde curve in the latter, deep lake. Much of the oxygen utilization in the shallow lake may occur after the organic material has settled into the sediments. Turbulence and horizontal currents in the hypolimnion, although small, are usually sufficient to distribute much of the lower deoxygenated water near the sediments into much of the hypolimnetic water. Thus, the relative oxygen deficit, which compensated for differences in hypolimnetic volume with depth, incorporated the intensity of trophogenic production into the consumptive capacity of the hypolimnion or approximate tropholytic zone.

This ***relative areal deficit***, as introduced by Strøm (1931) and modified by Hutchinson (1938, 1957), is the mean oxygen deficit below one cm^2 of hypolimnetic surface and consists of the summation of the individual deficits of a series of layers of decreasing volume with increasing depth. A computation from Gull Lake, southwestern Michigan, illustrates the general approach (Table 9-3). These data consist of measurements of oxygen concentration at several depths; a detailed hydrographic map is essential for accurate estimates of both volume and area. Since the oxygen concentrations did not differ greatly from one depth to the next in Gull Lake at this time, it is possible to find the average concentration in any layer by taking the mean of the concentration at the top of the layer and that at the bottom of the layer. When concentration gradients are steep, simple arithmetic means are not sufficiently accurate; a planimetric integration should then be used (Wetzel and Likens, 1991). This concentration is then multiplied by the volume of the layer to give the total amount of dissolved oxygen in the stratum, and the amounts for each layer of the hypolimnion are added. Thermal and morphometric data show that the surface of the hypolimnion of Gull Lake was 34.98 ha, or 349.8×10^8 cm^2. By division, the difference in oxygen was 2.67 mg cm^{-2} for the 55-day period between 6 June and 1 August, 0.0486 mg cm^{-2} day^{-1}, or 1.46 mg cm^{-2} month^{-1}.

Many of the calculations of areal oxygen deficits are from older investigations that make direct comparisons of deficits with various indices of biological productivity difficult. Nonetheless, as would be expected, there is a strong tendency in lakes of moderate depth for the relative areal deficit to increase with increasing productivity. Based on limited data, Hutchinson (1938, 1957) set the ranges among the rather ambiguous general categories of unproductive to productive lakes as: oligotrophic, < 0.017 mg O_2 lost cm^{-2} day^{-1}, and eutrophic, > 0.033 mg cm^{-2} day^{-1}. Mortimer (1941; Hutchinson, 1957) believes that the limits of 0.025 mg cm^{-2} day^{-1} for the upper limit of oligotrophy and 0.055 mg cm^{-2} day^{-1} for the lower limit of eutrophy are more realistic. These general limits are supported by other criteria for evaluating productivity (e.g., Lasenby, 1975; Burns, 1995).

Oxygen deficits are subject to numerous errors that detract from true representation of an index of trophogenic productivity. Significant inputs of allochthonous particulate and dissolved organic matter can cause large overestimates, while pelagic productivity of moderately to highly stained waters (> 10 Pt units) may be underestimated, owing to ultraviolet-light-mediated oxygen consumption by dissolved organic matter (cf. reviews of Leifer, 1988, and Brezonik, 1994). Furthermore, natural ultraviolet photolysis of dissolved humic compounds results in release of numerous small fatty acids that are readily metabolized by bacteria (Wetzel *et al.*, 1995). Although some pelagic and littoral photosynthesis commonly occurs in

the upper portion of the hypolimnion in both shallow and deep, clear lakes, this source of error is minimized in larger dimictic lakes with a maximum depth >20 m.

It is further assumed that the organic matter decomposing in the water column and in sediments of the hypolimnion includes most of that produced in the trophogenic zone and that a relatively constant amount sinks into the hypolimnion. Gliwicz (1979) has shown in insightful analyses that the steeper the vertical gradient of water temperature in the metalimnion (greater thermal resistance to mixing), the slower the sinking speed of sedimenting organic particles in the metalimnion. As a result, not only is a larger part of the sedimenting seston prevented from leaving the more turbulent epilimnion and metalimnion but the residence time for nutrients is prolonged in the epilimnion by release from partial decomposition. Consequently, the hypolimnetic relative oxygen deficits are lower in lakes with steeper metalimnetic thermal gradients. Epilimnetic productivity is greater, and respiratory oxidative consumption is largely complete before the organic matter ever reaches the hypolimnion.

Additional critical analyses of areal hypolimnetic oxygen deficits have demonstrated additional relationships to lake parameters (Ohle, 1956; Edmondson, 1966; Lasenby, 1975; Stewart, 1975; Cornett and Rigler, 1979; Charlton, 1980; Stauffer, 1987; Burns, 1995). Areal hypolimnetic oxygen deficits of a number of lakes indicate that (1) the deficit is positively correlated with primary productivity of phytoplanktonic algae; (2) the deficit is inversely proportional to epilimnetic transparency (Secchi disc depth); (3) lakes with higher total phosphorus concentrations have higher oxygen deficits; (4) the deficit is greater in lakes with higher mean summer hypolimnetic temperatures; and (5) oxygen deficits are larger in lakes of greater mean hypolimnetic thickness. The latter correlation, that a lake with a thicker hypolimnion has an oxygen deficit that is greater than a lake with a shallow hypolimnion, is seemingly incongruous with theoretical evaluations. This property may result from differential effects of turbulent oxygen transport across the metalimnion in lakes of varying hypolimnetic depth. Oxygen within the relatively turbulent metalimnion and heat and chemical fluxes into and from the metalimnion increase during windy intervals (Stauffer, 1987). As a result, lakes with shallow hypolimnia can have higher rates of oxygen depletion per unit volume of the hypolimnion but lower rates of oxygen depletion per unit area than do lakes with thicker hypolimnia.

Other parameters influence the rates of hypolimnetic dissolved oxygen depletion (Burns, 1995). Rates of depletion slow when concentrations decline below ca. 2 mg liter^{-1}. Many lakes deoxygenate slowly enough to permit the calculation of several monthly rates before this concentration occurs. An appreciable fraction of the decomposition of both particulate and dissolved organic carbon occurs in the epilimnion and never reaches the hypolimnion (e.g., Mitchell and Burns, 1979). Temperature differences of course affect decomposition rates, and corrections are necessary when comparing deficit results from different lakes. Net photosynthetic oxygen production in the lower metalimnion and upper hypolimnion can offset degradative consumption. River inflows to lakes can transport oxygen and organic matter to the hypolimnion if they underflow the metalimnion after entering the lake (e.g., Gibbs, 1992). Additionally, some of the organic matter settling into the hypolimnion and onto the sediments will not decompose during the stratified period under examination for the deficit calculation.

Oxygen deficit measurements are made because they are relatively easily done from commonly acquired data. However, other methods exist for evaluating lake productivity that are better than hypolimnetic oxygen deficits. Autochthonous productivity can be measured directly, and fluxes of particulate and dissolved organic matter can be evaluated in detail by chemical and biotic assays. Further, the hypolimnetic oxygen deficit method cannot be used effectively in lakes in which the hypolimnion becomes anaerobic during the period of summer stratification. When detailed data on productivity are lacking, however, the oxygen deficit can be informative about the general trophic status of a lake.

Changes in the hypolimnetic oxygen deficit rates over long periods of time can be indicative of overall changes in the productivity of the lake. An example of this is Douglas Lake in the northern part of the southern peninsula of Michigan. Although much is known about the characteristics and biota of this lake, which has been studied for many years, no good estimates of annual productivity exist (Lind, 1978). Analyses of the annual amount of oxygen below the metalimnion showed a progressive, slow decrease between 1911 and 1964 during each year except two (Fig. 9-13). Although considerable scatter in the annual rate of oxygen depletion was found, the rate of change appears to be increasing in recent years (Bazin and Saunders, 1971; Lind, 1978, 1987). The trend reflects an accelerated nutrient input and eutrophication associated with human activity first as a result of deforestation and second as a result of the development of the area for recreational purposes. This pattern has been repeated many times in other lakes, but long-term data are available only rarely. The well-known rapid eutrophication of a much larger lake, Lake Erie, has been followed in a similar way, largely on the basis of losses of hypolimnetic oxygen and benthic fauna (Carr, 1962; Charlton,

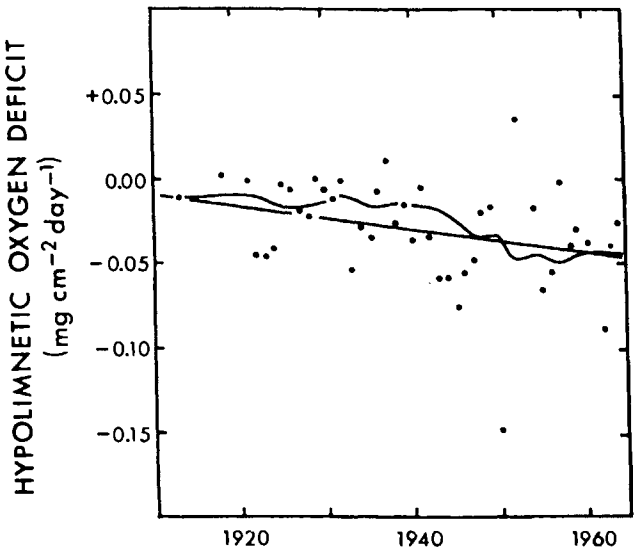

FIGURE 9-13 Change in estimated annual hypolimnetic oxygen deficits over a 53-year period in Douglas Lake, Michigan (negative values in all except two cases indicating a progressively greater rate of hypolimnetic oxygen reduction). The straight line represents the line of best fit by linear regression; the smooth curve represents an exponentially smoothed 1-year forecast at each year. (Modified from data of Bazin and Saunders, 1971.)

1980). Other indices of eutrophication and its reversal will be discussed in other chapters. Hypolimnetic oxygen deficits are but one index and must be used with great caution and careful consideration of differences in hypolimnetic temperatures and thicknesses.

VII. SUMMARY

1. Dissolved oxygen is essential to the respiratory metabolism of most aquatic organisms. The dynamics of oxygen distribution in inland waters are governed by a balance between inputs from the atmosphere and photosynthesis and losses from chemical and biotic oxidations. Oxygen distribution is important for the direct needs of many organisms and affects the solubility and availability of many nutrients and therefore the productivity of aquatic ecosystems.
2. Solubility of oxygen in water decreases as temperature increases. The solubility of oxygen decreases somewhat with lower atmospheric pressures at higher altitudes and increases with greater hydrostatic pressures at depth within lakes. Oxygen solubility decreases exponentially with increases in salt content.
3. Because diffusion of oxygen from the atmosphere into and within water is a relatively slow process, turbulent mixing of water is required for dissolved oxygen to be distributed in equilibrium with that of the atmosphere. Although oxygen content within small, turbulent streams is near saturation, marked variations occur spatially and temporally in larger rivers and are often coupled to variations in discharge and loadings of organic matter. Ground water is often largely or completely devoid of oxygen as a result of chemical and biological oxidations.
4. Distribution of oxygen in the water of thermally stratified lakes is controlled by a combination of solubility conditions, hydrodynamics, inputs from photosynthesis, and losses to chemical and metabolic oxidations.
   a. In unproductive oligotrophic lakes that stratify thermally in the summer, the oxygen content of the epilimnion decreases as the water temperatures increase. The oxygen content of the hypolimnion is higher than that of the epilimnion because the saturated colder water from spring turnover is exposed to limited oxidative consumption. Such a vertical distribution is called an ***orthograde oxygen profile*** (Fig. 9-2).
   b. The loading of organic matter to the hypolimnion and sediments of productive eutrophic lakes increases the consumption of dissolved oxygen. As a result, the oxygen content of the hypolimnion is reduced progressively during the period of summer stratification, usually most rapidly at the deepest portion of the basin where strata of less volume are exposed to the more intensive decomposition in surficial sediments. The resulting vertical distribution is termed a ***clinograde oxygen profile*** (Fig. 9-2).
   c. Oxygen saturation at existing water temperatures returns to all water strata during fall circulation.
   d. The exchange of oxygen with the atmosphere ceases for all practical purposes with the advent of ice formation. The oxygen content and saturation levels are reduced at lower depths in productive lakes, but not to the extent observed during summer stratification, because of prevailing colder water temperatures (greater solubility, reduced respiration).
   e. ***Metalimnetic oxygen maxima*** are often observed, in which the oxygen content in the metalimnion is much greater than, and often supersaturated in relation to, levels in the epilimnion and hypolimnion. The resulting ***positive heterograde oxygen curve*** is usually caused by photosynthetic oxygen production by algae in excess of oxidative consumption in the metalimnion.

f. ***Metalimnetic oxygen minima***, resulting in ***negative heterograde oxygen curves*** (Fig. 9-6), occur less commonly than metalimnetic maxima. Metalimnetic oxygen minima result from a combination of mechanisms. Most often, oxidation during decomposition exceeds oxygen inputs as the rate of organic matter sedimentation from the epilimnion decreases upon encountering the colder, denser metalimnetic water. Respiration by dense populations of microcrustacea in the metalimnion can also contribute to oxygen loss in this stratum.

g. Extreme clinograde oxygen distributions occur in meromictic lakes, in which the monimolimnion may be permanently anoxic.

h. Horizontal variations in oxygen content can be great, particularly in lakes and rivers where the photosynthetic production of oxygen of littoral flora exceeds that of the open-water algae. Rapid decay of massive littoral flora or phytoplankton can result in marked reductions in oxygen content in small, shallow lakes, causing the demise of many animals (called ***summerkill***). Oxygen distribution in reservoirs can vary greatly on an annual basis in relation to differences in organic loading from influents, open-water productivity, and discharge of water from the basin.

i. Under ice and snow cover where light is severely attenuated, photosynthesis augmentation of oxygen content can be eliminated. Respiratory oxidative consumption can reduce oxygen to levels insufficient to support organisms and result in ***winterkill***. Winterkill conditions are common in shallow, productive, temperate lakes and become severe in lakes with mean depths of <3 m.

j. In productive lakes and streams, epilimnetic oxygen concentrations can vary markedly on a diurnal basis. Daily photosynthetic augmentation and nighttime respiratory consumption can exceed turbulent exchange with the atmosphere and can result in rapid (hours) fluctuations between supersaturation and undersaturation.

5. The volumetric rate of dissolved oxygen loss from the hypolimnion during summer stratification, the ***relative areal hypolimnetic oxygen deficit***, has been used as an approximate index of the productivity of dimictic lakes. This method assumes that the organic matter production of the trophogenic zone is reflected in the oxygen consumption that occurs in the hypolimnion. Because of their simplicity of determination, oxygen deficits have often been used uncritically. Recent analyses indicate that differences in hypolimnetic temperatures and volumes (thicknesses) must be considered in comparisons among lakes. Empirical analyses using limited data indicate positive correlations between hypolimnetic oxygen deficits and primary productivity of phytoplankton algae, phosphorus concentrations of the water, mean summer hypolimnetic temperatures, and hypolimnetic thickness, and a negative correlation with epilimnetic water transparency (Secchi disc depth). Used properly and with caution, areal hypolimnetic oxygen deficits can serve to compare productivity approximately for large, deep, dimictic lakes of low to moderate productivity if little allochthonous loading of organic matter occurs.

10 SALINITY OF INLAND WATERS

VI. Summary

Salinity is the correct chemical term for the sum concentration of all the ionic constituents dissolved in inland waters, both fresh and saline. Salinity is best expressed as total ion concentration in mg liter^{-1} or meq liter^{-1}, which are essentially equivalent as mass or volume in dilute solutions. In saline lakes, the density of the waters diverge significantly from unity, and hence salt lake salinities should be expressed on a mass per mass basis, such as mass total ions per mass of solution (g kg^{-1}), which are temperature independent (Williams 1994). In open lakes with an outlet, the chemical composition of the water is governed largely by the composition of influents from the drainage basin and the atmosphere. Water salinity in closed basins is increased by evaporation and modified by precipitation of salts.

The ensuing summary of the ionic composition of inland waters views salinity along a gradient of concentrations from fresh waters of relatively low salinity to highly saline inland waters with ionic concentrations in excess of those of sea water. Although the volume of saline lakes is nearly equivalent to freshwater lakes (Chap. 1), saline lake ecosystems, though chemically and biologically fascinating, are of distinctly less use to humankind than is fresh water for agricultural, industrial, and domestic purposes, and thus are not given equal evaluation here. Such subordination does not denigrate their relevance, particularly in relation to important biodiversity among their highly specialized biota. Certain minerals are concentrated in saline waters and can be commercially valuable. Detailed summaries of inland saline ecosystems have been made by Eugster and Hardie (1978), Hammer (1986), Williams (1986, 1996), and Vareschi (1987).

I. IONIC COMPOSITION OF SURFACE WATERS

The ionic composition of fresh waters is dominated by dilute solutions of alkalis and alkaline earth compounds, particularly bicarbonates, carbonates, sulfates, and chlorides. The amounts of silicic acid, which occur largely in undissociated form, are usually small but occasionally are significant, particularly in hardwater lakes and streams. The concentrations of four major cations, Ca^{++}, Mg^{++}, Na^{+}, and K^{+}, and four major anions, HCO_3^-, CO_3^-, SO_4^-, and Cl^-, usually constitute the total ionic ***salinity*** of the water for all practical

purposes. Concentrations of ionized components of other elements such as nitrogen (N), phosphorus (P), and iron (Fe) and numerous minor elements are of immense biological importance but are usually minor contributors to total salinity.

Soft waters refers to waters of low salinity, which are usually derived from drainage of acidic igneous rocks (Hutchinson, 1957). ***Hard waters*** contain large concentrations of alkaline earths, usually derived from the drainage of calcareous deposits.

The salinity of fresh waters is best expressed as the sum of the ionic composition of the major cations and anions in mass or milliequivalents per liter. The quantity ***total solids,*** an estimation of inorganic materials dissolved in water by evaporation to dryness (105°C), is less satisfactory. Combustion of the residue at 550°C yields the ***nonvolatile solids*** per unit mass or volume, as CO_2 from organic carbon is lost. However, $MgCO_3$ and some alkalis and chlorides, which are true nonvolatile solids at normal temperatures, will also release CO_2 at 550°C and cause a considerable underestimate of the nonvolatile solids.

II. SALINITY DISTRIBUTION IN WORLD SURFACE WATERS AND CONTROL MECHANISMS

The salinity of the surface waters of the world is highly variable and depends upon ionic influences of drainage and exchange from the surrounding land, atmospheric sources derived from the rock–soil, ocean, and human activity, and equilibrium and exchange with sediments within the water body. The global mean salinity of river water is 120 mg liter^{-1} (Table 10-1; Livingstone, 1963; Walling and Webb, 1986), a value somewhat lower than Clarke's (1924) average but based on better data that compensate for the large amounts of dilute water draining tropical regions in major river systems. The dissolved composition of rivers is dominated by HCO_3^-, SO_4^-, Ca^{++}, and SiO_2, and 97.3% of global runoff has been classified as the calcium bicarbonate type (Meybeck, 1981). Differences among the continents are in the amounts of calcium and carbonate ions. Low values of these normally dominating ions are found particularly in South America and Australia (Table 10-1).

The three major mechanisms controlling the salinity of world surface water are rock dominance, atmospheric precipitation, and the evaporation–precipitation process (Gibbs, 1970, 1992; Feth, 1971; Kilham, 1975, 1990; Stallard, 1980; Stallard and Edmond, 1981; Meybeck and Helmer, 1989; Eilers *et al.*, 1992; Gibson *et al.*, 1995). Waters of the rock-dominated end of the spectrum are rich in calcium and bicarbonate ions (Fig. 10-1) and are more or less in equilibrium with materials of their drainage basins. Positions within this grouping depend on the climate, basin relief, and particularly the composition of the rock material in the basin (Table 10-2). The chemical composition of low-salinity waters, dominated by sodium and chloride, is influenced by dissolved salts derived from atmospheric precipitation acquired from the ocean. These fresh waters are limited to immediate maritime coastal regions. In very chemically dilute inland lakes with a strong precipitation dominance and little marine influence, appreciable sodium can be derived from weathering (Eilers *et al.*, 1992; Wu and Gibson, 1996). The major ionic composition of these lakes falls outside (lower left, salinity below 10 mg liter^{-1}) the primary envelope of Figure 10-1, which prevails for most inland waters of the world. Inland tropical humid areas of South America and Africa generally have high rainfall of an ionic composition that is either influenced primarily by terrestrial biological emissions

TABLE 10-1 Mean Composition of River Waters of the World (mg liter^{-1})[a]

[b] Values of calcium are likely less, on the average, than Na and Mg in Australian surface waters (Williams and Wan, 1972).

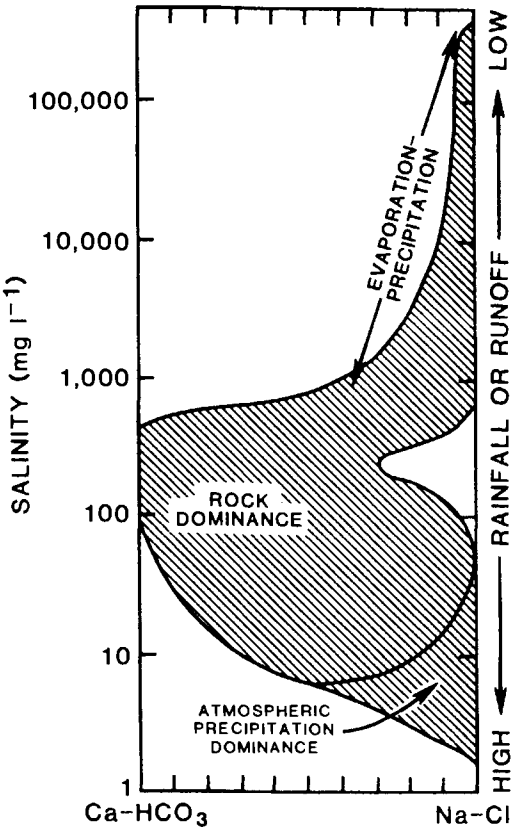

FIGURE 10-1 General processes controlling the ionic ratios and salinity of inland surface waters of the world. (Composite relationships based on the data of Gibbs, 1970; Stallard, 1980; and Kilham, 1975, 1990.)

and particulate dust or, once fallen, is then altered by rapid, intense rock weathering (Kilham, 1975, 1990; Stallard and Edmond, 1982). The third major process that influences the salinity of surface waters is evaporation and fractional crystallization with subsequent sedimentation of mineral salts. Fresh waters extend in a series from calcium- and bicarbonate-rich, to low-salinity waters of rock dominance or to sodium-dominated, high-salinity waters (Fig. 10-1). Rivers and lakes at the extreme saline end of this series are generally located in hot and arid regions. For example, the chemical composition of natural lakes, rivers, and springs in intertropical Africa are controlled primarily by rock dominance via weathering reactions and the evaporation–crystallization process of evaporative concentration and calcite precipitation (Kilham, 1990).

The data discussed above represent average concentrations and general conditions of distribution on a global basis. Within regions, the distribution of salinity of inland waters is highly variable and localized. Hence, some areas or lake districts can be found in which, because of uniform rock formations, the ionic proportions are relatively consistent (Table 10-3). In contrast, in some areas, such as in southwestern Michigan, extremely softwater seepage lakes may be found immediately adjacent to very hardwater calcareous lakes because of complex, varying patterns in the deposition of glacial till.

Over large regions of the temperate zone, dominance by calcium and bicarbonate ions prevails in open lake ecosystems:

$$\text{Cations: } Ca > Mg \geq Na > K$$

$$\text{Anions: } CO_3 > SO_4 > Cl$$

The relationships are very consistent with those of the average world river water (Tables 10-1 and 10-2), and there is a distinct tendency for the composition of lake waters to approach this average concentration (Rodhe, 1949; Gorham, 1955; Gorham *et al.*, 1983; Meybeck and Helmer, 1989). These salinity relationships led Rodhe (1949) to propose a general standard lakewater concentration, given in Table 10-4 in

TABLE 10-2 Global Average Chemical Composition (μeq liter^{-1}, except as noted) of Unpolluted Rivers and Variations in Composition according to Drainage from Dominant Rock Type[a]

[a] A hardwater lake that received large amounts of domestic effluents that had high sodium content, most likely from detergents. Nutrient loading to this lake has subsequently been reduced.

abbreviated form. Deviations from these proportions are common, particularly on the continents of South America and Australia and in drainage basins of igneous source materials and soft waters (see Tables 10-2 and 10-3). Drainage from igneous rock commonly has a salinity of less than 50 mg liter^{-1} and cationic proportions of

$$Ca > Na > Mg > K$$

The proportions of anions in softwater systems shift forward a decrease in carbonates and an increase in halides:

$$Cl \geq SO_4 > CO_3$$

Saline lakes form and persist when (a) outflow of water is restricted, as in hydrologically closed basins, (b) evaporation exceeds inflows, and (c) the inflow is sufficient to sustain a standing body of water (Eugster and Hardie, 1978; Hammer, 1986; Williams, 1994). The relative proportions of the major solutes vary greatly among saline lakes. Most saline waters are dominated by Na; very few saline lakes are found in which Ca or Mg is the major cation. Dominating major anions are highly variable, although Cl very commonly predominates. Certain elements, normally present in only trace amounts in surface waters, can occur in very high concentrations in saline lakes (e.g., bromine, strontium, phosphate, or boron) (Wetzel, 1964; Eugster and Hardie, 1978; Hammer, 1978, 1986).

The specific conductance of lake water is a measure of the resistance of a solution to electrical flow. The resistance of an aqueous solution to electrical current or electron flow declines with increasing ion content. Hence, the purer that water is, that is, the lower its salinity, the greater its resistance to electrical flow. By definition, the specific conductance of an electrolyte is the reciprocal of the specific resistance of a solution measured between two electrodes 1 cm^2 in area and

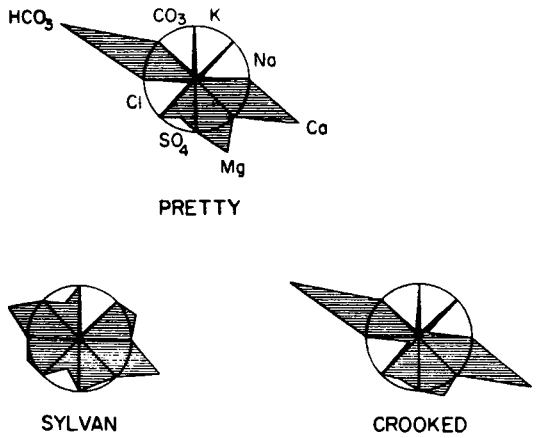

FIGURE 10-2 Ionic polygonic diagrams in which the relative concentrations in equivalent percentage of the major cations and anions are indicated for average concentrations of Pretty, Sylvan, and Crooked lakes, northeastern Indiana. The length of each radius bisecting a sector is proportional to the concentration of a particular ion in equivalent percentage of the total cations or total anions. (After Wetzel, 1966b.)

1 cm apart. The conductance is expressed in μSiemens cm^{-1} (previously μmhos cm^{-1}, the reciprocal of ohms).[1] The temperature of the electrolyte affects ionic velocities; conductance increases about 2% per °C. The international chemical standard reference of 25°C is recommended in all cases, even though 18 or 20°C has been used widely in past limnological studies.

The specific conductance of the common bicarbonate-type of lake and river water is closely proportional (see Table 10-3) to concentrations of the major ions (Juday and Birge, 1933; Rodhe, 1949). Once the concentrations of the major ions are known, changes in specific conductance reflect proportional changes in ionic concentrations (Otsuki and Wetzel, 1974). This relationship is not true, however, for minor constituents of lake water (e.g., N, Fe, Mn [manganese], Sr [strontium], or especially P) (Rodhe, 1951). As would be anticipated, a positive correlation exists between conductance and pH in the intermediate pH range of bicarbonate fresh waters, but this relationship deteriorates among lakes of low salinity and high dissolved organic matter content (Strøm, 1947).

The relative concentrations of the eight major ions of salinity can be shown graphically with ionic polygonic diagrams (Maucha, 1932). A 16-sided regular polygon of standard area is divided into eight equal sectors, the four to the right of the vertical diameter representing the cations and the four to the left the anions (Fig. 10-2). Lines are drawn from the center to bisect each sector. The length of each radius bisecting a sector is proportional to the concentration of a particular ion in equivalent percentage of the total cations or anions. Lines from the radii of the ionic sections are joined to the polygon and shaded. Details of calculation are given in Gessner (1959) and in Broch and Yake (1969).

where R is the resistance in ohms (cf. Rainwater and Thatcher, 1960; Golterman, 1969; Wetzel and Likens, 2006).

III. SOURCES OF SALINITY

A. Weathering of Soil and Rock

The composition of soil and rock and their ion-exchange capacities influence both rates of weathering and ion supply to runoff and percolating water. The adsorption and release of ions is dependent upon (a) the cationic availability, (b) ionic concentrations and proportions in a soil solution or leaching water, (c) the nature and number of exchange sites on the exchange complex of soil particles, and (d) the volume of water in contact with the exchange complex. Four general processes of weathering control ion supply: (a) solution, (b) oxidation-reduction, (c) the action of hydrogen ions, and (d) the formation of complexes (reviewed in detail by Gorham, 1961, and Carroll, 1962).

Ordinary solution not involving hydrolysis or acid weathering is important, primarily in sedimentary deposits rich in soluble salts. Leaching of marine salt deposits results in an enrichment of sodium, potassium, and chlorides relative to other ions in recipient lake and river waters. Relative leaching rates of different ions are time-dependent, and thus marked fluctuations in ionic proportions of runoff water occur during periods of high (flooding) or low rates of runoff because of differences in solubility.

Oxidation and reduction processes primarily affect iron, manganese, sulfur, nitrogen, phosphorus, and carbon compounds in soils. Iron sulfides are common constituents of rocks and water-saturated soils. Oxidation of these sulfides can be a major source of sulfate for natural waters, usually in the form of dilute sulfuric acid, which solubilizes other rock and soil constituents as well. Microbial decomposition of sulfur-containing organic compounds, particularly in woodland soils and peaty bog waters, adds sulfate to natural waters usually as sulfuric acid. Within lakes, oxidation–reduction processes play dominant roles in the sulfur cycle (see Chap. 14).

The action of hydrogen ions from the dissociation of carbonic acid, discussed at length in the following chapter, is of major importance in the weathering of

soils and rocks. Concentrations of CO_2 and H^+ ions increase in soils in which intensive microbial decomposition of organic matter occurs. The importance of carbonic acid in weathering is illustrated by the high proportion of bicarbonate ions in most river waters. The proportion is high even in waters of low salinity (< 50 mg liter^{-1}) draining igneous rocks (Table 10-2). Strong acids (H_2SO_4, HNO_3) in rainfall originating from air pollution accelerate the rate of weathering (Likens *et al.*, 1972, 1979; Likens, 1985). Colloidal acids of humic compounds and acid clays can also supply large amounts of H^+ ions for weathering. The "black" waters of tropical rivers draining acidic podzols are colored brown by humic substances originating from incomplete decomposition of forest, flood plain, and wetland/littoral plants. The low pH (3.5–5) of these waters results largely from dissociation of humic acids and the fact that the soils of lowland tropics contain very low levels of bases and of calcium.

Certain soluble organic molecules can chelate or complex ions by molecular bonding, thereby inhibiting these ions from reacting with others and increasing the solubility of the complex. The extent of this process in weathering and the transport of ions to rivers and lakes is probably quite significant but has not been studied adequately.

The exchange of ions between soils and the soil solution is governed by exchange equilibria between hydrogen ions and ions attached to the soil particles. Soil colloids have a finite absorptive capacity, and the exchange rate is highly variable. In humid, well-drained regions, water selectively removes cations from weathering rocks and soils. In areas of limited rainfall and stream activity, an accumulation of sodium and chloride deposited by rain in the soil water can result. The proportion of divalent to monovalent cations in the exchange positions on soil particles is a function of cation concentrations and their relative proportions in the soil water. Sodium ion adsorption to clay particles decreases with increasing concentrations of Ca^{++} and Mg^{++}. Calcium and magnesium are the dominant exchangeable cations in most neutral or alkaline soils. In well-drained situations, the cations added by rainfall will have little effect on exchange leaching from soils or weathering rock. In contrast, when soils are saturated, cations in exchange positions are in equilibrium with those in the soil water and ground water. Cations added by rainwater to the water surrounding clay minerals will establish equilibrium with those in exchange positions, and little weathering or removal of cations will occur. Under arid conditions, salts in soil solutions accumulate, for there is no removal of cations derived from rainfall. Exchange sites contain predominantly Ca^{++} and Mg^{++}; as the soil water becomes saturated with Na^+, the Ca^{++} and Mg^{++} are gradually replaced by Na^+ until all sites on the particle surfaces are filled. This Na^+ can then be released again during periods of rainfall and result in a much higher concentration of Na^+ than of divalent cations. Clay minerals are affected very little by these exchanges and do not weather appreciably.

The salinity of natural waters is influenced further by the depth and mode of water percolation through soils. Seepage lakes receiving relatively large amounts of surface runoff are usually very dilute in comparison to open lakes that drain deeper soil horizons, because the salinity of ground water is generally much higher than that of surface runoff.

B. Atmospheric Precipitation and Fallout

The atmosphere is a significant source of salinity for many dilute fresh waters and for some saline lakes of arid regions. Rainfall carries much of the atmospheric salt to some river and lake waters (cf. reviews of Gorham, 1961; Carroll, 1962; Sutcliffe and Carrick, 1983a, 1983b; and Lesack and Melack, 1991). In less humid regions, dry fallout of salt particles can occur in significant quantities and often exceed those washed down with rainfall. Snow is less efficient in removing atmospheric salts than rain, but at high latitudes, contaminants form an appreciable supply of salinity (e.g., Barica and Armstrong, 1971). All of the major anions in natural waters are cycled in part through the atmosphere as gases as well as in dissolved and particulate form.

The sea is a major source of atmospheric sodium, chloride, magnesium, and sulfate (Table 10-5). Sea

TABLE 10-5 Common Concentrations (mg liter^{-1}) of Major Ions in Continental and Marine Rainfall[a]

Ion	*Continental rain*	*Mean central Amazon rain*[d]	*Marine/coastal rain*
Ca^{++}	0.2–4[b]	0.030	0.2–1.5
Mg^{++}	0.05–0.5	0.013	0.4–1.5

H^+	pH = 4–6	pH 4.9[d]	pH = 5–6

[a] Modified from data of Berner and Berner (1987).
[b] In remote continental areas: Ca^{++} = 0.02–0.20; K^+ = 0.02–0.07; SO_4^{2-} = 0.2–0.8.
[c] In polluted areas: NH_4^+ = 1–2; SO_4^{2-} = 3–8; NO_3^- = 1–3.
[d] From data of Lesack and Melack (1991). Average pH value likely lowered because of abundant dissolved organic acids.

spray carries large amounts of sea water into the atmosphere that, on evaporation, forms salt particles which are capable of acting as nuclei for cloud and raindrop condensation. Atmospheric salinity can be carried for great distances. Although most atmospheric salinity is precipitated with rainfall in the coastal regions, decreasing amounts are carried inland before deposition occurs. Continental rain generally contains more sulfate than chloride; chloride ion concentrations usually increase with proximity to the sea (Table 10-5). In a similar fashion, sodium is the dominant cation of rain, and its concentration decreases in relation to amounts of magnesium and calcium with increasing distance from the sea. The effects of atmospheric transport of ions can be seen in lakes enriched with Na^+ and Cl^- in coastal maritime regions. This enrichment is particularly evident in igneous coastal region mountains, in which many of the maritime lakes of Japan can be found (Sugawara, 1961).

Windblown dust from the soil often contributes salts, especially of calcium and potassium, to rain and snow. This type of transport is the case, for example, in calcareous regions in Sweden. Wind-transported salts from salt pans of lakes in endorheic regions, such as in Russia, western Australia, or the United States, can be moved large distances to drainage basins of other river and lake systems.

A major source of atmospheric salinity is industrial and domestic air pollution. Although numerous ions and particles are emitted into the air, chlorides, calcium, and especially sulfates and nitrates are major contaminants. The magnitude of air pollution on the chemistry of surface waters has now reached such major proportions that global action is required to curtail its effects. Although much of atmospheric pollution returns to the ground in the areas immediately adjacent to the industrial sites of production, sufficient sulfuric, nitric, and hydrochloric acids enter the atmosphere to influence the water of precipitation and surface waters of entire countries or portions of continents. The most infamous example is in Scandinavia, which receives air currents from western and southwestern Europe for much of the year. Contaminants from heavily industrialized regions of the United Kingdom, the Ruhr Valley, and elsewhere caused a 200-fold increase in acidity of rain in a decade (Likens *et al.*, 1972). Values of pH less than 3 were observed, and over large areas of northern Europe, the pH of rain is still less than 4, despite recent reductions of air pollution.

An analogous situation developed in eastern New York and in the smaller eastern states. Acid rain falling in these areas can be traced to industrial origins in the central states and in Canada. In addition to direct effects on the leaching rates of nutrients from plant foliage and soil, plant metabolism is altered and major nutrient inputs to and acidification of surface waters can result in changes in entire drainage basins. In the Hubbard Brook drainage basin of the White Mountains of New Hampshire, sulfate was found to be the principal ion in precipitation (Fisher *et al.*, 1968) and supplied most of the sulfate that was discharged by the streams (Table 10-6). The input of ammonium and nitrate exceeded the discharge of these constituents. The annual deposition of hydrogen ion exceeded that of sulfate and is a major determinant of pH of the waters of that region.

TABLE 10-6 Allocation of Elements (in Percent) within the Hubbard Brook Experimental Forest Drainage Basin[a]

C. Environmental Influences on Salinity

Climate affects markedly the balance between precipitation and evaporation and thus the salinity concentrations of surface waters. This effect has been discussed already in global terms. At a more local level, climatic effects are manifested in a general increase in salinity with decreasing elevation of rivers and lakes. This correlation is because most of the salinity of rain and particulate fallout is deposited at lower elevations.

The salinity of lake waters of closed drainage basins is governed not only by inputs of dissolved ions from runoff but by the fate of these materials upon evaporation (Hutchinson, 1957). Most closed lakes occur in regions with long-term (several years) fluctuating climate and are often exposed to periods of severe aridity. Commonly very shallow, these lakes may evaporate completely or sufficiently to expose large expanses of sediments. Diversions of river inputs by human activities, as in the tragedy of the Aral Sea (Williams and Aladin, 1991), can also lead to the exposure of large areas of sediments of saline lakes. Loss of salts then can occur by wind deflation.

Saline lakes are generally categorized on the basis of dominating anionic concentrations into carbonate, chloride, or sulfate waters (Hammer, 1986; Williams, 1994, 1996). The range of salinity in these lakes is extraordinary, from several hundred to over 200,000 mg liter^{-1} in the Great Salt Lake of Utah and the Dead Sea. Borax Lake of northern California, one of the few shallow saline lakes that has been studied in detail over an annual period, exhibited a nearly fourfold decrease in volume and over a twofold increase in salinity, from less than 28,000 mg liter^{-1} to nearly 60,000 mg liter^{-1} (Wetzel, 1964). An analogous condition was recorded in Lake Chilwa, Malawi, which is typical of many shallow lakes of endorheic regions (Moss and Moss, 1969; Kalk *et al.*, 1979; Hammer, 1986).

Other significant climatic factors influencing salinity are temperature and wind. Temperature influences the rate of rock weathering. Tropical waters, for example, which drain strongly weathered soils, are usually poor in electrolytes, and a large part of their total composition consists of silica. Wind direction and speed may affect the chemical composition of atmospheric precipitation by altering the amount of incorporated sea salinity and sites of deposition inland. Losses of atmospheric salinity are greater in low-elevation, turbulent air masses. The type of vegetation growing on the drainage basin and its requirements for major ions are also influenced by climate. Mineral cycling in tropical perennial forests of dense vegetative cover, for example, differs greatly in higher rates of utilization and leaching of soil nutrients as compared to nutrient cycling in deciduous vegetation of temperate regions.

IV. DISTRIBUTION OF MAJOR IONS IN FRESH WATERS

The spatial and temporal distribution of the major cations and anions of salinity are separable into (1) ***conservative ions,*** whose concentrations within a lake and many streams undergo relatively minor changes from biotic utilization or biotically mediated changes in the environment, and (2) ***dynamic ions,*** whose concentrations can be influenced strongly by metabolism. Of the major cations, magnesium, sodium, and potassium ions are relatively conservative both in their chemical reactivity under typical freshwater conditions and their small biotic requirements. Calcium is more reactive and can exhibit marked seasonal and spatial dynamics. Of the major anions, inorganic carbon is so basic to the metabolism of fresh waters that it is treated in a separate chapter (Chap. 11), and later coupled with organic carbon cycling (Chap. 23). Similarly, sulfate is greatly influenced by microbial cycling and the chemical milieu and is treated separately (Chap. 14), along with iron and silica. Chloride is relatively conservative. The total ionic salinity, composed almost entirely of the eight major ions, is of major importance in osmotic regulation of metabolism and in the distribution of biota and is briefly discussed below.

A. Calcium

Calcium influences the growth and population dynamics of freshwater flora and fauna both directly and indirectly. Calcium is a required nutrient of normal metabolism of higher plants, as well as of prokaryotes (Smith, 1995). A universal requirement for calcium has not been demonstrated for algae but most likely it is required by the green algae and is considered an essential inorganic element of algae. Where demonstrated as essential, calcium is usually needed as a micronutrient. Substitution of calcium by a closely related element, strontium, is readily acceptable to some algae (e.g., *Chlorella, Scenedesmus*) that require calcium and are indifferent to strontium; in other algae, calcium utilization is strongly inhibited by strontium.

The two principal membranes of plant cells, the outer cytoplasmic plasmalemma and the inner cytoplasmic tonoplast, operate in ion transport, one of the basic biological functions of cell membranes (see reviews of Eppley, 1962, and Epstein, 1965). The central vacuole is the main repository of accumulated ions, and both cations and anions may be absorbed from dilute solutions until the vacuolar concentrations vastly exceed external concentrations. Membranes of higher plants have a very low permeability to free ions; ionic exchange is more common among algae. Active transport mechanisms presumably involve high-energy phosphate compounds of phosphorylation. The ion-transporting mechanisms are ion-selective and are often species-specific; the external concentrations of ions and ratios of divalent to monovalent cations can affect transport mechanisms markedly. Calcium is essential for maintenance of the structural and functional integrity of cell membranes.

The distribution of certain algae has been correlated to differing concentrations of calcium. While causality cannot be established definitely for such relationships by singling out one affecting chemical species from an array of simultaneously interacting parameters that regulate growth and distribution, it is clear that calcium is involved indirectly in the metabolism of certain organisms. The desmids are a large algal group that is found in large part in acidic (pH 5–6) waters of low salinity, especially waters of low calcium content. Of the few species of desmids studied, many have a narrow tolerance to calcium concentrations.

Their restriction to soft waters is by no means universal. Species of the larger genera are divisible into those adapted to acidic (pH < 6), calcium-poor (< 10 mg Ca liter^{-1}) waters and those adapted to increasingly alkaline, calcium-rich waters. The detailed studies of Höll on this subject have been verified and are reviewed by Hutchinson (1967). Again, causality between calcium concentration and the metabolism of these algae has not been established through experimental studies, even though evidence for such an interaction is very strong.

A ubiquitous relationship has been found between calcium, calcium-specific regulatory proteins, and cyclic adenosine 3′:5′-monophosphate (cAMP) in both prokaryotic and eukaryotic organisms. These molecules function synergistically to regulate a broad spectrum of important metabolic functions, in particular ion-transport and energy-transduction reactions (Kretsinger, 1979; Marx 1980; Smith, 1995). The relationships between these regulatory molecules in aquatic systems are only beginning to be appreciated. Cyclic AMP is produced and released by aquatic photoautotrophs and bacteria (Francko and Wetzel, 1980, 1981, 1982) and is found in highest concentrations in lake water and plant tissues in midsummer during periods of high photosynthetic demand for carbon and resultant epilimnetic and littoral decalcification (Francko and Wetzel, 1982).

Very few groups of freshwater animals exist in which the distribution of some species has not been related to calcium concentration (cf. Macan, 1961). As among algae and certain macrophytes, in some animal groups most of the species are found in calcareous waters, and their numbers decrease as the concentration of calcium declines. Other species, which are frequently closely related to those in hard, calcium-rich waters, are characteristic of waters poor in calcium. In particular, mollusks, leeches, and tricladian flatworms are divisible into hardwater species (≥ 20 mg Ca liter^{-1}), and those that can tolerate less than this concentration. Analogous but less clear correlations occur among the crustaceans. Although the requirements for calcium in invertebrates are known to some extent (cf. Robertson, 1941), little is known about how small differences in calcium concentrations affect distribution. Attempts to explain the metabolism and distribution of animal species on the basis of single chemical differences have been numerous but largely unrewarding, except where conditions are extreme. Calcium concentrations have been implicated in the aging of rotifers, a process that affects longevity and morphology by accumulation of calcium (Edmondson, 1948). These laboratory findings fit remarkably well into observed distribution and population dynamics of rotifers in lakes of varying calcium concentrations, in which longevity and population success increase in waters of lesser calcium content.

The calcium content of softwater lakes and streams remains well below saturation levels, and these concentrations exhibit minor seasonal variations with depth. The amount of calcium utilized by the biota is usually so small in comparison to existing levels that reduction or depletion by biota cannot be seen in normal analyses. Decomposition processes can lead to some calcium accumulation in the hypolimnion of productive softwater lakes during stratification.

The calcium content of hardwater lakes, however, undergoes marked seasonal dynamics. The changes depicted in Figure 10-3 for a hardwater lake in southern Michigan are quite typical. Between rather uniform concentrations during spring and fall periods of

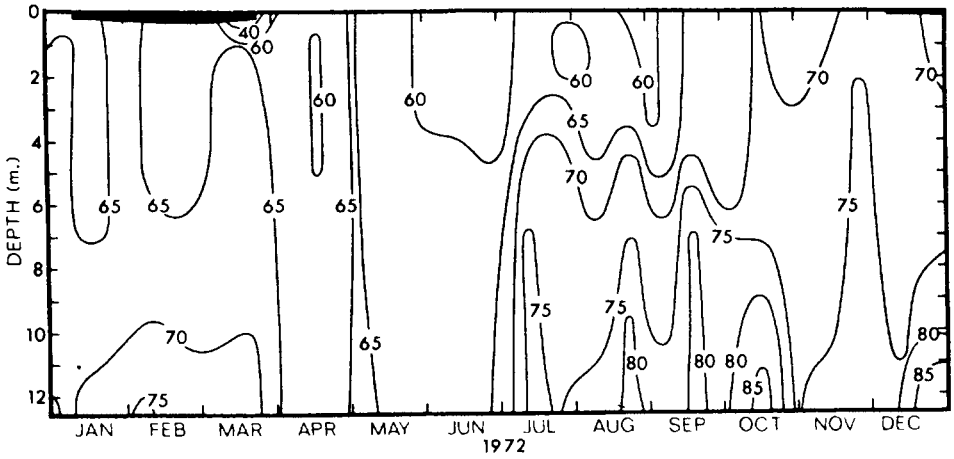

FIGURE 10-3 Depth–time distribution of isopleths of calcium concentrations (mg Ca^{+2} liter^{-1}) of oligotrophic, hardwater Lawrence Lake, Michigan. Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

circulation, a conspicuous stratification occurs that is repeated annually with only minor variations. Both the levels of calcium (Fig. 10-3) and bicarbonate (Fig. 11-3) decreased markedly in the epilimnion (0–4 m in Figs. 10-3 and 11-3) as a result of precipitation of $CaCO_3$ during the summer months from May through September. Similar losses were observed during the period of winter stratification. In winter, the decrease just beneath the ice is associated in part with dilution by rains permeating the ice and melting ice (cf. Canfield *et al.*, 1983), as well as with increases in photosynthesis just before ice loss. Decreases of concentrations of calcium and of inorganic carbon in the epilimnion and metalimnion are related largely to rapid increases in the rates of photosynthesis by phytoplankton and littoral flora (Otsuki and Wetzel, 1974) and indicate the major role of photosynthetic alteration of dissociation equilibria and induction of epilimnetic decalcification (cf. review of Küchler-Krischun and Kleiner, 1990).

The calcium and bicarbonate budgets of this hardwater lake illustrate relationships among influxes, dynamics within the lake, and outflow over an annual period. Calcium inputs of two spring-fed inlet streams were uniform and contributed from 93 to 98% of the total monthly inputs to the basin during the summer months. After compensation for potential evapotranspiration and precipitation, inputs of calcium from groundwater influxes varied from 2 to 58% of the total monthly inputs. Inputs of bicarbonate of the two inlet streams were also uniform annually and constituted from 82 to 97% of the total monthly influx during the summer period. Contributions from the streams decreased total inorganic carbon input anywhere from 35 to 67% during other times of the year because of the increase in groundwater influxes. The $CaCO_3$ precipitation rate was calculated to be 446 g m^{-2} y^{-1}. This loss of $CaCO_3$ influences the metabolism of hardwater lakes by coprecipitation of inorganic nutrients, such as phosphorus, and selective removal of humic organic acids and other organic compounds by adsorption (Stewart and Wetzel, 1981). Such adsorptive processes and potential biotic effects are discussed under specific sections in the following chapters. The general decalcification processes described here have been observed in many other lakes (e.g., Koschel *et al.*, 1983; Stabel, 1986; Duston *et al.*, 1986; Effler and Johnson, 1987; Küchler-Krischun and Kleiner, 1990).

Epilimnetic decalcification is reflected simultaneously in the distribution of specific conductance of hardwater lakes (Fig. 10-4). Because concentrations of Mg, Na, K, and Cl are relatively conservative, as discussed further on, the specific conductance follows changes in Ca^{+2} and HCO_3^- concentrations in nearly a 1:1 relationship (r = 0.997; Otsuki and Wetzel, 1974). A portion of the precipitating $CaCO_3$ is resolubilized in the hypolimnion, which is reflected in both the increased concentrations of Ca^{+2} and the specific conductance in hypolimnetic waters. Some of the $CaCO_3$ is entrained permanently in the sediments and commonly constitutes >30% of the sediments by weight in moderately hardwater lakes (Wetzel, 1970). Adsorption of organic compounds to $CaCO_3$ lowers the rates of dissolution in hypolimnetic strata of reduced pH. Further, calcium complexes with humic acids, especially in the sediments, alter exchange equilibria in the hypolimnion (Ohle, 1955a; Stewart and Wetzel, 1981a; Hering and Morel, 1988).

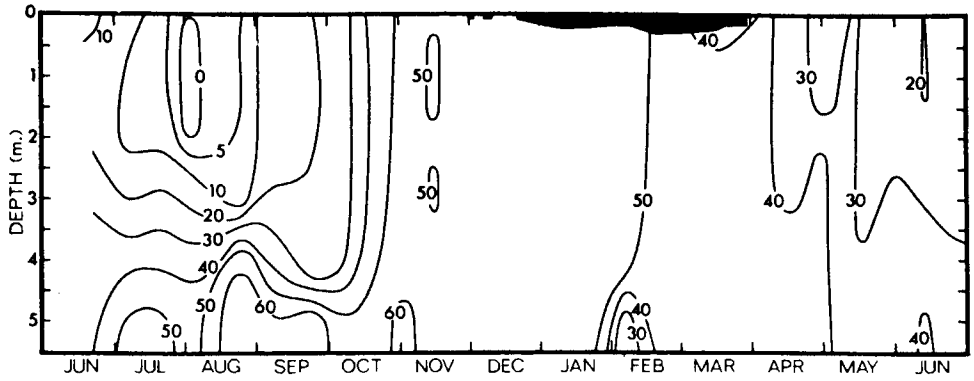

FIGURE 10-5 Depth–time distribution of isopleths of calcium concentrations (mg Ca^{+2} $liter^{-1}$) of hypereutrophic Wintergreen Lake, Kalamazoo County, Michigan, 1971–1972. Opaque area = ice cover to scale. (Wetzel *et al.*, unpublished data.)

Biogenically induced decalcification of the epilimnion reaches an extreme in very productive hard waters. For example, the calcium concentrations of the epilimnion of Wintergreen Lake, Michigan, were reduced from nearly 50 mg $liter^{-1}$ to below analytical detectability in a few weeks (Fig. 10-5). The magnitude of this loss from the trophogenic zone and the resulting increase in monovalent:divalent cation ratios should be recalled in subsequent discussion of the effects of the calcium content and of cationic ratios on species distribution.

B. Magnesium

Magnesium is required universally by chlorophyllous plants for the magnesium prophyrin component of chlorophyll molecules and as a micronutrient in enzymatic transformations, especially in transphosphorylations by algae, fungi, and bacteria. The demands for magnesium in metabolism are minor in comparison to quantities generally available in fresh waters. Magnesium compounds, moreover, are much more soluble than their calcium counterparts. As a result, significant amounts of magnesium rarely precipitate. The monocarbonates of hard waters are usually >95% $CaCO_3$ under ordinary CO_2 pressures (e.g., Murphy and Wilkinson, 1980). $MgCO_3$ and magnesium hydroxide precipitate significantly only at very high pH values (>10) under most natural conditions. The concentrations of magnesium are extremely high in certain closed saline lakes.

Because of magnesium's solubility characteristics and its minor biotic demand, concentrations of magnesium are relatively conservative and fluctuate little both in softwater streams and lakes (e.g., Likens, 1985) and in hardwater streams (e.g., Wetzel and Otsuki, 1974) and lakes (Fig. 10-6). This attribute has been used to

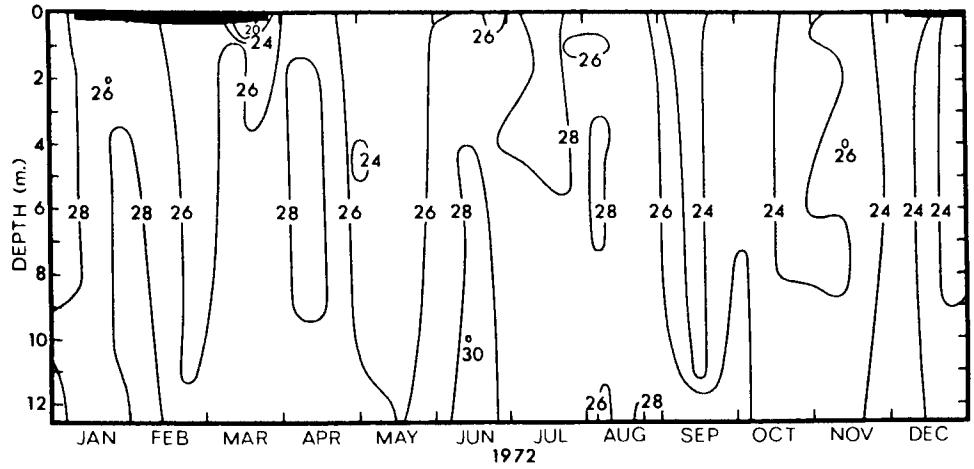

FIGURE 10-6 Depth–time distribution of isopleths of magnesium concentrations (mg Mg^{+2} $liter^{-1}$) of hardwater Lawrence Lake, Michigan. Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

advantage by employing the magnesium budget of inputs and outflows to determine groundwater influxes to a lake by magnesium mass balance (Wetzel and Otsuki, 1974).

Low available magnesium has been implicated as one of several factors influencing phytoplanktonic productivity in an extremely oligotrophic Alaskan lake (Goldman, 1960). However, such conditions are exceedingly rare in comparison to limitations imposed by the restricted availability of other nutrients.

C. Sodium, Potassium, and Minor Cations

The monovalent cations sodium and potassium are involved primarily in cellular ion transport and exchange. An absolute sodium requirement has been demonstrated in only a few plants. The sodium requirements are particularly high in some species of cyanobacteria (Allen, 1952; Gerloff *et al.*, 1952; Allen and Arnon, 1955) and is required for photosynthesis, bicarbonate transport, intracellular pH regulation, nitrogen fixation and nitrate reduction, and uptake of phosphate (Ward and Wetzel, 1975; Rees, 1985; Maeso *et al.*, 1987; Oleson and Makarewicz, 1990; Valiente and Avendaão, 1993). Potassium and other elements of this series—lithium (Li), rubidium (Rb), and cesium (Cs)—cannot substitute for Na. A threshold level of 4 mg Na^+ liter^{-1} is required for near optimal growth of several cyanobacterial species (Kratz and Myers, 1954), a concentration near mean for numerous hardwater lakes.

Cyanobacteria possess separate systems for the active transport of both CO_2 and HCO_3^-. The active transport system for molecular CO_2 assimilation is so efficient that extracellular CO_2 concentrations are reduced far below the equilibrium values by a transport system that recognizes molecular CO_2 and transports it into the cells (Miller *et al.*, 1991). Cyanobacteria also possess active transport systems for HCO_3^-. The bicarbonate transport system occurs in cells growing at low concentrations of extracellular CO_2, although bicarbonate transport appears to have no effect on CO_2

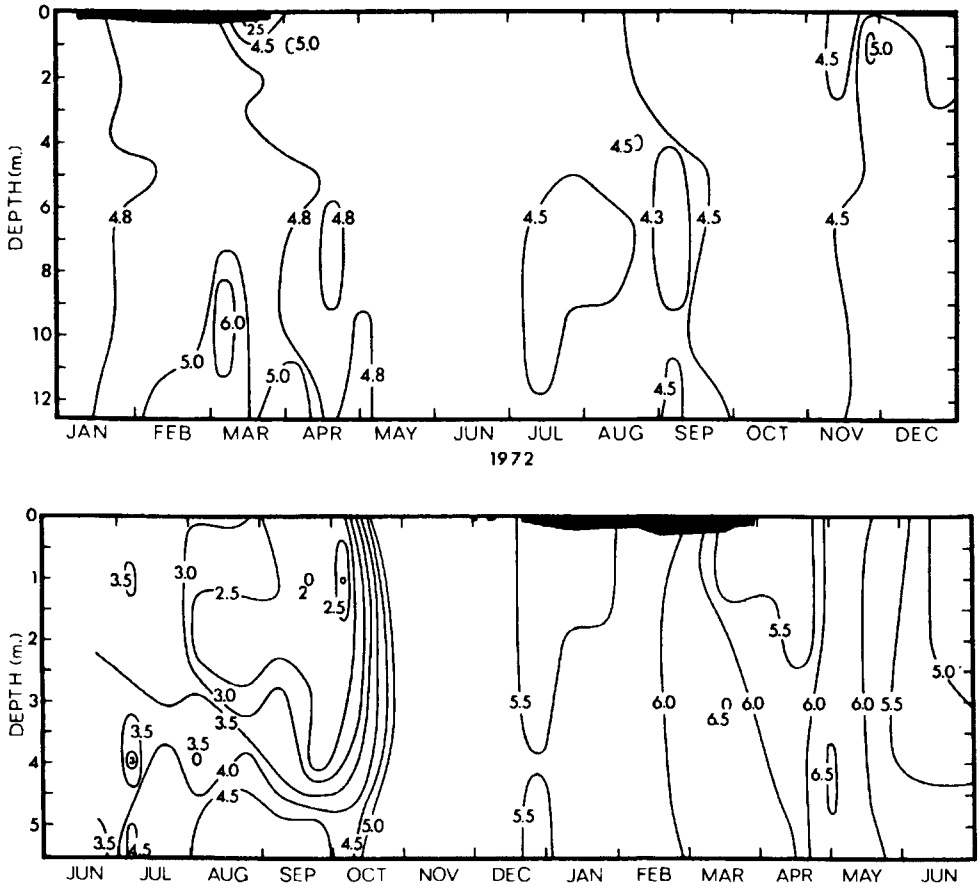

FIGURE 10-7 Depth–time distribution of isopleths of sodium concentrations (mg Na^+ liter^{-1}) of Lawrence Lake (*upper*) and potassium concentrations (mg K^+ liter^{-1}) of hypereutrophic Wintergreen Lake, Michigan, 1971–1972 (*lower*). Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

transport and CO_2 transport appears to have no effect on bicarbonate transport. One of the HCO_3^- transport systems is dependent on the presence of millimolar concentrations of sodium (Espie *et al.*, 1991). The active transport of CO_2, however, requires only micromolar levels of Na^+ (Miller *et al.*, 1990).

Therefore, sodium, along with many other factors, can influence the development of large populations of the cyanobacteria. Maximal growth of several cyanobacterial species was found at 40 mg liter^{-1}. The enrichment of waters with high levels of sodium and phosphorus, as is the case, for example, in domestic effluents with very high concentrations of both elements from synthetic detergents, was indicated as a potential contributor to effective competition among the cyanobacteria under bloom conditions (Provasoli, 1958; Wetzel, 1966a; Ward and Wetzel, 1975). Sodium and potassium occur in relative abundance as highly soluble cations of numerous salts. Alteration of their concentrations in natural waters is not common, except under conditions of pollution, for example, salinity from industry or domestic sources (Wetzel, 1966a) and animals (Kilham, 1982). Runoff from deicing salts for roads has resulted in major alterations of the ionic composition of streams and lakes (Hoffman *et al.*, 1981; Sutcliffe and Carrick, 1983a, 1983b; Demers and Sage, 1990; Rich and Murray, 1990; Rosenberry *et al.*, 1999). Alternative de-icing compounds, such as calcium magnesium acetate (Schenk, 1991), are equally effective and much less intrusive biologically.

The spatial and temporal distribution of sodium and potassium in lakes is relatively uniform. Only small seasonal variations are observed, particularly for sodium, in accord with the conservative nature of these ions (Fig. 10-7; see also Stangenberg-Oporowska, 1967). Moderate epilimnetic reductions in potassium concentrations have been observed in productive lakes (e.g., Fig. 10-7) and in fertilized, productive farm ponds (Barrett, 1957). This reduction is related to potassium utilization by the massive algal populations and by submersed macrophytes and their epiphytes (Mickle and Wetzel, 1978a; Barko, 1982). Potassium is actively assimilated into submersed plant tissues with a light-dependent exchange process of reciprocal sodium efflux (Brammer and Wetzel, 1984). Lake sediments are net sources of potassium during summer stratification, and some hypolimnetic enrichment and export occurs in stratified, eutrophic lakes (e.g., Fig. 10-7; see also Stauffer and Armstrong, 1986).

The concentrations of rarer alkaline earth and alkali cations of natural waters vary considerably in relation to the lithology of the drainage basins. Their distribution is discussed by Durum and Haffty (1961), Livingstone (1963), and Cowgill (1976, 1977a,b) in general, and in closed-basin lakes in particular by Whitehead and Feth (1961). General ratios of major to minor cations are given in Table 10-7. Strontium cycling is closely coupled with calcium, and Sr/Ca ratios maintain a nearly constant stoichiometry (Stabel, 1989). Nutritional requirements for these relatively rare elements have not been demonstrated, although they can sometimes substitute for the major cations in metabolic pathways.

TABLE 10-7 Approximate Ratios of Minor Alkaline Earths and Alkalis to the Major Cations[a]

Na/Li	1500	Ca/Ba	400
Na/Rb	3600	Ca/Sr	3000–4500
Na/Cs	31,900	Ca/Be	ca. 40,000
		Ca/Ra	5×10^{10}

[a] From data of Livingstone (1963).

D. Chloride and Other Anions

Earlier discussion of the general distribution of chloride ions in lakes emphasized that chloride is usually not dominant in open lake ecosystems. Streams and lakes near maritime regions, however, often receive significant inputs of chlorides from atmospheric transport from the sea. Pollutional sources of chlorides can modify natural concentrations greatly. For example, the concentration of chloride in Lake Erie increased threefold in 50 years, largely (ca. 70%) from industrial sources, runoff from road salting, and municipal wastewaters (Ownby and Kee, 1967). Chloride is influential in general osmotic salinity balance and ion exchange, but metabolic utilization does not cause large variations in the spatial and seasonal distribution within most lakes (Fig. 10-8). Variations observed in Lake Erie and in many saline lakes are associated with hydrology of the basin and seasonal fluctuations (e.g., Ownbey and Kee, 1967; Wetzel, 1964).

Concentrations of minor halides (Table 10-8) vary somewhat with the lithology within the drainage basin, and higher concentrations often occur in lakes and streams in proximity to marine regions or in those that possess marine rock formations within their drainage basins. Boron is of greater limnological interest because it is a micronutrient required by many algae and other organisms. Concentrations of boron in natural waters are relatively high in comparison to other minor elements. The average concentration in rain and snow is also high (4.7 μg B liter^{-1}) and apparently is of terrestrial origin rather than from the sea (Nishimura *et al.*, 1973). Concentrations reach exceedingly high levels in

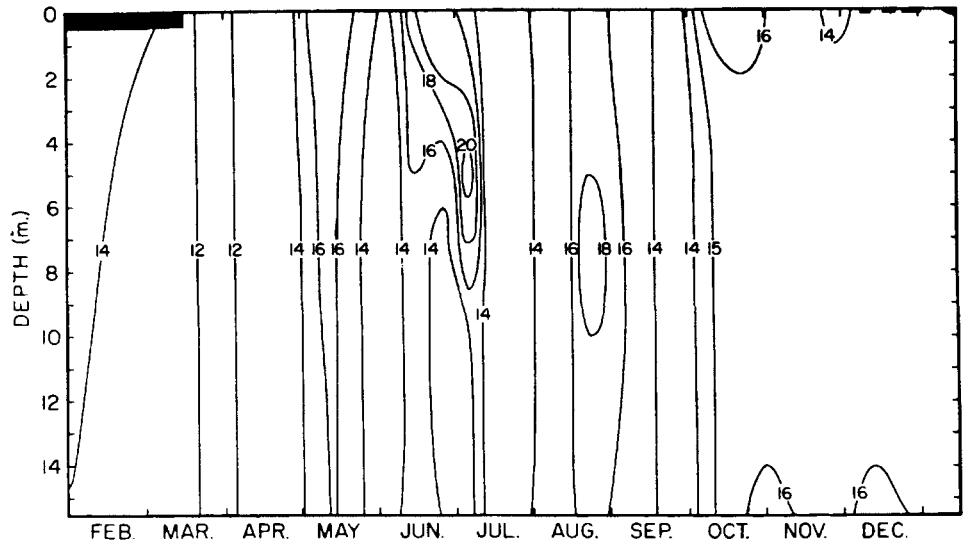

FIGURE 10-8 Depth–time distribution of isopleths of chloride concentrations (mg Cl liter^{-1}) of eutrophic Little Crooked Lake, Whitley County, Indiana, 1964. Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

certain closed, saline lakes and can approach 1 g per liter. As is the case with most micronutrients, high concentrations are generally toxic to most organisms, as was exemplified by the well-known excessive use of the micronutrient copper as a bioicide. Organisms adapted to high concentrations of boron, to > 800 mg B liter^{-1}, were affected little by additions of further borate (Wetzel, 1964). Aquatic angiosperms normally living in waters of very low boron content show a high resistance to large concentrations of boron. Boron additions were found to be stimulatory to photosynthesis to levels of 100 mg liter^{-1}, beyond which inhibitory responses occurred (Baumeister, 1943).

E. Cation Ratios

The ratio of monovalent to divalent cations (M:D) is particularly interesting in relation to the distribution and dynamics of algae and higher aquatic plants in fresh waters. Three major genera of diatoms common to oligotrophic waters, *Fragilaria, Asterionella,* and *Tabellaria,* are stimulated by high levels of calcium (Chu, 1942; Vollenweider, 1950). Increasing levels of potassium permit increased tolerance of these algae to high concentrations of Ca and Mg. Numerous studies, particularly by Provasoli and co-workers (Provasoli, 1958), indicate that the M:D ratio is significant to the observed growth of these algae. Concentrations of Ca and Mg can be manipulated over a wide range as long as the M:D ratio is maintained within reasonably narrow limits for different species. Calcium and Mg are widely interchangeable, and many species are quite tolerant to different Ca:Mg ratios. These experimental results provide excellent confirmation of the much earlier perceptive ecological observations of Pearsall (1922, 1932), who considered a M:D ratio below 1.5 favorable to diatoms and much higher ratios favorable to desmid algae. Diatoms dominate the algal flora of very hard-water lakes with M:D ratios much less than 1.5. This relationship is most strongly correlated with the concentrations of calcium (Shoesmith and Brook, 1983). As the epilimnion undergoes biogenically induced decalcification in early summer in calcareous waters, calcium concentrations following the spring diatom maximum are often halved. It is unknown whether, along with other factors, the resulting shift in M:D ratio, which is concomitant with the shift to mixed populations of predominantly green algae with diatoms, influences phytoplanktonic succession.

TABLE 10-8 Approximate Average Concentrations of Halides and Boron in Natural Fresh Waters[a]

Element	*Average concentration (mg liter^{-1})*	*Chloride ratio*	
Chloride	8.3		
Fluoride	0.26	Cl/F	32
Bromine	0.006	Cl/Br	1400
Iodine	0.0018	Cl/I	4600
Boron	ca. 0.01		

[a] From data of Livingstone (1963).

The effects of cations on the photosynthesis and release of dissolved organic matter were studied on a submersed angiosperm, *Najas flexilis,* a macrophyte that grows poorly in extremely calcareous hardwater lakes (Wetzel, 1969; Wetzel and McGregor, 1968). Concentrations of Ca over 30 mg liter^{-1} and Mg over 10 mg liter^{-1}, both greatly exceeded in hardwater lakes, suppressed rates of photosynthetic carbon fixation and altered the secretion rates of fixed organic carbon as dissolved organic matter. Increasing concentrations of Na above levels commonly found in hardwater lakes increased both the rates of fixation and secretion. The overall effects observed were decreased rates of photosynthetic carbon fixation with decreasing M:D ratios.

Dissolved organic compounds of fresh waters could potentially regulate M:D ratios and indirectly influence rates of photosynthesis (Wetzel, 1968). Sequestering of divalent cations by chelation with amino substances and peptides is well known. Complex formation is also possible by pyrophosphates, binding with macromolecules such as proteins, and the formation of peptized metal hydroxides of humic acids. The mechanisms have not been adequately investigated in relation to controls over algal succession and dynamics, but it is clear that such sequestering mechanisms are additional means of the many by which dissolved organic matter exerts major influences on productivity. This subject is discussed in greater detail in Chap. 15.

F. Ionic Budgets within a Drainage Basin

As we have seen, the temporal and spatial loading, distribution, and fate of ions vary greatly with the lithology, climatic conditions, drainage and limnological characteristics, and biotic activities of soils, streams, and lakes. Examination of a representative example of an ionic budget is instructive to evaluate relative proportions of inputs and fates of ions.

The ionic budget of the Mirror Lake ecosystem within the Hubbard Brook Valley of New Hampshire has been studied many years (Likens, 1986). In this drainage basin, nearly all of the precipitation runoff not lost to evapotranspiration flows through the soil and is collected in streamflow. Precipitation is acidic (pH 4.1) and strongly influenced by air pollution. Cationic loadings in stream water greatly exceed inputs in bulk precipitation, as gains are obtained by weathering, evapotranspiration, biomass, and exchange processes within the soils (Table 10-9). Dissolved cations in stream water draining aggrading forests remained relatively constant despite extremes in hydrologic output and climatic variations. Particulate loadings and outputs were very small and were dependent on storm peaks (Table 10-9). Inputs to the lake and

outputs from the lake were largely via cations dissolved in the stream water. Regulation of fluxes to the lake can be changed appreciably by disturbances within the drainage basin, such as deforestation and loadings from atmospheric, sewage, road salt leaching, and other sources of pollution. For example, clearcutting forest disturbance resulted in large losses of potassium in particular to stream water (Likens *et al.*, 1994). Of the major cations, potassium was the slowest to recover from clearcutting disturbances.

V. SALINITY, OSMOREGULATION, AND DISTRIBUTION OF BIOTA

A. Origins and Distribution of Freshwater Biota

The salinity of inland waters is generally very low in comparison to that of the sea, although in semiarid regions the salinity of closed-basin lakes occasionally exceeds that of sea water by several times. The distribution of biota in fresh waters has been influenced by a long evolutionary history of physiological adaptations to a wide range of salinities. These mechanisms developed against a background of large differences between the salinity of the environment and that of the cytoplasm or body fluids. The general distribution of the freshwater biota and their tentative origins in terrestrial, freshwater, or marine sources are summarized in the detailed review of Hutchinson (1967). That summary, coupled with reviews of the physiological mechanisms and adaptation of osmotic regulation (Krough, 1939; Beadle, 1943, 1957, 1959; Gessner, 1959; Robertson, 1960; Potts and Parry, 1964), provides an introduction to adaptations to freshwater life. The distribution of biota in brackish water interface regions between marine and fresh waters is summarized in the symposium on brackish waters (1959) and by Remane and Schlieper (1971).

The number of species living in brackish water is very much smaller than the number living in marine regions with similar habitats and much smaller than the number of species in fresh water (Fig. 10-9). However, it should be noted immediately that a paucity of species in this region in no way implies low productivity; productivity of adapted organisms can be exceedingly high. The lowest number of species occurs in salinities of about 5–7‰. The salinity gradient depicted here, with its associated osmotic and ionic properties, is the predominant factor influencing the distribution of biota in brackish waters. In these transitional waters, as in the spectrum of salinities of inland waters, the salinity range occupied by a species depends on the efficiency of the physiological mechanisms by which it is adapted to changes in salinity in the environment.

B. Osmotic Adaptations of Aquatic Plants and Animals

Osmotic regulation functions primarily in the maintenance of a difference in concentrations of ions inside and outside of the cells at appropriate operational physiological levels. The aquatic bacteria and cyanobacteria. Monera (lacking mitochondria or chromoplastids) and the more primitive Protista (algae, fungi, and protozoa with mitochondria and, if they are photosynthetic, with chromoplastids) demonstrate high evolutionary adaptability to changes in salinity (cf. Hutchinson's 1967 description of evolutionary eurihalinity) through relatively small genetic changes. Most freshwater bacteria and cyanobacteria are relatively homoiosmotic and tolerate only a narrow range of salinity but adapt to increasing salinity relatively rapidly by means of genetic change. Extensive adaptive radiation is seen among these groups. Members of the Protista, which are largely single-celled, retain considerable evolutionary euryhalinity and are widely distributed with respect to salinity, although some groups, especially among the green algae, are restricted to fresh water. The contractile vacuole is the primary osmoregulatory organelle among the Protista.

Higher aquatic plants, which are of terrestrial origin, have developed adaptations to fresh water secondarily. Only a few major groups of angiosperms

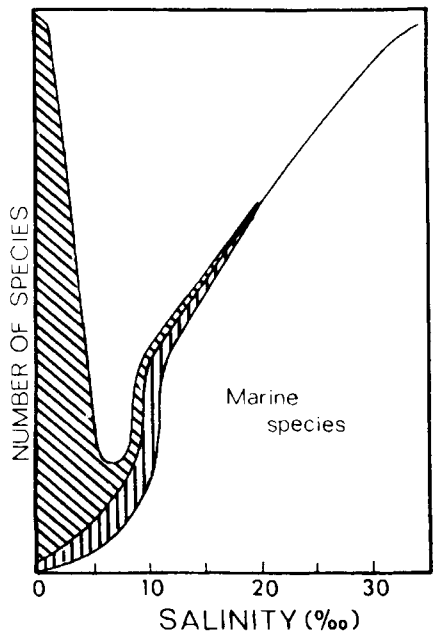

FIGURE 10-9 Number of species in relation to salinity. Diagonal hatching: proportion of freshwater species; vertical hatching: proportion of brackish-water species; lower open area: marines species. (Modified from Remane and Schlieper, 1971.)

have developed extensively in fresh waters, and very few groups extend into saline waters of brackish or marine areas or into hypersaline closed-basin lakes.

Nearly all of the higher freshwater animals originated from the sea, although most aquatic insects are of terrestrial origin. Both in terms of evolutionary and contemporary life in fresh water, osmoregulation is a major problem, for which diverse mechanisms have developed to regulate salt and water content. Adaptation to low salinities by some marine animals has been achieved without osmoregulation. Such ***poikilosmotic*** animals adjust the osmotic pressure of their body fluids to become more or less isotonic with the salinity of the medium. In contrast, a ***homoiosmotic*** animal will tend to retain its initial internal osmotic concentration upon being exposed to modest changes in the salinity of the medium. The general relations between the osmotic pressure among different types of animals, expressed as salinity of the blood versus salinity of the external water, can be visualized in Figure 10-10. The range depicted by area A extends over a wide variation in osmotic pressure of body fluids that is found in brackish-water animals, which tend to be more poikilosmotic at high concentrations and more homoiosmotic at lower salinities. The range of the osmotic pressure curve extends from the most homoiosmotic (a_1) to the most poikilosmotic species (a_2). The lower limits are very variable, represented by the undefined left-hand edge of area A, but all of these species have failed to colonize fresh water.

A few species have succeeded in penetrating fresh water without a renal osmoregulatory mechanism. These brackish-water animals are partially homoiosmotic (area B, Fig. 10-10) and maintain a very high osmotic pressure in hypertonic body fluids by the active uptake of ions from the water. Excretory organs are not involved, since the urine produced is isotonic with the blood.

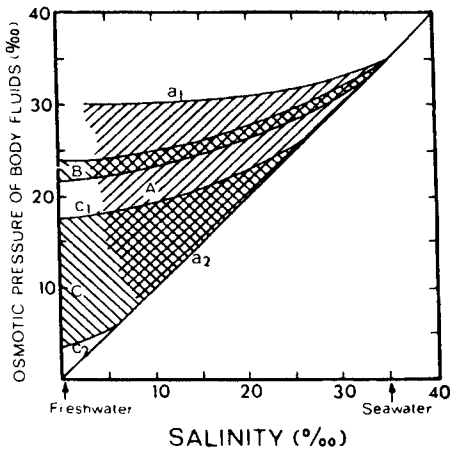

FIGURE 10-10 Relationship between the osmotic pressure, expressed as salinity, of body fluids of brackish-water organisms (A) and freshwater animals (B, C) and the salinity of external water. (Modified from Beadle, 1959.) Relationships of the curves are detailed in the text.

In most freshwater animals, however, osmotic pressures of the body fluids have decreased to levels equivalent to 5–15‰ salinity to reduce osmotic gradients. These organisms have developed excretory organs that effectively recover ions and produce urine hypotonic to the body fluids. Most freshwater animals therefore effect osmoregulation by active uptake of ions and by a renal mechanism of ion retention. Extremes in osmotic pressures of blood delineate area C of Figure 10-10 by curves c_1 and c_2. The isotonic line along the right-hand edge of area C indicates the upper salinity tolerance limit of most freshwater animals and that they are incapable of hypotonic regulation. Although most freshwater animals are capable of living in water of low salinity, adaptation of body fluids of low osmotic pressure is apparently irreversible, and with few exceptions freshwater organisms are restricted to salinities of <10‰.

Because of the slow diffusion of oxygen in water relative to that in air, movement of water over permeable membranes or tissue surfaces for respiratory needs is almost universal among aquatic animals. The pumping process places high energetic demands on the animals and additionally exposes cellular surfaces to osmotic gradients. Mechanisms for taking up salts against a concentration gradient vary greatly among freshwater animals. In a few organisms, incorporation of salts with the food may be adequate, but more often organs have developed for this purpose. Aside from resorption mechanisms of the excretory organs, which are advantageous energetically, active uptake mechanisms for ions, especially sodium and chloride, are often associated with the respiratory organs (commonly gills) of many invertebrates and vertebrates.

The fauna of extremely saline inland lakes are relatively insensitive to the high salinity of these lakes and to large interseasonal fluctuations in the chemical composition of the water (Beadle, 1969). Most of the animals of saline lakes are of freshwater origin and include particularly representatives of the aquatic insects, phyllopods, copepod and cladoceran crustacea, and rotifers, all of which belong to predominantly freshwater groups. The blood of these saline-inhabiting animals maintains osmotic pressures at levels characteristic of those living in fresh waters. The body surface of these animals exhibits very low permeability, and they possess effective excretory mechanisms for maintaining the body fluids strongly hypotonic to the external medium. Furthermore, the water balance of saline inland waters frequently fluctuates widely; freshwater animals with resting stages capable of withstanding desiccation have

a distinct advantage over marine animals, which lack strong development of this characteristic.

VI. SUMMARY

1. Total ***salinity*** of inland waters is usually dominated by four major cations [calcium (Ca^{++}), magnesium (Mg^{++}), sodium (Na^{+}), and potassium (K^{+})] and the major anions [bicarbonate (HCO_3^{-}), carbonate (CO_3^{-}), sulfate (SO_4^{-}), and chloride (Cl^{-})].
2. The salinity of surface waters has a world average concentration of about 120 mg liter^{-1} but varies among continents and with the lithology of the land masses and drainage basins (Tables 10-1 and 10-2).
   a. The salinity of water is a composite of ionic contributions leaching from rock and soil in runoff from the drainage basin, atmospheric precipitation and deposition, and the balance between evaporation and precipitation.
   b. Concentrations of major ions of many surface waters of the world exist in the proportions of $Ca > Mg \geq Na > K$ and HCO_3–$CO_3 > SO_4 > Cl$. In soft waters and in surface waters of coastal regions, Na and Cl often occur in greater equivalent concentrations (Table 10-3).
3. The release of ions as soil and rock weather is controlled by the processes of solution and oxidation–reduction, the action of hydrogen ions, and the formation of organic complexes. A major source of salinity to many dilute fresh waters and certain saline lakes of arid regions is the ionic content of atmospheric precipitation and particulate deposition.
4. Concentrations of the cations magnesium, sodium, and potassium and the major anion chloride are relatively conservative and undergo only minor spatial and temporal fluctuations within a lake from biotic utilization or biotically mediated environmental changes. Calcium, inorganic carbon, and sulfate are dynamic, and concentrations of these ions are influenced strongly by microbial metabolism.
   a. Proportional concentrations of major cations and the ratios of monovalent:divalent cations can influence the metabolism of many organisms, particularly certain algae and submersed macrophytes, as much as absolute concentrations do.
   b. Processes that influence the availability of some cations disproportionately to others (e.g., organic complexing of calcium or biologically induced decalcification of the epilimnion) can indirectly affect seasonal population succession and productivity.
5. The relatively low salinity of fresh waters has influenced greatly the distribution of biota and their long evolutionary history of physiological adaptations for osmotic and ionic regulation in an extremely hypotonic environment.
   a. Although some groups of bacteria and algae are relatively homoiosmotic and can tolerate only a narrow range of salinity, most of the lower flora and fauna are euryhaline, that is, adaptable to a wide range of salinity.
   b. Most higher freshwater animals originated from the sea or from land and adapted to fresh water secondarily. In comparison to marine forms, nearly all of these organisms have reduced osmotic pressures of body fluids and have developed efficient mechanisms for active uptake of ions and renal mechanisms for ion retention.

VI. Summary

Inorganic carbon, largely as dissolved carbon dioxide and bicarbonate, is the primary source of carbon for photosynthesis and the generation of organic substances. These organic compounds are generated by cyanobacteria, algae, and higher plants both within the lakes or rivers or externally within the drainage basin and variously imported to the water bodies. These organic carbon-based compounds provide the materials and energy for subsequent metabolism within the ecosystem. Inorganic carbon utilization is balanced by respiratory production of CO_2 by most organisms and by influxes of CO_2 and HCO_3^- from incoming water and from the atmosphere.

The atmosphere and minerals are the sources of inorganic constituents dissolved in fresh water. Precipitation falling on the surface of the Earth as rain or snow contains a variety of gases, aerosols, and dust particles. As the precipitation flows over or penetrates into plants or the soils, water dissolves more gases, particularly carbon dioxide, and provides an acid that reacts with bases of rocks and various mineral substances with which it comes into contact. The water can also lose dissolved carbon to the sediments by precipitation reactions.

Dissolved inorganic carbon is a major constituent of inland waters and can influence many characteristics of gaseous and nutrient availability, as well as serving as the foundation of organic productivity. The loadings of carbon dioxide to and quantities within the atmosphere are increasing progressively, largely from anthropogenic combustion of fossil deposits of organic matter (e.g., Schlesinger, 1991). The dissolved inorganic carbon constituents also influence water quality properties such as acidity, hardness, and related characteristics. Thus, it is essential that the rudiments of dissolved inorganic carbon reactivity be evaluated.

I. THE OCCURRENCE OF INORGANIC CARBON IN FRESHWATER SYSTEMS

A. Carbon Dioxide and Its Solution in Water

The carbon dioxide (CO_2) content of the atmosphere varies with locality and potential enrichment from industrial pollution. The global average is approximately 0.0355% by volume, as of 1991, and is increasing at ca. 2% per year (Machta, 1973; Broecker

et al., 1979; Gates, 1993). Carbon dioxide is very soluble in water, some 200 times more than oxygen, and obeys normal solubility laws within the conditions of temperature and pressure encountered in lakes. The amount of CO_2 dissolved in water from atmospheric concentrations is about 1.1 mg liter^{-1} at 0°C, 0.6 mg liter^{-1} at 15°C, and 0.4 mg liter^{-1} at 30°C.

As CO_2 dissolves in water, the solution contains unhydrated CO_2 at about the same concentration by volume (approximately 10 μM) as in the atmosphere (reviewed extensively by Hutchinson, 1957; Kern, 1960; J. C. Goldman *et al.*, 1972; Morel and Hering, 1993; Stumm and Morgan, 1995):

$$CO_2(\text{air}) \rightleftharpoons CO_2(\text{dissolved}) + H_2O$$

Dissolved CO_2 hydrates by a slow reaction (a half-time of approximately 15 s):

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

This reaction predominates at a pH of less than 8, with the equilibrium concentration of H_2CO_3 only about 1/400 that of the unhydrated CO_2. Above a pH of 10, $CO_2 + OH^- \rightleftharpoons HCO_3^-$ is the dominant reaction.

H_2CO_3, is a fairly weak acid that dissociates rapidly relative to the hydration reaction:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$
$$HCO_3^- \rightleftharpoons H^+ + CO_3^{2-}$$

The pK_1 dissociation value of the first reaction, including both hydrated and unhydrated CO_2 as the undissociated molecule, is 6.43 at 15°C. The pK_2 of the second reaction is 10.43 (15°C).

The bicarbonate and carbonate ions also dissociate to establish an equilibrium:

$$HCO_3^- + H_2O \rightleftharpoons H_2CO_3 + OH^-$$
$$CO_3^{2-} + H_2O \rightleftharpoons HCO_3^- + OH^-$$
$$H_2CO_3 \rightleftharpoons H_2O + CO_2$$

The hydroxyl ions generated in the first two of these reactions result in alkaline waters (above a pH of 7) in lakes and streams that have a naturally high content of carbonates derived from surface and ground water of the drainage basin. As water percolates through soil of the drainage basin, it becomes enriched with CO_2 from plant and microbial respiration. The carbonic acid that forms solubilizes limestone of calcium-enriched rock formations and produces calcium bicarbonate [$Ca(HCO_3)_2$], which is relatively soluble in water, and increases the amount of ionized Ca^{++} and HCO_3^- of the water. As HCO_3^- and CO_3^{2-} increase in hard waters of calcareous regions, common to much of the glaciated temperate region, the pH also increases from the release of hydroxyl ions. In normal hard waters of the midwestern United States, for example, HCO_3^- is the dominant anion (ca. approximately 60%), so that the pH of the water is >8 and $[HCO_3^-] > 100$ mg 1iter^{-1}. Saline lakes of endorheic regions often have a carbonate dominance ($CO_3^{2-} > 10{,}000$ mg 1iter^{-1} and $HCO_3^- > 1000$ mg liter^{-1} with pH >9.5). Such highly saline carbonate brines, in which total inorganic carbon exceeds several moles per liter, are rare.

Photosynthesis and respiration are two major factors that influence the amounts of CO_2 in water. However, the equilibria of the reactions given here result in the buffering action of alkaline waters, which contain appreciable amounts of bicarbonate. Water tends to resist change in pH as long as these equilibria are operational. An addition of hydrogen ions neutralizes hydroxyl ions formed by the dissociation of HCO_3^- and CO_3^{2-} but more hydroxyl ions are formed immediately by reaction of the carbonate with water. Consequently, the pH remains essentially unaltered, unless the supply of carbonate or bicarbonate ions is exhausted. Similarly, when hydroxyl ions are added they react with bicarbonate ion:

$$HCO_3^- + OH^- \rightleftharpoons CO_3^{2-} + H_2O$$

If the pH of a solution is held constant with buffer reactions, and it is permitted to equilibrate with gaseous carbon dioxide, the total hydrated and unhydrated CO_2 in solution is independent of pH, while the bicarbonate and carbonate concentrations increase with pH in accordance with the pK values. These equilibria are influenced by temperature and by salt concentration (ionic strength). At the salinity of sea water, the pK_1 for HCO_3^- is about 0.5 pH unit and the pK_2 for CO_3^{2-} is about 1 unit lower than in fresh water. Both oceanic and fresh waters are close to equilibrium with atmospheric CO_2. In the marine habitat, the inorganic carbon pool contains about 2 mmol C liter^{-1}, largely as HCO_3^-, a reservoir some 50 times that of the atmosphere. In fresh waters, the total inorganic carbon (ΣCO_2) is much more variable, within a typical range of 50 μmol to 10 mmol liter^{-1}, and more pH dependent. From these dissociation relationships, the proportions of CO_2, HCO_3^-, and CO_3^{2-} at various pH values can be evaluated (Fig. 11-1). Free CO_2 dominates in water at pH 5 and below, while above pH 9.5 CO_3^{2-} is quantitatively significant (Table 11-1). Between pH 7 and 9, HCO_3^- predominates.

B. CO_2 Exchange between the Atmosphere and Water

The diffusion of CO_2 from the atmosphere and the dissociation kinetics of dissolved carbonates are obviously of major importance to photosynthetic organisms

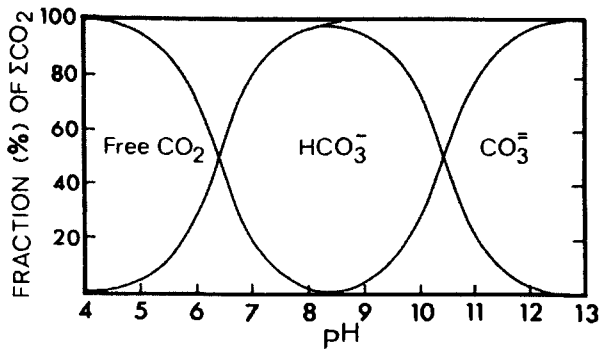

FIGURE 11-1 Relation between pH and the relative proportions of inorganic carbon species of $CO_2(+H_2CO_3)$, HCO_3^-, and CO_3^{2-} in solution. (Slightly modified from Goiterman, H. L. (ed.): *Methods for Chemical Analysis of Fresh Waters*, IBP Handbook No. 8, Oxford England, Blackwell Scientific Publications, 1969.)

dependent on the availability of inorganic carbon for photosynthesis. The magnitude of CO_2 exchange between the atmosphere and water cannot be determined by partial pressure differences alone. Diffusion of atmospheric CO_2 has been examined by utilizing radium-226 and the flux of radon-222 to determine gas transfer rates between the atmosphere and water (Broecker *et al.*, 1965, 1971, 1973). When applied to a very soft-water lake of the Canadian Shield of very low ΣCO_2, atmospheric invasion of CO_2 was adequate (0.12 ± 0.06 g C m^{-2} day^{-1}) to account for 30–90% of the carbon fixed by phytoplankton (Schindler *et al.*, 1972). In this sheltered lake, an invasion rate of CO_2 from the air of 17 ± 8 mmol CO_2 m^{-2} day^{-1} was estimated through a hypothetical "stagnant boundary layer" at the surface of about 300 μm in thickness (Emerson *et al.*, 1973). This layer decreased in thickness with increased exchange as wind velocities increased, particularly above 1.5 m sec^{-1}. Consumption of CO_2 by epilimnetic photosynthesis can enhance the flux of atmospheric CO_2 to these soft waters (Weiler, 1974; Wood, 1974, 1977; Emerson, 1975). As noted earlier (Chap. 2), organic substances dissolved in or present on the water surface can also decrease rates of gas exchange and of evaporation.

TABLE 11-1 Proportions of CO_2, HCO_3^-, and CO_3^{2-} in Water at Various pH Values[a]

pH	Total free CO_2	HCO_3^-	CO_3^{2-}
4	0.996	0.004	1.25×10^{-9}
5	0.962	0.038	1.20×10^{-7}
6	0.725	0.275	0.91×10^{-5}
7	0.208	0.792	2.6×10^{-4}
8	0.025	0.972	3.2×10^{-3}
9	0.003	0.966	0.031
10	0.0002	0.757	0.243

[a] From Hutchinson, G. E.: *A Treatise on Limnology*, New York, John Wiley & Sons, Inc., 1957, p. 657.

An extensive survey of the partial pressure of CO_2 in the surface waters from a large number of lakes (1835) of worldwide distribution showed that only a small proportion (<10%) were near equilibrium with the atmosphere and that most samples (87%) were supersaturated (Cole *et al.*, 1994). The average partial pressure of dissolved CO_2 was about 3 times the value in the overlying atmosphere. Data presented for one lake in this paper and many other studies have demonstrated a distinct seasonality to CO_2 evasion to the atmosphere (e.g., Otsuki and Wetzel, 1974; Kling *et al.*, 1991; many others). For example, in a hardwater lake in Michigan that receives high inputs of inorganic carbon as bicarbonate, Otsuki and Wetzel (1974) determined that the partial pressure in two inlet waters and ground water was about 30 times higher than that in the atmosphere. In the outlet, the partial pressure of dissolved CO_2 was 7 times higher during the spring period, and 3 times higher even during the summer period of maximum utilization by photosynthesis and large losses by precipitation and sedimentation of $CaCO_3$. CO_2 in this and most lakes is released into the atmosphere throughout the year.

As discussed later in this chapter, CO_2 from the respiratory processes of decomposition can accumulate to large quantities in the hypolimnia of lakes. Under certain conditions of lake basin morphometry and annual mixing, as in certain deep, tropical crater lakes, CO_2 can accumulate to extraordinarily high concentrations. Decompression of CO_2-saturated water can, with changes in seasonal stabilities of stratification, erupt to the surface at explosive rates (range, 50–90 m s^{-1}) (Zhang, 1996). So much CO_2 is released by this exsolution and evasion to the atmosphere that the dense CO_2 over the lake surface can temporarily cascade over the surrounding terrain. Such massive evasions occurred in Lake Nyos and Lake Monoun of Cameroon, and over 1700 humans and many terrestrial animals died by asphyxiation (Kling *et al.*, 1987, 1991). The sources of the hypolimnetic accumulations of CO_2 and CH_4 were largely biogenic; volcanic sources were minor (Kling *et al.*, 1989).

C. Proportions of Dissolved Inorganic Carbon in Fresh Waters

Carbon is transported continuously by rivers as particulate and dissolved organic carbon (POC, DOC) and as dissolved inorganic carbon (DIC) that functions

in weathering reactions. Of the global carbon fluxes to the oceans from the continents, about 18% moves in riverine transport as POC, 37% as DOC, and 45% as DIC (Meybeck, 1993a). Proportions of DIC, POC, and DOC in the rivers of the world are variable; differences emanate from lithology, which controls DIC levels, and differences in relief that control the DOC/POC ratios. DIC is very low in many tropical rivers of humid regions, and there DOC is the dominating form of exported carbon. Within the pelagic zone of lakes and reservoirs, however, the ratio of DOC/POC is ca. 10:1 (Wetzel, 1984).

An average of 80% of the DIC alkalinity of North American river water is attributable to carbonate rock dissolution and 20% to the weathering of aluminosilicate rocks (Morel and Hering, 1993). Of world average river water with higher alkalinity, about 60% of the alkalinity is contributed by dissolution of carbonates, and most of the remainder originates from dissolution of calcium, magnesium, and alumino-silicates. On a global discharge-weighted basis, however, the dissolved content of surface waters is dominated by HCO_3^-, Ca^{+2}, SO_4^{-2}, and SiO_2, and over 97% of global runoff has been classified as of the calcium bicarbonate type (Meybeck, 1993b).

The total inorganic carbon concentration in fresh water depends on the pH, which is governed largely by the buffering reactions of carbonic acid and the amount of bicarbonate and carbonate derived from the weathering of rocks. Carbonates exist as a number of polymorphic and hydrated forms. The most important carbonate of aquatic systems is $CaCO_3$, which occurs in natural waters principally as calcite and the metastable polymorphic aragonite.

The solubility of CO_2 increases markedly in water that contains carbonate. A definite amount of free CO_2 will remain in solution after equilibrium is reached between calcium, bicarbonate, carbonate, and undissociated calcium carbonate. The amount of excess CO_2 required to maintain stability of $Ca(HCO_3)_2$ in solution increases very rapidly with increasing content of bicarbonate in the water derived from carbonates. If the amount of free CO_2 is increased above that required to maintain a given amount of $CaCO_3$ in solution at equilibrium as $Ca(HCO_3)_2$, this aggressive CO_2, as it is termed, will dissolve additional $CaCO_3$.

If a solution of calcium bicarbonate in equilibrium with CO_2, H_2CO_3, and CO_3^{2-} loses a portion of the CO_2 required to maintain the equilibrium (e.g., CO_2 assimilated by photosynthetic organisms), $CaCO_3$ will precipitate until the equilibrium is reestablished by the formation of CO_2:

$$Ca(HCO_3)_2 \rightleftharpoons CaCO_3 \downarrow + H_2O + CO_2$$

The excess CO_2 that is required to maintain large amounts of HCO_3^- in solution at equilibrium can be lost in several ways, and result in massive precipitation of $CaCO_3$. Ground water of limestone regions, heavily enriched with CO_2 from terrestrial decomposition, can release much CO_2 into the atmosphere when it flows to the surface, with resulting precipitation of $CaCO_3$. When such spring water, rich in bicarbonate, surfaces in streams or lakes, all substrata become covered with a dense encrustation of $CaCO_3$. A major cause of the loss of aggressive CO_2 in hardwater lakes and certain streams is photosynthetic utilization of CO_2 by phytoplankton and littoral-submersed macrophytes and epiphytic algae (e.g., Otsuki and Wetzel, 1974; Nebrasova, 1984; Dustin *et al.*, 1986; Stabel, 1986; Küchler-Krischun and Kleiner, 1990). Some of the CO_2 used in photosynthesis is generated by the calcification process, which raises pCO_2 immediately adjacent to the photosynthesizing surface (McConnaughey, 1994). Hardwater lakes rich in bicarbonate commonly undergo massive epilimnetic decalcification during the summer stratification period as a result of photosynthetic removal of CO_2 (a subject discussed later). In the littoral zone of hardwater lakes, the submersed macrophytic vegetation is densely encrusted with $CaCO_3$ precipitated by photosynthetic utilization of CO_2 by the macrophytes and epiphytic algae. The marl encrustations are frequently large and often exceed the weight of the plant (Wetzel, 1960). Cyanobacteria growing attached to substrata in the littoral of lakes and in streams also produce large deposits of carbonates (Golubić, 1973).

In addition to highly dynamic demands for CO_2 from and inputs of CO_2 to fresh water, complex shifts in precipitation and dissolution reactions of carbonate occur spatially and temporally. In alkaline hardwater lakes, often twice the concentrations of calcium and bicarbonate are found than would be expected on the basis of equilibrium with atmospheric pressures of CO_2 (Ohle, 1934, 1952; Wetzel, 1966b, 1972; Otsuki and Wetzel, 1974). The solubility product of $CaCO_3$ is low (0.48×10^{-8}), and $CaCO_3$ can start precipitating from calcareous waters when the pH is sufficiently high in a uniformly buffered system or where equilibria are shifted in microzones associated with sites of active photosynthesis. However, large amounts of inorganic carbon can exist as carbonate and $CaCO_3$ in metastable conditions (House, 1984; Stumm and Morgan, 1995). Once crystallization has started, often in association with a particle such as an algal cell, the rate of crystallization is proportional to the concentrations of calcium and carbonate (Nancollas and Reddy, 1971). A large percentage of the calcite crystals are rhombohedral or dendritic in structure (e.g., Raidt and

Koschel, 1988; Küchler-Krischun and Kleiner, 1990). Although calcite is clearly the most common crystal of $CaCO_3$ formed in lakes and streams, more dense aragonite of differing structure often originating from mollusk shells can dominate in certain lakes, such as seepage, groundwater-dominated marl lakes (e.g., Brown *et al.*, 1992).

The rate of $CaCO_3$ precipitation is slow, unless induced metabolically, as by photosynthesis. The result is a supersaturation with respect to both Ca^{++} and HCO_3^- at concentrations often two to three times that predicted on the basis of equilibria. There is strong evidence that appreciable $CaCO_3$ occurs in stable colloidal form in hardwater lakes (White and Wetzel, 1975). The trophogenic zone in moderately hard Lake Mendota was found to be supersaturated with respect to Ca^{++} and HCO_3^- in all seasons except winter (Morton and Lee, 1968). Extremely hard Lawrence Lake was found to be supersaturated continually (Otsuki and Wetzel, 1974), a situation common where dissolved CO_2 is not in equilibrium with atmospheric CO_2.

The importance of colloidal $CaCO_3$, in addition to larger particulate $CaCO_3$, is poorly understood in relation to indirect effects upon metabolism and flux rates of organic carbon (Wetzel and Rich, 1972). Organic compounds (amino acids, fatty acids, and humic acids) adsorb to particulate and colloidal $CaCO_3$ (Chave, 1965; Suess, 1968, 1970; Chave and Suess, 1970; Wetzel and Allen, 1970; Meyers and Quinn, 1971a; Orlov *et al.*, 1973; Otsuki and Wetzel, 1973; Stewart and Wetzel, 1981). Although such adsorption could be viewed as a scavenging and concentrating process whereby labile dissolved organic carbon from dilute solution is rendered more concentrated for utilization by bacteria, empirical evidence indicates, rather, a chemical competition with the bacteria for the organic substrates. During photosynthetic removal of CO_2, a large fraction of $CaCO_3$ is precipitated by algae and macrophytic vegetation. Frequently, the plant cells serve as a nucleus for particulate $CaCO_3$ formation, which is where organic compounds are being secreted. This association of dissolved organic detrital carbon with $CaCO_3$ is a component of certain freshwater systems that affects the chemical milieu without clearly defined energetic transformations (Wetzel *et al.*, 1972). The organic coatings also reduce the rate of dissolution of sedimenting $CaCO_3$ in lakes and can form a major sink for inorganic and organic detrital carbon in hardwater ecosystems (Wetzel, 1970, 1972; Kleiner, 1990).

D. Alkalinity and Acidity of Natural Waters

Natural waters exhibit wide variations in relative acidity and alkalinity, not only in actual pH values but also in the amount of dissolved material producing the acidity or alkalinity. The concentration of these compounds and the ratio of one to another determine the actual pH and the buffering capacity of a given water. Since the lethal effects of most acids begin to appear near pH 4.5 and of most alkalis near pH 9.5, that buffering can be of major importance in the maintenance of life.

Alkalinity is historically a term that referred to the buffering capacity of the carbonate system in water. Alkalinity is now used interchangeably with ***acid neutralizing capacity (ANC)***, which is the capacity to neutralize strong inorganic acids. Alkalinity in water results from any dissolved species, usually weak acid anions, that can accept and neutralize protons. Because CO_2 is quite soluble and relatively abundant in water in gaseous and dissolved forms, and carbonates are common as primary minerals over much of the Earth, the property of alkalinity of most fresh waters is imparted by the presence of bicarbonates and carbonates, and the CO_2—HCO_3^-—CO_3^{2-} equilibrium system is the major buffering mechanism in fresh waters. Carbonate and hydroxide ions may be present when the pH is very high (Fig. 11-2). Hydroxide, borate, silicate, phosphate, and sulfide are usually present in small quantities in fresh waters, but can be major sources of alkalinity in certain saline inland waters. Dissolved organic anions derived from large amounts of dissolved organic carbon can add alkalinity, particularly among soft waters with limited dissolved inorganic carbon.

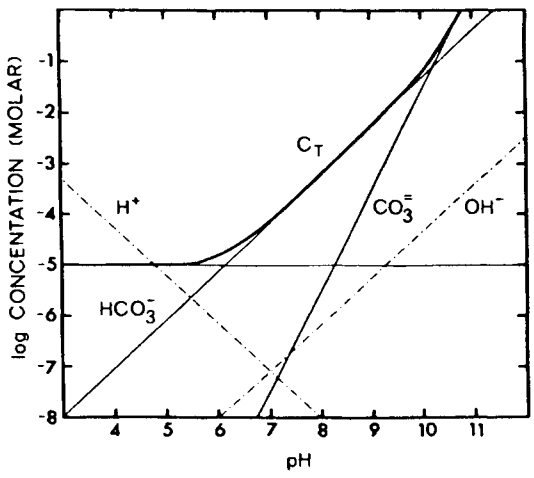

FIGURE 11-2 Model of distribution of carbon species of the carbonate system of natural waters. Pure water is equilibrated with atmospheric CO_2 at a constant partial pressure ($pCO_2 = 10^{-3.5}$ atm, 25°C). The pH can be varied by the addition of a strong acid or strong base, thereby keeping the solution in equilibrium with pCO_2. $\Sigma CO_2 = [CO_2(aq)] + [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}]$. (From Wetzel and Likens, 2000, modified from Stumm and Morgan, 1981, 1995.)

The terms ***alkalinity, carbonate alkalinity, alkaline reserve, titratable base,*** or ***acid-binding capacity*** are frequently used to express the total quantity of base (usually in equilibrium with carbonate or bicarbonate) that can be determined by titration with a strong acid (Hutchinson, 1957). The milliequivalents of acid necessary to neutralize the hydroxyl, carbonate, and bicarbonate ions in a liter of water are known as the ***total alkalinity.*** Alkalinity is numerically the equivalent concentration of titratable base and is determined by titration with a standard solution of a strong acid to equivalency points dictated by pH values at which the alkaline contributions of hydroxide, carbonate, and bicarbonate are neutralized.

The least ambiguous usage of alkalinity is to express values as mass per unit volume; that is, milliequivalents per liter (meq liter^{-1}). In effect, alkalinity measures the proton deficiency with respect to the reference proton level CO_2—H_2O (this topic is reviewed at length by Stumm and Morgan, 1995). Alkalinity is often expressed in milligrams per liter (or parts per million) of $CaCO_3$. This expression assumes that alkalinity results only from calcium carbonate and bicarbonate, which in some lakes (e.g., closed alkaline lakes), implies much greater calcium than actually is present. In moderately hard waters, nearly all of the base is present as bicarbonate, and the term ***bicarbonate alkalinity,*** as mg HCO_3^- liter^{-1}, is sometimes used. The clearest expression, however, is milliequivalents per liter (1 meq liter^{-1} = 50 mg liter^{-1} as $CaCO_3$).

The term ***hardness*** is frequently used as an assessment of the quality of water supplies. The hardness of a water is governed by the content of calcium and magnesium salts, largely combined with bicarbonate and carbonate (temporary hardness) and with sulfates, chlorides, and other anions of mineral acids (permanent hardness). The carbonate hardness can be removed by boiling, which causes precipitation of $CaCO_3$. The fraction of calcium and magnesium remaining in solution as sulfates, chlorides, and nitrates after boiling constitutes the residual noncarbonate hardness. The extent of hardness has been expressed numerically in a remarkably heterogeneous system of scales among different countries (equivalents are given in Table 11-2). For example, one degree of hardness (H°) in the United States equals 1 mg $CaCO_3$ 1liter^{-1}; one German H° corresponds to a concentration of 10 mg lime (CaO) liter^{-1}. Although Höll (1972) has proposed that the international unit be expressed in mval (1 mval = 1 milliequivalent per liter of the material concerned), this terminology has been rescinded by the Système International d'Unités (SI) (see the critical evaluation of the unit Val (= gram equivalent) by Hochmüller and Simoneth (1980a,b).

TABLE 11-2 Various Scales of Hardness of Water[a]

1 German degree of hardness, dH°	= 10 mg CaO liter^{-1} = 7.14 mg Ca liter^{-1} = 17.9 mg $Ca(HCO_3)_2$ liter^{-1}
1 French degree of hardness, French H°	= 10 mg $CaCO_3$ liter^{-1}
1 English degree of hardness, English H°	= 10 mg $CaCO_3$ liter^{-1} = 0.8° dh
1° dh	= 1.25 English H° = 1.79 French H°
1 French H°	= 0.56 German dH° = 0.7 English H°
1 American degree of hardness	= 1 mg $CaCO_3$ liter^{-1} = 0.056 German dH°
International degree of hardness, mval	= 1 meq liter^{-1} = 2.8 German dH°

[a] Afrer Höll, K.: Water: *Examination, Assessment, Conditioning, Chemistry, Bacteriology, Biology,* Berlin, Walter de Gruyter, 1972. See also Hochmüller and Simoneth (1980a,b).

Acidity is used infrequently as a parameter in limnological investigations. Uncombined carbon dioxide, organic acids such as tannic, humic, and uronic acids, mineral acids, and salts of strong acids and weak bases are usually responsible for the acidity of natural waters. Free CO_2 of most waters is seldom present in large quantities because of its reactions in the carbonate equilibria and exchange with the atmosphere, discussed earlier. In practice, acidity is a measure of the quantity of strong base per liter required to attain a pH equal to that of a solution of sodium carbonate (Na_2CO_3) equivalent to the total inorganic carbon; that is, it is a measure of the active or free CO_2 expressed as meq or mg liter^{-1} $CaCO_3$ rather than as a concentration of CO_2. Mineral acid acidity measures those materials present, other than CO_2, which result in the pH value of water below 4.5. Details on methodology for the evaluation of alkalinity and acidity are given in Golterman and Clymo (1969), Wetzel and Likens (2000), and in the American Public Health Association publication (1998).

II. HYDROGEN ION ACTIVITY

Pure water dissociates weakly to H^+ and OH^- ions. The dissociation constant is very small (10^{-14}), however, and the amounts of H^+ and OH^- present are 10^{-7} g-ions per liter. Natural waters are, of course, not pure, and salts, acids, and bases contribute to the H^+ and OH^- ions in varying ways, depending on the

individual circumstances. Since the dissociation constant of water is fixed, the addition of one ion will result in a decrease of the other. The pH is usually defined as the logarithm of the reciprocal of the concentration of free hydrogen ions.[1] The "p" of pH refers to the power (*puissance*) of the hydrogen ion activity. Therefore, more H^+ activity in an acid reaction increases the power from neutrality (10^{-7} or pH 7) to, say, 10^{-4} (pH 4). In more alkaline reactions, H^+ ion activity is decreased from neutrality to, for example, 10^{-10} (pH 10). By definition, pH values cannot be averaged arithmetically, but the average must be estimated from the logarithm of the reciprocals.

The pH of natural waters is governed to a large extent by the interaction of H^+ ions arising from the dissociation of H_2CO_3 and from OH^- ions produced during the hydrolysis of bicarbonate. The pH of natural waters ranges between the extremes of $<2-12$. Nearly all natural, unpolluted waters with pH values less than 4 occur in volcanic regions that receive strong mineral acids, particularly sulfuric acid. The oxidation of pyrite of rocks and clays in drainage basins can result in sulfuric acid drainage to lakes.

Low pH values are often found in natural waters rich in dissolved organic matter. An appreciable portion (often >50%) of dissolved organic matter occurs as organic acids derived from humic compounds (cf. Chap. 23). Humic compounds are comprised of a large number of complex ligands that have numerous p*K* and charge density (CD, mole sites per mole of carbon) values (Lydersen, 1998). The concentration of organic acids (CD) varies from 5 to 22 μeq mg C^{-1}, often with an average CD of carboxylic acids of ≈ 10 μeq mg C^{-1}. Recent studies demonstrate organic acids can modify both the acidity of surface waters and changes in strong acid inputs in waters with low or little bicarbonate alkalinity. Organic acids may depress water from 0.5 to 2.5 pH units ANC range of 0–50 μeq liter^{-1} (Lydersen, 1998). Despite these direct additions to acidity, organic acids have a large buffering capacity for strong acids and can reduce pH fluctuations from strong acids in precipitation.

Low pH values are particularly common in bogs and bog lakes that are dominated in the littoral mat by the moss *Sphagnum*. The pH of *Sphagnum* bogs is usually in the range of 3.3–4.5 (0.5–0.03 meq H^+ liter^{-1}). The sources of the H^+ ion activity are several (Clymo, 1963, 1964). Although acidic precipitation resulting from industrial pollution can influence the pH of poorly buffered waters significantly (Likens *et al.*, 1972), in bog areas with no great pollution, the supply of H^+ in rain is unlikely to exceed 30% of the total annual input of H^+. The metabolism of proteins and the reduction of SO_4^- by sulfur-metabolizing bacteria may contribute some H^+ ions to these waters, but their contributions are likely to be small. Although live *Sphagnum* plants secrete organic acids, concentrations of these acids are usually insufficient to account for the observed acidity. Most of the H^+ ion concentrations appear to result from the active cation exchange by the cell walls of *Sphagnum*, during which H^+ is released.

Very high pH values in lakes are usually found in endorheic regions, where lake water contains exceedingly high concentrations of soda (e.g., Na_2CO_3). The range of pH of most open lakes is between 6 and 9. Most of these lakes are the "bicarbonate type," that is, they contain varying amounts of carbonate and are regulated by the CO_2—HCO_3^-—CO_3^{2-} buffering system. Calcareous hardwater lakes commonly are buffered strongly at pH values >8. Seepage lakes and lakes within igneous-rock catchment areas are less well buffered and more acidic, with pH values usually somewhat <7.

III. SPATIAL AND TEMPORAL DISTRIBUTION OF TOTAL INORGANIC CARBON AND pH IN RIVERS AND LAKES

As will be discussed later, in streams decomposition dominates over in-channel photosynthetic production. High production of CO_2 results. In addition, inflowing water from runoff of soils of both surface and groundwater sources is usually nearly or totally devoid of oxygen but contains large concentrations of CO_2 from bacterial respiration. Spring waters are often anoxic at discharge sites.

Carbon dioxide in high concentrations above equilibrium values is relatively rapidly lost to the atmosphere, particularly in the water turbulence of streams. Respiration within the stream and river water is high, however, and production can exceed evasive losses to the atmosphere and photosynthetic utilization. For example, several Danish streams contained about 8 times more free CO_2 ($pCO_2 = 10^{-2.6}$ atm) than did water in equilibrium with air ($pCO_2 = 10^{-3.5}$ atm) (Rebsdorf *et al.*, 1991). As a result, variations in the CO_2 concentrations are common; higher concentrations and reduced pH can be found in quiescent regions or, times of reduced flows, particularly near wetland areas of high loadings of dissolved and particulate organic matter (Talling, 1958; Minckley, 1961). Changes in alkalinity and pH can also be induced by rapid changes in

[1] It should be noted that measurements of pH involve not the concentration but the activity of the hydrogen ion. One measures the differences of hydrogen ion activity, rapidly being released and incorporated from proton-donor molecules, between unknown solutions and standard buffers of known pH values.

discharge. For example, alkalinity depressions in stream water can result from dilution by snowmelt water (Molot *et al.*, 1989). Although discharge was positively correlated with alkalinity in circumneutral streams, in acidic streams with little buffering capacity the snowmelt can induce marked short-term reductions in pH and create conditions that can be lethal to certain biota.

In hardwater bicarbonate rivers, such as the Rhine and the Rhone, total CO_2, largely as bicarbonate, increased downstream from the source, mostly as a result of increased organic loadings and decomposition (Golterman and Meyer, 1985). Seasonality was evident in both the bicarbonate concentrations and pH, largely as a result of temperature on the solubility of CO_2. Upon entering reservoirs, many of the features discussed later for lakes apply. However, the complexities of reservoir morphometry, inflow volumes and density-mediated distributions, and retention times make generalizations difficult (cf. Thornton *et al.*, 1990).

Total inorganic carbon (ΣCO_2) is distributed uniformly with depth during periods of circulation in dimictic and monomictic lakes and in shallow lakes of insufficient depth for thermal stratification. The ΣCO_2 content of the water is dependent upon the equilibria established between atmospheric CO_2, the bicarbonate–carbonate system, external loadings, contributions from metabolic respiration, and utilization in photosynthesis. Metabolism is markedly influenced by numerous parameters; in the spring, increasing light and temperature exert major controls on photosynthetic uptake of CO_2, and generation rates of CO_2 from microbial decomposition of organic matter is temperature- and oxygen-dependent.

During the period of thermal stratification, several conspicuous changes occur in the vertical distribution of ΣCO_2. Oligotrophic lakes that exhibit an orthograde oxygen curve and do not possess high concentrations of bicarbonate and carbonate usually also have an orthograde ΣCO_2 curve (Fig. 11-3). Where the dissolved CO_2—H_2CO_3 component constitutes an appreciable part of the total CO_2, as in softwater lakes, the warmer epilimnetic waters contain less CO_2 because of decreased solubility. Photosynthetic utilization may exceed rates of replacement if mixing of the epilimnion is relatively incomplete, but this phenomenon is uncommon in the open water. A slight increase in the ΣCO_2 is often observed in the hypolimnetic water overlying the sediments. The vertical pH distribution exhibits a pattern approximately the inverse to that of ΣCO_2.

The vertical distributions of ΣCO_2 and pH are strongly influenced by various biologically mediated

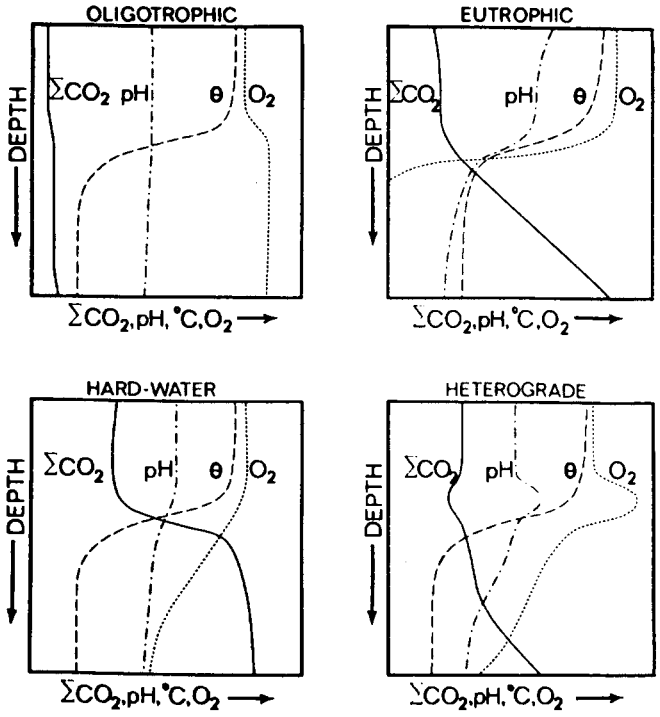

FIGURE 11-3 Generalized vertical distributions of ΣCO_2 and pH in stratified lakes of very low and high productivity, hardwater calcareous lakes exhibiting pronounced epilimnetic decalcification, and a lake with a distinct positive heterograde oxygen curve (θ = temperature).

redox reactions (each of which is treated separately elsewhere). Most conspicuous is the photosynthetic utilization of ΣCO_2 in the trophogenic zone, which tends to reduce CO_2 content and to increase pH, and the respiratory generation of CO_2 throughout the water column and sediments, which tends to decrease pH. In addition to heterotrophic degradation of organic matter, the generation of CO_2 and reduction of pH are augmented by microbial methane fermentation, nitrification of ammonia, and sulfide oxidation. Further, denitrification of nitrate to molecular nitrogen, reduction of sulfate to sulfide, and iron and manganese reduction can result in a net increase in pH and alkalinity (e.g., Kling *et al.*, 1991b; Dillon *et al.*, 1997). The combination of decompositional processes results in an increase in ΣCO_2 of the hypolimnetic waters and a decrease in pH.

As the intensity of decomposition increases in the tropholytic zone, the amount of CO_2 and especially of HCO_3^- increases markedly. The accumulation of ΣCO_2, both free and combined, exceeds the rate of oxygen consumption, and decomposition shifts from aerobic to anaerobic as the hypolimnion becomes anoxic. The origin of increasing concentrations of HCO_3^- in the hypolimnion, especially near the sediments, stems in part from bacterial production of ammonium bicarbonate in the sediments (Ohle, 1952). Ferrous and manganous ions are released as bicarbonates from the sediments when the redox potential is reduced sufficiently under anoxic conditions. In hardwater lakes, part of the $CaCO_3$ sedimenting from the epilimnion undergoes dissolution in the colder, more acidic hypolimnion and results in increases in HCO_3^- concentrations. It is clear, however, as discussed previously, that adsorbed coatings of dissolved organic matter reduce the rates of $CaCO_3$ dissolution. The hypolimnetic increases of cations, especially Ca, usually are delayed somewhat from proportional increases in hypolimnetic HCO_3^-. Under oxidized conditions, Ca^{++} is complexed with the sediments. Under the reducing conditions of anoxia, Ca^{++} is released nearly in proportion to bicarbonate, although some Ca^{++} may be complexed with humic acids (Ohle, 1955; Stewart and Wetzel, 1981; Wetzel, 1990c, 1992b). Hutchinson (1941) demonstrated conclusively that during stratification, the extent of sediment contact per volume of water (and therefore the morphology of the basin) in the metalimnion and hypolimnion is related directly to the development of increasing HCO_3^- as the period of stratification progresses. Therefore, in eutrophic lakes possessing a clinograde oxygen curve, a marked inverse clinograde ΣCO_2 curve can be observed (Fig. 11-3) and pH decreases markedly in the hypolimnion.

The vertical distribution of ΣCO_2 of very hard calcareous lakes shifts seasonally, because photosynthetic utilization of CO_2 in the trophogenic zone occurs rapidly and induces the precipitation of $CaCO_3$ (Fig. 11-4). This epilimnetic biogenic decalcification was described long ago (e.g., Minder, 1922; Pia, 1933), and has been observed frequently. Although precipitation of $CaCO_3$ can be induced by many physical and biotic agents (increasing temperature and bacterial metabolism), photosynthetic utilization of CO_2 by algae and submersed macrophytes is by far the dominant mechanism (cf. Otsuki and Wetzel, 1974). The result is a marked decrease in the ΣCO_2 of the epilimnion by the end of summer stratification (see Fig. 11-3) and a slow progressive increase in the hypolimnion (Fig. 11-4). In the example shown, the hypolimnion became anoxic below a depth of 11 m in September and October, 1968, as reflected in the increasing HCO_3^- in this layer. The pH of the water of the trophogenic zone of unproductive calcareous lakes fluctuates very little seasonally (Fig. 11-5). The bicarbonate buffering capacity

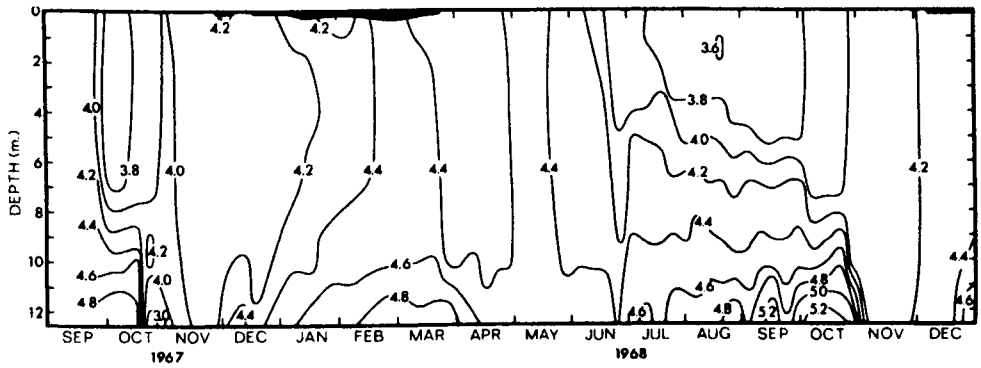

FIGURE 11-4 Depth–time diagram of isopleths of alkalinity, predominately bicarbonate, in meq liter^{-1}, Lawrence Lake, a calcareous hardwater lake of southwestern Michigan. Opaque area = ice cover to scale. (From Wetzel, unpublished data.)

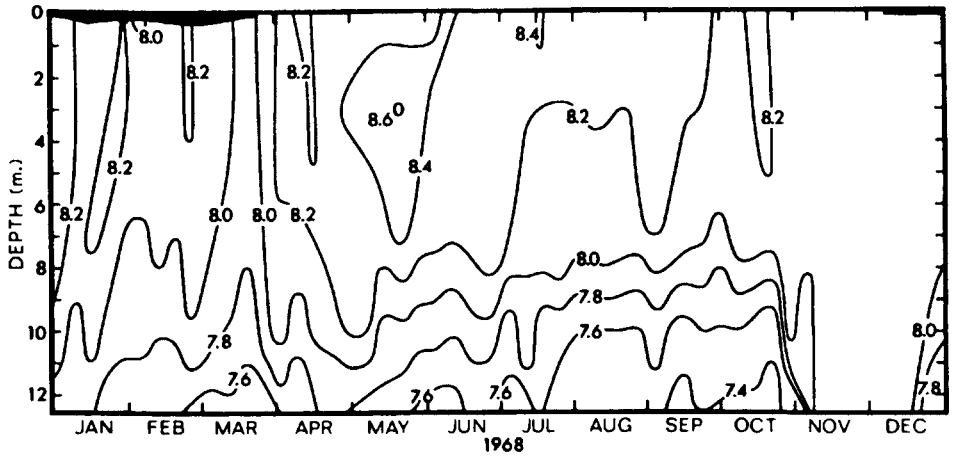

FIGURE 11-5 Depth–time diagram of isopleths of pH in hardwater Lawrence Lake, Michigan. Opaque area = ice cover to scale. (From Wetzel, unpublished data.)

is adequate to compensate for metabolic changes in ΣCO_2. The pH of the hypolimnion in the example progressively decreased throughout the period of stratification. Similar changes also were observed under ice cover, but they were less marked than during the summer period, when rates of production and decomposition were higher.

Vertical changes in ΣCO_2 and pH occur much more rapidly in eutrophic lakes (Figs. 11-6 and 11-7). In the example given in the figures, the hypolimnion below 3 m became anoxic within a month after the onset of thermal stratification and became nearly anoxic under ice cover. The pH values of the epilimnion represent midmorning measurements. Under the conditions of intensive photosynthesis by phytoplankton, the pH can undergo appreciable diurnal fluctuations, often exceeding 10 in the late afternoon and decreasing below 8 during darkness. Biogenic decalcification of the epilimnion also is apparent in this moderately hard hypereutrophic lake (Fig. 11-6).

Where photosynthetic activity in a layer is particularly intense, as might occur in the metalimnion, a positive heterograde oxygen curve is frequently found (see Chap. 9). Commonly associated with this metabolism is a corresponding positive heterograde pH curve and a negative heterograde ΣCO_2 curve (Fig. 11-3, and at 3 m in May of Fig. 11-5). The opposite situation of a negative heterograde oxygen curve, with concomitant ΣCO_2 and pH curves, occasionally is found in strata of intensive respiration, for example, containing plates of bacteria or aggregations of zooplankton (see Nagasawa, 1959).

The total alkalinity of clear softwater rivers and lakes is often very low, particularly those waters of granitic and sedimentary sandstone regions. River and lake water of these areas have relatively poor buffering

capacities and can be modified quickly by modest inputs of acidic water, such as from rapidly melting snow in spring that had accumulated acidity from atmospheric sources. The literature on the subject of acidification of soils, ground waters, and surface waters is enormous, with thousands of scientific articles and hundreds of books on the subject of sources of natural and anthropogenic acidity and their effects upon the chemistry and biota of fresh waters. Brief reference here is largely limited to effects on the DIC and pH of soft waters.

Atmospheric deposition of particulate and dissolved acid anions has resulted in sustained loads adequate to cause thousands of lakes and streams of low alkalinity to become acidic (e.g., Baker *et al.*, 1991). Major ions in atmospheric deposition that contribute significantly to such acidification are H^+, usually associated with H_2SO_4 and HNO_3, and NH_4^+. Atmospheric H^+ deposition in many areas of sensitive aquatic ecosystems have been in the range of 50–125 meq m^{-2} yr^{-1} (Dillon *et al.*, 1983), although attempts have been made, with mixed success, to reduce these loadings.

In regions where the soils and rock deposits contain high carbonates, acidified precipitation can increase rates of carbonate weathering and result in increased alkalinity and equilibrium pH in softwater seepage lakes (Kilham, 1982). In drainage basins and waters with little buffering capacity, however, the deposition has resulted in loss of acid-neutralizing capacity (alkalinity), decreased pH, increases in sulfate and in dissolved aluminum concentrations, and in marked alterations in ionic speciation and ratios. These acidification changes can persist on a long-term basis or, in less affected areas, chemical changes occur reversibly for short-term periods. In many softwater streams and lakes, for example, melting of acidic snow accumulations can result in rapid (few days), precipitous declines in pH and alkalinity (e.g., Catalan and Camarero, 1993). Lower pH values occurring during late winter and early spring in softwater seepage lakes, on the other hand, were attributed to increases in pCO_2 under the ice because total alkalinity did not change at that time (Kratz *et al.*, 1987).

Much controversy has arisen over the natural versus anthropogenic components of acidification of natural waters and about balances from biologically mediated generation of alkalinity. In remote areas, complex humic and other organic acids, as for example from bog drainage (Schindler *et al.*, 1986), as well as H^+ ions generated from nitrification of NH_4^+, manganese oxidation, ferrous iron oxidation, and sulfide oxidation, all discussed in detail in later chapters, can contribute to acidity and reduction of alkalinity in some lakes (Galloway *et al.*, 1984; Gorham, 1986; Davison, 1987). However, the overwhelming loading of acidity to sensitive softwater surface waters has resulted from anthropogenic pollution from fossil fuel combustion and production of H^+ ionized from several strong acids (Galloway *et al.*, 1984; Morgan, 1991; many others).

Biological generation of alkalinity within lakes has been known for many years (e.g., Hutchinson, 1941; Mortimer, 1941, 1942; Ohle, 1952). Internal alkalinity generation in very softwater lakes is usually dominated by biological reduction of sulfate and nitrate (Baker *et al.*, 1986; Cook *et al.*, 1986; Rudd *et al.*, 1986; Schindler, 1986, 1988; Schindler *et al.*, 1986; Kelly *et al.*, 1987; Giblin *et al.*, 1990). The exchange of base cations and redox reactions, particularly associated with manganese, iron, and sulfate reduction, can also contribute to alkalinity generation (Carignan, 1985; Schiff and Anderson, 1986; Davison, 1987). Anoxia in the water column is not essential, as reduction can occur in surficial sediments, which are nearly always anoxic, with the release of DIC. Despite these sources

of in-lake generation of CO_2 and hence alkalinity, these biological sources constitute a relatively small contribution (<7%) to alkalinity budgets of drainage lakes in relation to loadings from the drainage basin (Shaffer and Church, 1989). In seepage lakes or lakes with long hydrological residence times, in-lake processes of alkalinity generation can constitute a greater contribution.

IV. HYPOLIMNETIC CO_2 ACCUMULATION IN RELATION TO LAKE METABOLISM

As in the case of hypolimnetic oxygen deficits discussed earlier, changes in the concentrations of ΣCO_2 in the hypolimnion have been used to indirectly estimate the organic production of the trophogenic zone. The concept is that the accumulation of CO_2 in the hypolimnetic tropholytic zone from decomposition is proportional to the production of organic matter in the trophogenic zone that settles into the hypolimnion. This approach to an estimate of lake metabolism is complicated by inputs of organic matter that do not originate in the trophogenic zone and by losses of carbon from the system that are not represented in CO_2 changes in the tropholytic zone. For many lake systems, the measurement of hypolimnetic CO_2 accumulation can provide a reasonable estimate of the intensity of lake metabolism.

The idea of estimating production from CO_2 accumulation was first suggested by Ruttner in his treatise on tropical lakes (1931). Einsele (1941) compared the CO_2 accumulation in the hypolimnion with several other estimates of production in his critical evaluation of the effects of phosphorus fertilization on productivity of algae and found them to be in agreement. By far the most comprehensive application of the hypolimnetic CO_2 accumulation principle to lakes, and its comparison with other measures of production, especially the oxygen deficit, was done by Ohle (1934, 1952, 1956). The CO_2-accumulation approach has the advantage of being able to follow metabolically mediated changes under both aerobic and anaerobic conditions, whereas the oxygen deficit method is applicable only when the hypolimnion is oxic. More fundamentally, carbon, which is the initial and end product of organic metabolism, is one of the best parameters by which to evaluate productivity.

There are several assumptions underlying calculations of hypolimnetic CO_2 accumulation. First, it is important that the water under consideration be relatively well isolated from the atmosphere and from CO_2 exchange; these conditions may be found in the hypolimnia of small, sheltered lakes with steep thermal stratification gradients or when the entire lake is under ice cover. As discussed earlier in this chapter, most lakes release CO_2 to the atmosphere because of the excess biotic generation of CO_2 in relation to partial pressures for retention in solution. Some seasonality exists in net evasion to the atmosphere, with lower evasion rates often occurring in the productive summer periods of stratification when hypolimnetic accumulation estimates would be made. Second, it is assumed that the allochthonous inputs of organic matter from outside the basin are very small in comparison to autochthonous production within the basin, a situation that probably is not realized very often (cf. Chap. 23). Loss of organic production from the trophogenic zone via the outlet is assumed to be small—a condition which, again, is highly variable in open lakes. A major assumption is that most of the synthesized organic matter of the trophogenic zone decomposes only after it has sedimented to the tropholytic zone. This assumption certainly causes underestimations, because some decomposition of algae, littoral macrophytes, and sessile algae occurs in the warm epilimnetic and metalimnetic layers before reaching the relatively quiescent, cool hypolimnion. The rates of decomposition in the trophogenic zone depend upon many physical and biological factors. Important factors include the proportion of production by the littoral flora vs. phytoplankton, seasonal shifts in the proportion of phytoplankton algae reaching the hypolimnion—for example, silicious diatoms sediment more rapidly than small algae, which are more neutrally buoyant—and water temperature. A significant amount of organic production will be incorporated permanently into the sediments without complete decomposition; the proportion permanently lost in this way generally increases in lakes of greater productivity. Perhaps the greatest problem rests in the assumption of a respiratory quotient ($RQ = CO_2/O_2$) of 0.85, an average figure for the aerobic decomposition of a mixture of carbohydrate, lipid, and protein organic compounds. As will be discussed later (Chap. 23), anaerobic decomposition produces CO_2 utilizing alternate electron acceptors after oxygen has been depleted and often leads to RQ values much greater than 1 (Rich, 1975, 1980; Rich and Wetzel, 1978). Despite these numerous limitations, many estimates of hypolimnetic CO_2 accumulation correlate with general lake productivity and are directly proportional to mean depth of the basin.

Analysis of hypolimnetic CO_2 accumulation requires evaluation of the various components of total CO_2 and their origins. In bicarbonate-poor waters, the difference in CO_2 content at the beginning and after a period of stratification is determined. In bicarbonate-rich waters, the amount of free CO_2 is very small at the onset of

TABLE 11-3 Summary of Method of Evaluating the Hypolimnetic CO_2 Accumulation of a Lake with a Sample Calculation[a]

Calculations	*Lake example*
(1) NH_4:HCO_3 = 18.04:61.02	(1) 1.85 mg NH_4 liter^{-1} present as NH_4HCO_3
(2) $HCO_3 = \frac{(NH_4)(61.02)}{18.04} = (3.38)(NH_4) = \beta$	(2) $\beta = (1.85)(3.38) = 6.25$
(3) HCO_3:CO_2 = 61.02:44.01	(3) $b = (6.25)(0.721) = 4.51$
$CO_2 = \frac{(HCO_3)(44.01)}{61.02} = (0.721)(HCO_3)$	
$b = \beta(0.721)$	
(4) $\alpha = HCO_3$; $\alpha - \beta = x$	(4) α = 32.4 mg HCO_3 liter^{-1} $x = 32.4 - 6.25 = 26.15$
(5) $a = \frac{x(0.721)}{2} = x(0.361)$	(5) $a = (26.15)(0.361) = 9.43$
(6) $c = CO_2$	(6) c = 13.10 mg CO_2 liter^{-1}
(7) $\Sigma CO_2 = a + b + c$	(7) $\Sigma CO_2 = 9.43 + 4.51 + 13.10 = 27.04$
(8) δO_2 = actual O_2 deficit	(8) mg O_2 liter^{-1} = 0.56
$\frac{CO_2}{O_2} = \frac{44}{32} = 1.375$	°C = 6.7, O_2 at turnover = 12.27 mg liter^{-1}
δO_2 (1.375) = δCO_2	$\delta O_2 = 12.27 - 0.56 = 11.71$
RQ = 0.85[b]	$\gamma = (11.71)(1.375)(0.85) = 13.69$
$\gamma = \delta CO_2$ (0.85)	
(9) $\Sigma CO_2 - \gamma = \Delta^1 CO_2$	(9) $\Delta^1 CO_2 = 27.04 - 13.69 = 13.35$
(10) $z = \Delta^1 CO_2(2)$	(10) $z = (13.35)(2) = 26.70$
(11) $\xi = z + \gamma$	(11) $\xi = 26.70 + 13.69 = 40.39$
$\frac{\xi(30)}{\text{No. of days}} = \xi$ *per* month	ξ *per* month $= \frac{(40.39)(30)}{120} = 10.1$ mg CO_2 liter^{-1}

[a] Example based on 1.85 NH_4 liter^{-1}; 13.1 mg CO_2 liter^{-1}; 32.4 mg HCO_3 liter^{-1}; 0.56 mg O_2 liter^{-1}; °C = 6.7; period of stratification of 4 months. (After Ohle, 1952.)

[b] An RQ value (CO_2/O_2) of 0.85 is a mean value based on a number of analytical analyses of plant and animal respiration and agrees approximately with some whole closed-lake evaluations (but see discussion of RQ variations in Chap. 23).

hypolimnetic isolation. As stratification is maintained, respiration during aerobic and anaerobic decomposition allows the accumulation of free CO_2 and bicarbonate. In addition, a portion of the bicarbonate is present as "volatile" ammonium carbonate of metabolic origin; additional carbon exists as volatile bicarbonates, half of which are of metabolic origin. Half of the nonvolatile bicarbonate is bound CO_2 of $CaCO_3$, which largely becomes incorporated into the sediment. The sum of these CO_2 inputs is assumed to be an estimate of lake metabolism. A sample calculation is given in Table 11-4 (see Wetzel and Likens, 2000). If CO_2 accumulation is calculated for the entire hypolimnion, and this is divided by the volume of the epilimnion, the quantity termed the *relative assimilation intensity* results. In the example given (Table 11-3),

$$(10.10 \text{ mg } CO_2 \text{ liter}^{-1} \text{ month}^{-1})\left[\frac{4.620 \times 10^6 \text{m}^3}{7.442 \times 10^6 \text{m}^3}\right] = 6.3 \text{ mg } CO_2 \text{ liter}^{-1} \text{ month}^{-1}$$

This estimate implies that, in the epilimnion of this lake, approximately 6.3 mg CO_2 were photosynthetically combined into carbohydrate per liter of water per month during the period of observation. The CO_2-accumulation method of calculating production usually leads to underestimation because of the confounding factors mentioned earlier. Further, some CO_2 loss from the upper hypolimnion occurs by turbulence, and some bicarbonate is released from the reduction of ferric hydroxide as redox potential decreases during stratification.

The hypolimnetic CO_2 accumulations in several lakes are compared in Table 11-4, along with several other indices of increasing productivity (Ohle, 1955b). The general correlations among various criteria hold. Einsele (1941) applied the CO_2-accumulation evaluation of productivity, along with several other measures, to the trophogenic zone of Schleinsee, Germany, before and after extensive fertilization of the lake with phosphorus (Table 11-5). Schleinsee lends itself well to such analyses because of its limited inflow and outflow.

TABLE 11-4 Comparison of the Relative Assimilation Intensity to Other Indices of Productivity in Lakes of Northern Germany[a]

	Relative assimilation intensity (mg CO_2 liter^{-1} *epilimnion month*$^{-1}$)	*Chlorophyll of Epilimnion* (*μg liter*$^{-1}$)	*Estimate of photosynthetic efficiency of solar radiation* (%)	*Hypolimnetic O_2 deficit* (*mg O_2 liter*$^{-1}$)
Schaalsee	1.91	1.3	0.76	3.30
Schöhsee	2.13	1.4	0.56	6.96
Zanzen	2.33	1.6	0.96	—
Schmaler Lucin	2.70	1.8	0.80	3.16
Breiter Lucin	4.64	3.1	1.90	2.16
Techiner Binnensee	5.45	3.6	1.65	7.86

Edebergsee	14.60	9.7	2.27	10.00

[a] After data of Ohle (1952, 1955b).

Although Einsele's estimations were quite approximate, again the comparison was good. When used in a relative manner, this method is of value.

V. UTILIZATION OF CARBON BY ALGAE AND MACROPHYTES

Algae and submersed aquatic macrophytes require an abundant and readily available source of carbon for high sustained growth. The supply of carbon is regulated by *availability*, a problem of regulation by physical processes of diffusion along concentration gradients within the water and within the communities, and by *physiological assimilation* processes, a problem of transport and biochemical utilization capabilities. The former is discussed elsewhere (Chaps. 7 and 19); discussion here focuses on the utilization of inorganic carbon sources.

Abundant physiological evidence indicates that free CO_2 is most readily utilized by nearly all algae and larger aquatic plants. A number of algae and submersed macrophytes, particularly the mosses, can utilize only free CO_2. Many algae and aquatic vascular plants are capable of utilizing CO_2 from bicarbonate ions when free CO_2 is in very low supply and HCO_3^- is abundant; a few species of algae require HCO_3^- and cannot grow with free CO_2 alone. There is no clear evidence that algae or higher aquatic plants assimilate CO_3^{2-} directly as a carbon source, although it has been implicated in growth at very high pH values (see Felföldy, 1960). The most comprehensive review of the subject is given by Raven (1970, 1984; cf. also Allen and Spence, 1981, Lucas and Berry, 1985).

A. Heterotrophic Augmentation

A large number of algae are heterotrophic, that is, they can remain viable in the absence of light in bacterial-free culture by chemo-organotrophic uptake of dissolved organic compounds (cf. Danforth, 1962;

TABLE 11-5 Estimations of Total Production in the Trophogenic Zone of Schleinsee, Germany, during Summer Stratification (May–September) in the Years Before and in the Year After Application of Phosphorus Fertilization[a]

Basis for calculated production	*kg dry weight*		*Ratio*
	1935–1937	*1939*	
Biogenic decalcification	1900	5000	2.6

Hypolimnetic CO_2 accumulation	3800	9600	2.5
Apparent total production	5600	17,200	3.1
Related to surface area	43 g m^{-2}	117 g m^{-2}	2.7

[a] After data of Einsele (1941).

Provasoli, 1963; Stanier, 1973; Droop, 1974; Neilson and Lewin, 1974; Raven, 1984). However, the rates of growth under the experimental conditions used are very low in comparison with normal, light-mediated autotrophic growth, and the levels of substrate concentrations employed are usually exceedingly high, often several orders of magnitude in excess of what would be found in natural waters. The range of organic compounds that support growth in the dark of cyanobacteria is very narrow, because the pentose phosphate pathway is the energy-yielding dissimilatory pathway. Consequently, only exogenous substrates that are readily convertible to glucose-6-phosphate can support growth in the dark. Among obligately photoautotrophic algae, suitable enzymes (e.g., glucose permease) are absent. Investigations conducted at naturally occurring substrate concentrations have consistently shown that bacteria possessing active permease enzyme systems effectively outcompete algae for organic substrates under natural conditions (Wright and Hobbie, 1966; Wetzel, 1967; Hobbie and Wright, 1965; and others). Where active heterotrophic uptake of simple organic substrates is found under natural conditions, carbon assimilation is still low in comparison to the amount assimilated in photoautotrophy, even under very low light conditions. It might be anticipated that any significant augmentation of autotrophy by chemoorganotrophy would be confined largely to the cyanobacteria, which have numerous morphological and physiological similarities to heterotrophic bacteria. This potential heterotrophic augmentation is seen in the cyanobacterium *Oscillatoria,* which grows in massive densities in the microaerobic zone at the metalimnetic–hypolimnetic interface of some productive lakes (Saunders, 1972). Photoheterotrophic growth in the light in the absence of exogenous CO_2 has been shown in two species of cyanobacteria (Ingram, 1973a,b). Studies indicate that respired CO_2 from the substrate oxidation is assimilated by the photosynthetic reactions within the cells. Photoheterotrophy in natural waters was first critically evaluated by McKinley (1977; McKinley and Wetzel, 1979; see also Ellis and Stanford, 1982). Photoheterotrophic contributions to overall carbon cycling were greatest in the morning periods at depths of low light and during spring turnover and late summer stratification. Photoheterotrophic and chemoheterotrophic (not light-mediated) utilization of organic substrates was small in this moderately productive lake in comparison with normal photosynthetic utilization of inorganic carbon.

All of the existing evidence for heterotrophic growth by algae indicates that under natural conditions, photoautotrophy by inorganic carbon uptake overwhelmingly dominates in freshwater systems. Supplementation of photosynthesis by algal heterotrophy is limited to a few specialized conditions. Although probably insignificant for overall plant synthesis, these supplementary processes are potentially important to the survival of some species and in selective competitive interactions.

B. Photosynthetic Inorganic Carbon Use

In most freshwater systems, dissociation rates of ionic CO_2 species and the maintenance of near-equilibrium conditions between atmospheric CO_2 and that of the water are sufficiently rapid that severe inorganic carbon limitation to algal photosynthesis is unlikely in well-mixed pelagic regions, even under conditions of low ΣCO_2. CO_2 limitation can occur, however, in attached algal communities and in submersed angiosperms. Below a pH of 8.5, the theoretical dissociation kinetics of the CO_2—HCO_3^-—CO_3^{2-} complex, derived from pure solutions, agree very well with the concentrations of the ionic species found in natural waters (Talling, 1973). Above pH 8.5, however, the total inorganic carbon dioxide concentrations fall considerably below the values calculated on the basis of the apparent dissociation constants K'_1 and K'_2 of carbonic acid, as derived from measurements of alkalinity (Fig. 11-8). Although the explanation for this phenomenon is not completely clear, it appears to be associated with the presence of a noncarbonate, nonhydroxide alkalinity component resulting from ionized silicate and can be corrected for (Talling, 1973).

Despite the solubility of CO_2 and relatively turbulent water strata of the pelagic trophogenic zone, the photosynthetic carbon supply is not very favorable. Much of the total carbon is in the form of bicarbonate and carbonate, which is not readily available to many aquatic plants. Rapid photosynthesis can rapidly reduce the total DIC and increase pH of the water and shift dissociation equilibria so that dissolved $[CO_2]$ is nearly zero. Diffusion of CO_2 in water along concentration gradients is very slow relative to that in air. Experimental evidence on freshwater photosynthetic utilization of inorganic carbon indicates a strong relationship between physiological availability and the forms of inorganic carbon (Raven, 1970, 1984; Wetzel and Hough, 1973; Hough and Wetzel, 1977; Smith and Walker, 1980; Maberly and Spence, 1983).

The primary enzyme of inorganic carbon fixation in all photosynthetic oxygen-evolving organisms is ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco). This carboxylase is involved in fixing some 95% of the carbon assimilated in plants with C_3 metabolism, in which 3-phosphoglycerate is the first major product. Most algae and aquatic macrophytes have C_3 biochemistry, and thus at least 95% of the carbon

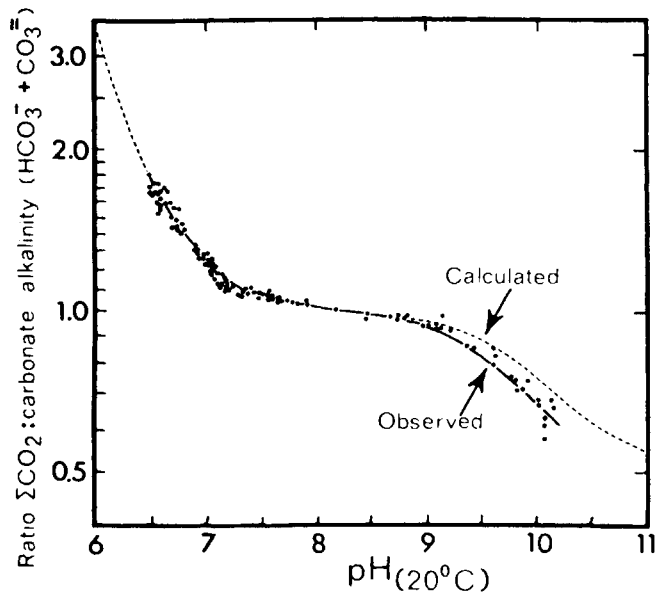

FIGURE 11-8 Variation in the ratio of ΣCO_2 to carbonate alkalinity resulting from HCO_3^- and CO_3^{2-} with pH for samples of water from the surface and bottom (14 m) layers of Esthwaite Water, England. The broken line indicates the relationship calculated from appropriate values of pK_1' (6.38) and pK_2' (10.32). (Slightly modified from Talling, 1973.)

fixed must be supplied as CO_2 at the carboxylase site (Raven, 1984, 1995). The enzyme carboxydismutase is involved in the carboxylation reaction, which produces 3-phosphoglycerate as the first product of carbon fixation, and uses free, unhydrated CO_2 as its immediate substrate.

Carbonic anhydrase, an enzyme that catalyzes the reversible hydration of carbon dioxide, is found universally in photosynthetic cells of plants. Where CO_2 is the carbon species entering the cell, there is no obvious biochemical role for carbonic anhydrase found in plants, although some evidence indicates that this enzyme accelerates the diffusion of CO_2 and transport to sites of biochemical fixation by carboxylases (Raven, 1995). Bicarbonate ions have been implicated as a critical factor in the evolution of oxygen during photosynthesis (Stemler and Govindjee, 1973; Raven, 1984). At high pH values and HCO_3^- concentrations, bicarbonate moves less effectively from binding sites to the chloroplast. When HCO_3^- enters cells, carbonic anhydrase is needed to supply CO_2 to Rubisco. Carbonic anhydrase activity is found in plants that cannot use bicarbonate as well as those that can, although such activity generally increases among algae and certain submersed macrophytes that can utilize bicarbonate (Weaver and Wetzel, 1980; Raven, 1995).

The ability to assimilate bicarbonate ions is variable among planktonic algae, macroalgae, and submersed angiosperms (Raven, 1970, 1984; Allen and Spence, 1981; Maberly and Spence, 1983). When this ability does occur, an additional reaction is needed for HCO_3^- assimilation that is not required for CO_2 assimilation. Active bicarbonate transport followed by HCO_3^- dehydration within the cytoplasm is apparently required and is coupled with a similarly active stoichiometric excretion of hydroxyl ions from the cells. Assimilated bicarbonate ions are used to produce high internal CO_2 pools by action of carbonic anhydrase.

When aquatic plants have similar affinities for CO_2 and the HCO_3^- ion, utilization of bicarbonate generally occurs when the bicarbonate concentration exceeds that of CO_2 by more than 10 times. Free CO_2 concentrations (about 10 micromolar) of most fresh waters and of the sea are in approximate equilibrium with the atmosphere, although many fresh waters contain bicarbonate concentrations far in excess of 10 times that quantity. Equilibrium concentrations of dissolved CO_2, particularly in alkaline hardwater lakes with a pH >8.5, are inadequate to saturate photosynthesis in plants adapted to utilize bicarbonate. As these waters become more productive, and in densely populated littoral zones of less productive lakes, pH is rapidly altered by metabolism on a diurnal basis (pH ranges from a low of 6 to a high of 10 or more per 24 h) and can be associated with reduced carbon fixation and bicarbonate assimilation (e.g., Spencer *et al.*, 1994). Under stagnant conditions, common to heavily colonized littoral zones of lakes, the shift to bicarbonate metabolism, as well as the increased pH, is often associated with severe reduction in CO_2.

Stagnant layers around plant cells (algae) and tissues (macrophytes) clearly have major effects on limiting the assimilation of both CO_2 and HCO_3^- by actively photosynthesizing plants (Smith and Walker, 1980). Even when the plants are exposed to water movements by turbulence or sinking, a residual layer (approximately 10–100 μm thick) parallel to the surface remains. The rate of solute movement across this residual layer approximates that of molecular diffusion. Diffusion of CO_2 and HCO_3^- through these stagnant layers is an important rate-limiting process to both availability of CO_2 and membrane transport of HCO_3^- ions. Mucilage sheaths surrounding algal cells, especially among cyanobacteria, can further reduce the uptake rates of inorganic carbon (Chang, 1980).

Bicarbonate assimilation in media of high pH assumes greater significance in large aquatic macrophytes that have morphologically long diffusion paths. Active transport of HCO_3^- originating from the dissociation of calcium bicarbonate and the secretion of OH^- ions results in the precipitation of $CaCO_3$. Many submersed angiosperms and algae can utilize bicarbonate. Aquatic

mosses are able to utilize only free CO_2, and are restricted to waters of relatively low pH and abundant CO_2 (e.g., springs, mountain streams, bogs, or shallow waters) or the lower trophogenic zone where free CO_2 is higher than elsewhere in the lake. CO_2 of the rhizosphere can diffuse into rooting tissues, move to the leaves via internal gas lacunae, and be fixed photosynthetically (Loczy *et al.*, 1983; Steinberg and Melzer, 1983; Wetzel *et al.*, 1985). Although this benthic source of inorganic carbon is widely utilized in submersed macrophytes, the percentage of the total carbon fixed photosynthetically from the rooting tissues is greater among small plants growing in poorly mineralized waters. Moreover, many angiosperms with large intercellular gas lacunae refix the CO_2 of respiration and photorespiration rather efficiently (Hough and Wetzel, 1972; Søndergaard and Wetzel, 1980). The efficiency of refixation and the photosynthetic efficiency of carbon fixation must be highly plastic, related in part to induced shifts to bicarbonate assimilation, and can affect rates of net primary production significantly.

In summary, evidence is available that, among the diversity of concentrations and states of inorganic carbon in fresh waters, there exists a large number of situations where free CO_2, even in equilibrium with the atmosphere, may be inadequate for metabolism at high sustained levels (see especially Talling, 1976). In other cases, free CO_2 may be inadequate as a result of slow diffusion rates and chemical losses from the system. Although it is unusual for inorganic carbon per se to be seriously limiting to phytoplanktonic photosynthetic metabolism under most natural situations, assimilation of bicarbonate at metabolic expense is known and can be induced among plants that have an affinity for both CO_2 and HCO_3^- ions under conditions of low free CO_2 and high bicarbonate concentrations (e.g., Beer and Wetzel, 1981; Goldman and Graham, 1981; Novak and Brune, 1985). Possession of an affinity for bicarbonate is an adaptive advantage in fresh waters and is certainly instrumental in altering competitive succession of algal and certain submersed macrophyte communities.

VI. SUMMARY

1. Most carbon of fresh waters occurs as equilibrium products of carbonic acid (H_2CO_3). A smaller amount of carbon occurs in organic compounds as dissolved and particulate detrital carbon, and a very small fraction occurs as carbon of living biota.
2. The complex equilibrium reactions of inorganic carbon and the distribution of the chemical species of total CO_2 [$\Sigma CO_2 = CO_2 + HCO_3^- + CO_3^{2-}$] are understood in considerable detail.
   a. As atmospheric CO_2 dissolves in water containing bicarbonate (primarily associated with the calcium cation), dissociation kinetics of the inorganic carbon of fresh waters below a pH of 8.5 closely follow those predicted by pure dilute solution chemistry.
   b. Free CO_2 is very soluble, and in water some becomes hydrated to form carbonic acid:

$$CO_2(\text{air}) \rightleftharpoons CO_2(\text{dissolved}) + H_2O \rightleftharpoons H_2CO_3$$

   c. H_2CO_3 is a weak acid and rapidly dissociates to bicarbonate and carbonate:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons H^+ + CO_3^{2-}$$

   d. At equilibrium, bicarbonate and carbonate ions dissociate and hydroxyl ions (OH^-) are formed by the hydrolysis of carbonic acid:

$$HCO_3^- + H_2O \rightleftharpoons H_2CO_3 + OH^-$$
$$CO_3^{2-} + H_2O \rightleftharpoons HCO_3^- + OH^-$$
$$H_2CO_3 \rightleftharpoons H_2O + CO_2$$

   e. As carbonic acid percolates over rock and through soils, carbonates are solubilized; ionized Ca^{++} and HCO_3^- are released to the water. The dilute solution of bicarbonate of many fresh waters is weakly alkaline because slightly greater concentrations of OH^- ions than H+ ions result from the dissociation of HCO_3^-, CO_3^{2-}, and H_2CO_3.
   f. Losses of CO_2 by photosynthetic utilization or additions of CO_2 from biotic respiration tend to change the pH (H^+ ion activity) of the water. The ***buffering action*** of the water, however, tends to resist changes in pH as long as the equilibria of the ΣCO_2 complex are operational. Addition of H^+ ions is neutralized by OH^- ions formed by the dissociation of HCO_3^- and CO_3^{2-}. The pH remains essentially the same as before, unless the supply of HCO_3^- and CO_3^{2-} is exhausted. Similarly, added OH^- ions react with HCO_3^- ions:

$$HCO_3^- + OH^- \rightleftharpoons CO_3^{2-} + H_2O$$

   g. If the solution of calcium bicarbonate in equilibrium with CO_2, H_2CO_3, and CO_3^{2-} loses a portion of the CO_2 required to maintain the equilibrium, such as by photosynthetic uptake exceeding replacement of CO_2, the relatively insoluble calcium carbonate (marl) will precipitate:

$$Ca(HCO_3)_2 \rightleftharpoons CaCO_3\downarrow + H_2O + CO_2$$

   until the equilibrium is reestablished by the for-

mation of sufficient CO_2. As $CaCO_3$ forms and precipitates, inorganic (e.g., PO_4^{-3} ions) and organic compounds can adsorb to or coprecipitate with the $CaCO_3$ and be carried out of the trophogenic zone of lakes. Metabolic activity can be reduced as a result of nutrient reductions associated with this adsorption and/or coprecipitation.

3. The distribution of ΣCO_2 and pH in surface waters varies both seasonally and vertically in lakes in relation to loading from allochthonous sources, physical conditions, and biotic inputs and consumption.
   a. Although the exchange of CO_2 of the water with that of the atmosphere is rapid and relatively complete in aerated open water of streams and lakes, the spatial and temporal distribution of ΣCO_2 and pH is altered by microbial respiratory metabolism and by photosynthetic consumption, especially in quiescent strata in the pelagic zone of stratified lakes and in productive littoral areas.
   b. Relatively unproductive lakes exhibiting an orthograde oxygen curve generally have an orthograde ΣCO_2 curve.
   c. In productive waters exhibiting a clinograde oxygen curve, an inverse clinograde ΣCO_2 curve is generally found. The pH decreases in the hypolimnion in relation to the increased hypolimnetic concentrations of CO_2 and bicarbonate.
   d. The ΣCO_2 distribution of hardwater calcareous lakes is greatly modified by biologically induced decalcification of the epilimnion.
   e. There is a constant net efflux of excess CO_2 from most lakes of the world; most of this net CO_2 evasion to the atmosphere derives from metabolic respiration of organic compounds.
4. In thermally stratified lakes of low to moderate productivity with minimal inputs of organic matter from outside the basin, the accumulation of CO_2 in the hypolimnion is positively correlated to rates of organic production in the trophogenic zone.
5. Inorganic carbon is a major nutrient of photosynthetic metabolism. However, phosphorus and nitrogen limit photosynthesis more frequently than does inorganic carbon, which occurs in much greater abundance. Because assimilation of CO_2 and HCO_3^- occurs more rapidly than resupply, and conditions of reduced availability result from diffusion resistance at the uptake sites, potential photosynthetic productivity by both algae and submersed macrophytes is not always fully realized. Many algae and vascular aquatic plants have developed compensatory mechanisms to enhance utilization and recycling of respired CO_2.

VIII. Summary

Nitrogen is abundant on the surface of the Earth but less than 2% is available to organisms (Galloway, 1998). Reactive nitrogen (defined as N bonded to C, O, or H, as in NO_x, NH_x, organic N) is created largely by biological nitrogen fixation of unreactive nitrogen (triple-bonded N_2) and provides about 90–130 Tg N yr^{-1} (Tg = 10^{12} g) on the continents. Lightning creates only about 1% of reactive nitrogen. Human activities have resulted in the fixation of an additional ~150 Tg N yr^{-1} by energy production, fertilizer production, and cultivation of crops (e.g., legumes and rice) that utilize symbiotic N-fixing microbes. Rates of loss or storage of anthropogenic nitrogen are less accurately known, but clearly nitrogen is accumulating in the environment. Because nitrogen is required for expanding food production for expanding human populations, greater amounts of nitrogen will be converted from unreactive to reactive forms in the future. Much of this reactive nitrogen will enter surface and groundwater ecosystems.

I. SOURCES AND TRANSFORMATIONS OF NITROGEN IN WATER

Nitrogen occurs in fresh waters in numerous forms: dissolved molecular N_2; a large number of organic compounds from amino acids, amines, to proteins and recalcitrant humic compounds of low nitrogen content, ammonia (NH_4^+), nitrite (NO_2^-), and nitrate (NO_3^-). Sources of nitrogen include: (a) precipitation falling directly onto the lake surface, (b) nitrogen fixation both in the water and the sediments, and (c) inputs from surface and groundwater drainage. Losses of nitrogen occur by (a) effluent outflow from the basin, (b) reduction of NO_3^- to N_2 by bacterial

denitrification with subsequent return of N_2 to the atmosphere, and (c) permanent sedimentation loss of inorganic and organic nitrogen-containing compounds to the sediments.

A. Nitrogen in Precipitation and Fallout

The amount of influent nitrogen to lakes and their drainage areas from atmospheric sources generally has been considered to be minor in comparison with that from direct terrestrial runoff. However, on closer inspection, and in view of exponentially increasing inputs of nitrogen from atmospheric sources, the amount of nitrogen reaching lakes in this way is often significant to the nitrogen cycle and for productivity. For example, in relatively oligotrophic mountainous regions of granitic bedrock, precipitation is a major source of nitrogen (Likens and Bormann, 1972; Likens *et al.*, 1977). Inorganic nitrogen input by precipitation similarly was found to be a major source of loading to the drainage basin of Lake Tahoe, California–Nevada (Coats *et al.*, 1976; Jassby *et al.*, 1994). Nitrogen from precipitation and direct bulk (particulate) fallout is extremely variable depending on local meteorological conditions, wind patterns, and the location of streams and lakes with respect to industrial and agricultural outputs.

Nitrogen may enter a drainage basin in many forms: as dissolved N_2, nitric acid, NH_4^+, and NO_3^- as NH_4^+ adsorbed to inorganic particulate matter, and as organic compounds, which can occur in either dissolved or particulate phases. No direct relationship exists between the volume of rainfall or snowfall and the quantity of nitrogen influx per area of land or water (Chapin and Uttormark, 1973). Dry fallout can contain as much as 10 times the quantity of nutrients commonly found in rain. The nitrogen content of snow is often much higher than that of rain and can contribute up to half of the total annual nitrogen influx to a stream or lake, even though snow generally constitutes a small proportion of total precipitation. N_2-fixing bacteria occur in rainwater in low numbers (Visser, 1964a), but their contribution to the total input of nitrogen is most likely small in comparison to other sources. In nonpolluted areas, most of the combined nitrogen in the atmosphere is ammonia, much of which originates from the decomposition of terrestrial organic matter (Hutchinson, 1944). Atmospheric ammonia associated with dust particles can be oxidized to nitrate so that precipitation contains both ammonia and nitrate (Hutchinson, 1944, 1975).

The inputs of NO_3^- and NH_4^+ from atmospheric sources average about 0.1 g N m^{-2} yr^{-1} over the continental United States but are highly irregular in distribution. The north central and eastern regions, especially bordering the southern Great Lakes, receive the largest input of nitrogen from precipitation, on the order of 0.3–0.35 g N m^{-2} yr^{-1} (Chapin and Uttormark, 1973). Dry fallout sources increase these values by a factor of 3–4, so that in the Great Lakes region, atmospheric contributions of nitrogen occur at a rate of approximately 1 g N m^{-2} yr^{-1}. Bulk deposition of nitrogen from both wet and dry precipitation in North America now ranges from 0.55 to 1.2 g N m^{-2} yr^{-1} and occurs in approximately equal proportions of NO_3^-, NH_4^+, and dissolved organic nitrogen (Boring *et al.*, 1988; Morris, 1991). Urea can account for nearly half of the water-soluble organic nitrogen compounds deposited from the atmosphere (Timperley *et al.*, 1985). Nitrogen mass-balance techniques applied to a large number of drainage basins and lakes in central Ontario, for example, indicated that on a regional area-weighted basis, 67% of bulk atmospheric total nitrogen was stored or denitrified terrestrially, 12% was denitrified in lakes, 4% was stored in lake sediments, and 17% was exported from the lakes (Molot and Dillon, 1993). Neglecting other nutrients for the time being, this influx alone corresponds to the approximate amounts of nitrogen that are generally required to shift shallow lakes of a mean depth of <5m from moderate to high productivity (Vollenweider, 1968). In this region of the country, which also receives high inorganic inputs from runoff of nitrogen-containing sedimentary rock formations, it would be very difficult to control productivity of lakes by limiting nitrogen inputs because of large atmospheric contributions. We will return to this subject in later discussions.

B. Molecular Nitrogen and N_2 Fixation

Although N_2 is not particularly soluble in water, N_2 is usually saturated with respect to surface temperature and pressure in streams and during periods of circulation of lakes (Birge and Juday, 1911). Maximum concentrations are found in winter owing to increased solubility at colder temperatures (approximately 15–20 ml $liter^{-1}$). During summer thermal stratification, the heating of the epilimnion decreases N_2 solubility, while N_2 concentrations in the metalimnion and much of the hypolimnion may be slightly supersaturated as a result of hydrostatic pressure maintaining a higher gas concentration despite the heating in these water strata (Fig. 12-1). A decrease in the N_2 content in the lower hypolimnion above the sediments has been observed (Fig. 12-1), which presumably is related to bacterial fixation of N_2 in productive lakes (Kuznetsov and Khartulari, 1941). Conversely, late in the summer stratification of Lake Mendota, N_2 of the hypolimnion

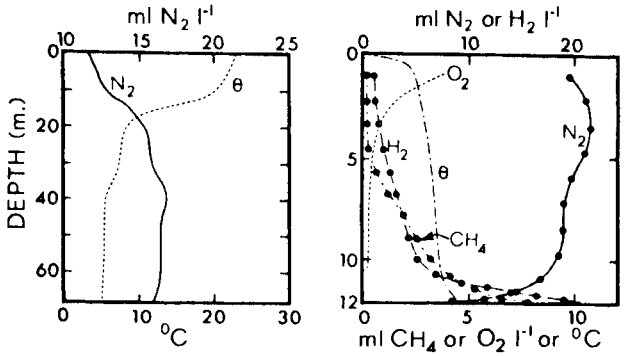

FIGURE 12-1 Vertical distribution of dissolved gases (*left*) in Green Lake, Wisconsin, summer, 1906 (Birge and Juday, 1911) and (*right*) in Beloie Lake, Russia, March 1938. θ = °C. (After Kuznetsov and Khartulari, 1941.)

increased somewhat above what would be expected on the basis of solubility (Brezonik and Lee, 1971); this may be the result of denitrification of nitrate in this lake (see following discussion).

C. Nitrogen Fixation: Cyanobacteria and Other Photosynthetic Bacteria

The importance of *in situ* nitrogen fixation to the productivity of streams and lakes has emerged only within the last two decades, even though the cyanobacteria (formerly termed *blue-green algae*) were implicated in this process many years earlier (Burris *et al.*, 1943). Excellent comparative reviews are given by Hardy *et al.* (1973) and Howarth *et al.* (1988a).

Nitrogen fixation in the open waters of lakes has been correlated strictly with the presence of cyanobacteria that possess heterocysts (Fogg, 1971a, 1974; Riddolls, 1985). Heterocysts are specialized cells that occur singly in most filamentous cyanobacteria, except for the Oscillatoriaceae, and are the sole site of nitrogen fixation in aerobically grown, heterocyst-forming cyanobacteria (Wolk, 1973; Haselkorn and Buikema, 1992). Nitrogen fixation has been found to occur in some unicellular forms that do not produce heterocysts (Fogg, 1974). However, among many species of cyanobacteria, such as *Anabaena* spp., numbers of heterocysts correspond approximately to observed nitrogen-fixing capacity (Horne and Goldman, 1972; Horne *et al.*, 1972, 1979; Riddolls, 1985).

Nitrogen fixation is primarily light-dependent in that the process requires reducing power and adenosine triphosphate (ATP), both of which are generated in photosynthesis. Electrons for the reduction of N_2 are supplied by dinitrogenase reductase in a highly endergonic reaction that requires about 12–15 mol of ATP per mol of N_2 reduced (Fay, 1992). Nitrogen-fixing photosynthetic bacteria can fix limited quantities of N_2 in the dark, but at rates usually <10% of maximum daytime rates (Horne, 1979; Levine and Lewis, 1984; Livingstone *et al.*, 1984; Storch *et al.*, 1990). Determinations *in situ* show a relationship of nitrogen fixation with depth similar to that of photosynthesis (Ward and Wetzel, 1980a). In full sunlight, N_2 fixation is often inhibited at the surface, reaches a maximum some depth below the surface, and shows rapid, nearly exponential decrease with greater depth and associated light attenuation (Fig. 12-2; cf. Chap. 5) (Dugdale and Dugdale, 1962; Goering and Neess, 1964; Horne and Fogg, 1970; Horne, 1979; Lewis and Levine, 1984).

Comparison of N_2—N, NO_3—N, and NH_4—N as nitrogen sources for *Aphanizomenon flos-aquae* (heterocystous) and *Microcystis aeruginosa* (nonheterocystous) at high, low, and variable light intensities revealed that highest growth rates always occurred with NH_4—N, followed by NO_3—N, and then N_2—N (Ward and Wetzel, 1980a). These findings were consistent with those expected from energy expenditures required to assimilate these nitrogen sources (i.e., N_2—N>NO_3—N>

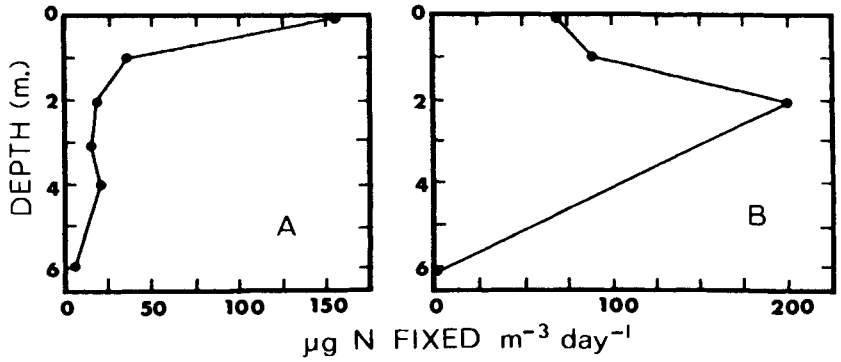

FIGURE 12-2 Variations in nitrogen fixation with depth (a) in Lake Windermere, and (b) in Esthwaite Water, England, 30 August 1966. (Modified from Horne and Fogg, 1970.)

NH_4—N). *Aphanizomenon* would not grow at low light intensities with N_2—N as the sole nitrogen source, although growth could be maintained with either NO_3—N or NH_4—N.

Readily utilizable sources of combined nitrogen suppress synthesis of the nitrogenase complex rather than the activity of any existing enzyme (Fogg, 1971, 1974; Wolk, 1973). Suppression of heterocyst formation by nitrate, even at very high concentrations, is often only partial (Ogawa and Carr, 1969; Ohmori and Hattori, 1972). Similarly, ammonia at low concentrations represses the formation of additional nitrogenase but does not affect activity of extant nitrogenase. In general, then, one would expect an inverse relationship between the rate of nitrogen fixation by cyanobacteria and the concentration of combined nitrogen in stream and lake waters; this is often the case. But because of the carryover of residual nitrogenase activity, the relationship is not always consistent. Thus N_2 fixation by cyanobacteria sometimes may occur at reduced levels in the presence of appreciable quantities of combined nitrogen in the water. The importance of the microenvironment surrounding the cell also should be noted. Molecular N_2 is in higher concentrations and diffuses more readily than either ammonium or nitrate ions. Within the massive mucilage sheaths surrounding many cyanobacteria, a steep gradient could easily develop in which other inorganic nitrogen sources are greatly reduced in comparison to N_2 availability, regardless of the inorganic concentrations of the water (cf. Chang, 1980).

Nitrogen fixation has also been correlated positively with concentrations of dissolved organic nitrogen occurring in the water (Horne and Fogg, 1970; Horne *et al.*, 1972; Paerl, 1985). Algae and cyanobacteria release extracellularly many simple and complex organic carbon and nitrogen compounds. Heterotrophic bacteria colonize common nitrogen-fixing cyanobacteria, such as *Anabaena*, particularly during the maxima of N_2-fixing blooms (Paerl, 1978, 1985; Paerl and Prufert, 1987). These cyanobacterial-heterotrophic bacterial aggregates form internal microenvironments with microzones of redox conditions distinct from those of the surrounding pelagic or benthic habitats. These oxygen-depleted microzones adjacent to the heterocysts protect the highly oxygen-sensitive nitrogenase. Environmental conditions, such as increased water turbulence, that increase diffusion rates of oxygen into the microzones reduce the rates of N_2 fixation. Similarly, reductions of dissolved organic carbon reduce rates of bacterial respiration, consumption of inhibiting oxygen, and rates of N_2 fixation. Many other strategies have evolved to protect nitrogenase from oxygen, such as the heterocyst structure, elaborate sheaths—particularly in nonheterocystous cyanobacteria—rapid changes in respiration, temporary protein inactivation, and production of enzymes to catalyze oxygen radicals (Fay, 1992)

Diurnal rates of nitrogen fixation in open lake water are typically low in the early morning, reach a maximum midday at maximum insolation, and then decline to low rates during the afternoon and evening (Rusness and Burris, 1970; Horne, 1979; Ward and Wetzel, 1980b). The most commonly observed seasonal pattern in temperate lakes is for both the percentage and the absolute rates of N_2 fixation to increase to maximum levels as heterocyst-bearing cyanobacterial populations develop and sources of combined nitrogen are reduced or depleted. High concentrations of total phosphorus are necessary (Lean *et al.*, 1978; Lundgren, 1978; Fiett *et al.*, 1980; Brownlee and Murphy, 1983; Wurtsbaugh *et al.*, 1985). Rates of N_2 fixation decline abruptly as the cyanobacterial populations decrease (cf. Chap. 15 on algal successions). In winter, the N_2 fixation is nonexistent or greatly reduced (Billaud, 1968; Horne and Fogg, 1970; Toetz, 1973). In productive tropical lakes where the periodicity of physicochemical factors and cyanobacteria is less marked, nitrogen fixation rates can extend for longer periods of the year but still exhibit distinct seasonality (e.g., Moyo, 1991).

Evaluations of nitrogen cycles of lakes or streams require estimates of the total nitrogen fixed per annum. Extensive measurements of nitrogen fixation are required because of the marked spatial and temporal heterogeneity of cyanobacterial populations (e.g., Horne and Galat, 1985; Levine and Lewis, 1985; Dudel and Kohl, 1991; Moyo, 1991). Planktonic nitrogen fixation tends to be low in oligotrophic and mesotrophic lakes (generally $<<0.1$ g N m^{-2} yr^{-1}) but often is high in eutrophic lakes (0.2–9.2 g N m^{-2} yr^{-1}) (Howarth *et al.*, 1988a,b). Direct estimates of N_2 fixation obtained by measuring $^{15}N_2$ uptake and acetylene reduction by nitrogenase of plankton in oligotrophic lakes, or in lakes of moderate productivity but which contain large pools of combined inorganic nitrogen, are consistently undetectable (Ward and Wetzel, 1980a).

Nitrogen fixation rates and control variables are poorly documented for benthic regions of freshwater ecosystems. Benthic fixation in oligotrophic ecosystems is often dominated by cyanobacteria (Howarth *et al.*, 1988) and tends to increase in cyanobacterial mats of very productive, shallow environments (1–76 g N m^{-2} yr^{-1}). In spite of the relatively small areas of such mats, their nitrogen contributions to the entire ecosystem can be disproportionally large. In moderately productive Lake Windermere, the nitrogen fixation by benthic cyanobacteria growing in abundance on littoral rocks and stones to a depth of 3.5 m was estimated conservatively to be 1 g N m^{-2} yr^{-1} (Horne and Fogg, 1970).

TABLE 12-1 Estimated Annual Rates of Nitrogen Fixation by Phytoplankton and Benthic Algae[a]

Lake	*Area (km^2)*	*N_2 Fixation ($g\ N\ m^{-2}$)*	*Total N fixed (megagrams = metric t)*
Phytoplankton			
Windermere, England			
North basin 1966	8.2	0.037	0.30
South basin 1965	6.7	0.287	1.92
1966	6.7	0.107	0.72
Esthwaite, England			
1965	1.01	0.127	0.13
1966	1.01	0.061	0.06
Clear Lake, California, 1970			
Upper arm	127.0	0.352	361
Lower arm	37.2	0.759	49
Oaks arm	12.5	0.250	50
Total for lake	176.7	0.384	460
Benthic Algae			
Windermere, England	2.9	1.0	0.8
Taharoa, New Zealand			
Exposed beach	—	0.62	—
Submersed beach	—	0.15	—
California stream	—	0.04–0.36	—
Everglades wetland, Florida	>5000	0.42–2.60	—
Range of wetland types	—	0.05–12	—

[a] From data of Horne and Fogg (1970), Horne and Goldman (1972), Horne and Carmiggelt (1975), Lam *et al.* (1979), Bowden (1987), and Browder *et al.* (1994).

For a minimal rocky area of 2.86 km^2, the estimated total annual fixation by the benthic cyanobacteria in Windermere is 0.8 megagrams. In this example, the littoral benthic contribution is considerably larger than the nitrogen fixed by the phytoplankton (Table 12-1). Even though these values are large, the total N_2 fixation by cyanobacteria contributes at most a small proportion (<1%) to the total combined nitrogen income of this lake. An estimate (probably high) for small, eutrophic Chernoye Lake, Russia, indicated that the nitrogen fixation constituted about 13% of the total nitrogen income (Kuznetsov, 1959). In eutrophic Clear Lake, California, biological N_2 fixation, largely associated with cyanobacterial blooms, contributed at least 43% of the nitrogen income, almost as much as NO_3^- from river inflows. Therefore, the importance of nitrogen fixation to the total nitrogen budget is variable. Nitrogen fixation is relatively unimportant as a nitrogen source in many oligotrophic and mesotrophic lakes (<1–10% of total nitrogen inputs). In eutrophic and hypereutrophic lakes of high phosphorus loadings, nitrogen fixation can account for >80% of the annual nitrogen inputs.

A detailed study of the nitrogen fixation in a small subarctic lake of interior Alaska demonstrated that ammonia was more important than N_2 fixation (Billaud, 1968). Of two main algal production periods, the first consisted largely of microflagellates under the ice and depended on ammonia as a nitrogen source. Immediately after the ice melted from the lake, a phytoplankton population composed almost exclusively of the cyanobacterium *Anabaena flos-aquae* developed. During the peak of the *Anabaena* bloom, molecular nitrogen constituted over 25% of the nitrogen assimilated by the plankton. Nitrogen fixed by the plankton in the south basin of Lake Windermere in 1965 amounted to 72% of the amount available as nitrate, although in 1966 and in other water bodies this proportion was less (<0.2–48%) (Horne and Fogg, 1970; Tison *et al.*, 1977; Ward and Wetzel, 1980a). Rates of N_2 fixation are greatly enhanced when the productivity of a lake is increased by phosphorus fertilization (e.g., Lean *et al.*, 1978; Lundgren, 1978).

Nitrogen metabolism is dependent upon the availability of trace quantities of molybdenum and iron for enzymes involved in N_2 fixation, assimilatory nitrate reduction, and denitrification (Miller, 1991). In oxygenated waters, molybdenum occurs primarily in the form of molybdate ion. Uptake follows saturation kinetics by natural phytoplankton assemblages and is light-dependent (Cole *et al.*, 1986). Sulfate anion is very similar to molybdate and is a competitive inhibitor of molybdate assimilation by planktonic algae and bacteria. Because concentrations of dissolved sulfate are

several orders of magnitude greater than those of molybdate, sulfate can suppress the availability of molybdate and nitrogen fixation (Howarth *et al.*, 1988b). As sulfate concentrations increase, as in sea water and saline lakes (Marino *et al.*, 1990), the availability of molybdate is further reduced.

Iron is also required as a cofactor for enzyme molybdenum nitrogenase protein activity in nitrogen fixation. Where phosphorus loadings are very high, iron availability can become limiting to N_2-fixation rates (Wurtsbaugh and Horne, 1983; Wurtsbaugh *et al.*, 1985). Combinations of high phosphorus and high dissolved organic matter favor cyanobacterial communities and may be partly related to organic complexation and increased solubility of iron and molybdenum. Under reducing conditions, as in or near sediments, particularly in wetlands and littoral areas, the level of dissolved organic matter tends to be much higher than in pelagic regions (e.g., Mann and Wetzel, 1995). The high level of dissolved organic matter and reducing conditions increase iron solubility and molybdenum stability. The resulting enhanced conditions for N_2 fixation may be counterbalanced by high concentrations of ammonium released from bacterial metabolism in the sediments.

Nitrogen fixation capabilities are widespread throughout other photosynthetic bacteria. As will be discussed in greater detail in Chap. 14, photosynthetic bacteria can develop in great densities in highly structured strata at the interface regions between the aerobic epilimnion or metalimnion and the anaerobic hypolimnion of eutrophic or meromictic lakes, given sufficient light to permit photosynthesis in these strata. N_2 fixation occurs only in the light, and intensive rates occur only under anaerobic conditions among the green and purple photosynthetic bacteria (Kondrat'eva, 1965). N_2 fixation by photosynthetic bacteria occurs simultaneously with the release of molecular H_2 by a noncyclic electron flux resulting from photophosphorylation. The source of these electrons is an exogenous H-donor, such as thiosulfate.

All three families of photosynthetic bacteria of the order Rhodospirillales produce bacteriochlorophyll and carry out anoxygenic photosynthesis (Roberts and Ludden, 1992). The Rhodospirillaceae (Athiorhodaceae), or purple nonsulfur bacteria, are facultative autotrophs but are unable to use elemental sulfur as an electron donor for photosynthesis. The Chromatiaceae (Thiorhodaceae), or purple sulfur bacteria, use elemental and nonelemental sulfur as electron donors for photosynthesis. The Chlorobiaceae (Chlorobacteriaceae), or green sulfur bacteria, use the sulfur of hydrogen sulfide as an electron donor for the photosynthetic reduction of CO_2.

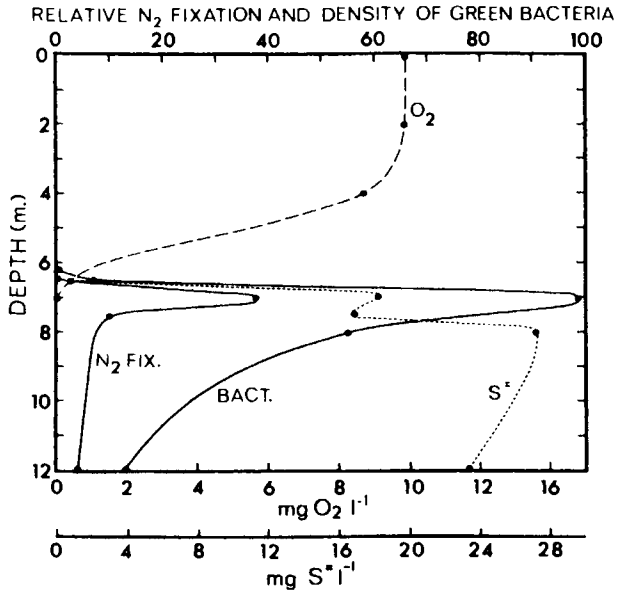

FIGURE 12-3 Nitrogen fixation in a Norwegian meromictic lake, June 1966, in relation to a dense layer of green photosynthetic bacteria, primarily *Pelodictyon*, on the surface of the monimolimnion. (Drawn from data of Stewart, 1968.)

Despite considerable understanding of the biochemical physiology of these organisms, little information is available on the relative quantitative contributions of the nitrogen-fixing capabilities of photosynthetic bacteria in comparison to the cyanobacteria and heterotrophic bacteria in lakes, wetlands, and rivers. In the example given in Figure 12-3, nitrogen fixation is clearly associated with green photosynthetic bacteria, mainly *Pelodictyon*, of the chemolimnion in this meromictic lake. In contrast, the nitrogen-fixation capabilities of photosynthetic sulfur bacteria were not found to contribute significantly to the organic nitrogen loading of Lake Kinneret in Israel (Bergstein *et al.*, 1981). Generalizing from the latter conclusion, however, is not warranted on the basis of existing data.

D. Nitrogen Fixation: Heterotrophic Bacteria

Quantitative information on nonphotosynthetic bacterial nitrogen fixation in lakes is also sparse. Heterotrophic nitrogen fixation is commonly disregarded, on the premise that these nitrogen-fixing bacteria are limited by the low availability of exogenous carbohydrate. One to 25 mg of nitrogen can be fixed per gram of carbohydrate utilized (Stewart, 1969; Hill, 1992). Sufficiently large quantities of soluble carbohydrate rarely are available in natural waters, and there is an intense competition for these substrates by heterotrophic bacteria incapable of N_2 fixation.

TABLE 12-2 Occurrence of Nitrogen-Fixing Bacteria in Water and Sediments of Lakes[a]

Lake type	Number lakes studied	In water (no. ml^{-1})		In sediment (no. g^{-1} wet wt)	
		Azotobacter	*Clostridium pasteurianum*	*Azotobacter*	*Clostridium pasteurianum*
Oligotrophic	5	0	0	0–10	0–10
Mesotrophic	5	0–10	0–10	0–10	0–1000
Eutrophic	10	0–10	1–20	0–10	100–10,000
Eutrophic with high humic content	2	10	1	—	—
Dystrophic with high humic content	3	1–10	0–1	—	—
Eutrophic reservoir	1	5–10	1–5	10–1000	1000–10,000

[a] Modified from Kuznetsov (1970).

The most common heterotrophic N_2-fixing bacteria comprise several species of *Azotobacter* and *Clostridium pasteurianum,* which are found in fair abundance living free in the water, epiphytically on submersed aquatic plants, and in the sediments (Kuznetsov, 1959, 1970). The numbers of these bacteria are generally lowest in the open water, where soluble organic concentrations are low, and tend to increase, with *Azotobacter* being dominant, in bog lakes, which contain high concentrations of dissolved humic organic matter (Table 12-2). Based on scant data from eutrophic Chernoye Lake, Russia, numbers of open-water *Clostridium* increase in the spring just before and after ice loss, decrease to a low in summer, and increase in autumn. This pattern is somewhat analogous to the seasonality of other, non-N_2-fixing bacteria populations that lag slightly behind the productivity pulses of phytoplankton (cf. Chap. 17). In contrast, Niewolak (1972) observed a maximum of *Azotobacter* in spring and summer in Polish lakes.

Azotobacter is found in particular abundance as an epiphyte on submersed aquatic angiosperms and submersed portions of emergent macrophytes. A symbiotic relationship between the *Azotobacter* and the macrophytes is possible since the plants secrete many dissolved organic compounds (Wetzel, 1969) that can serve as substrates for nitrogen-fixing bacteria. The nitrogen released by the bacteria may be utilized by the macrophytes. In the littoral water, populations of the planktonic bacterium *Azotobacter* are higher than those of the open water (J. Overbeck, personal communication). Although few quantitative data are available, the littoral zone may serve as a major site of nitrogen fixation by both heterotrophic bacteria and sessile cyanobacteria. Further investigation is needed.

Large numbers of N_2-fixing bacteria occur in the sediments of lakes; most are concentrated in the upper 2 cm. Bacterial numbers are much higher in productive lakes than in oligotrophic lakes, particularly in the case of *Clostridium* (Table 12-2). Seasonal changes in the numbers of *Clostridium* in the sediments of Chernoye Lake were similar to those observed in the open water: maximum numbers occurred in the fall, followed by low winter populations, that increased to another maximum in the spring. Lowest populations in the sediments were found in midsummer. Similar results were observed for *Azotobacter* populations of sediments in Polish lakes (Niewolak, 1970, 1972).

Several methane-oxidizing bacteria are capable of N_2 fixation (reviewed by Zeikus, 1977; Rudd and Taylor, 1980). The N_2 fixation of these bacteria increases when sources of combined inorganic nitrogen are depleted either within water or at the sediment–water interface where methane is abundant. Although N_2 fixation is physiologically important to the methane-oxidizing bacteria, these nitrogen fixers have not yet been demonstrated to constitute a major source of fixed nitrogen to a lake (Rudd and Taylor, 1980).

In two lakes (Mary and Mize, Table 12-3), N_2 fixation by planktonic heterotrophic bacteria (*Azotobacter*) occurred at a rate several orders of magnitude lower than rates in lakes dominated by the cyanobacterium *Anabaena.* In waters rich in dissolved humic organic compounds (such as in lakes Mary and Mize), cyanobacteria are rare and nitrogen-fixation rates are very low.

E. Nitrogen Fixation: Wetland Sources

In addition to the inputs of nitrogen from drainage runoff from terrestrial sources, lakes and streams often are bordered by dense stands of shrublike trees that fix nitrogen from the atmosphere. Common species of the genera *Alnus* and *Myrica* are nonleguminous angiosperms that form large nodules containing an actinomycetal fungal endophyte at or just below the soil surface. Nitrogen fixation by dense stands of *Alnus* can

TABLE 12-3 Estimates of Fixation of Molecular Nitrogen by Heterotrophic Bacteria and Cyanobacteria in Several Lakes[a]

Lake	*Organisms*	*N_2 Fixation*	*N_2 Fixation in g, whole lake, summer stratification period*
Chernoye, USSR, 1937	*Azotobacter*	1.6×10^{-11} mg cell^{-1} day^{-1}	0.14
	Anabaena scheremetievi	1.12×10^{-9}	13,100

be as high as 22.5 g N m^{-2} yr^{-1}, most of which enters the plant. Subsequently, leachate from direct leaf-fall or release during decomposition of foliage can reach nearby streams and lakes.

Alnus trees have been implicated as a significant nitrogen source for streams and lakes in glaciated regions of Alaska that are particularly nitrogen-deficient (Goldman, 1960; Dugdale and Dugdale, 1961). In Castle Lake, an alpine cirque lake of northern California, alder (*Alnus*) trees were abundant on only one side of the lake (Goldman, 1961). *Alnus* leaves contained over four times as much nitrogen as those of other deciduous species. Soils, lake sediments, and spring waters draining to the lake from the alder side all contained higher nitrogen levels than those from the non-alder side of the lake. Bioassay of *in situ* rates of photosynthesis by the phytoplankton demonstrated that these nitrogen sources were stimulatory and also that the primary productivity of the lake was significantly higher along the side on which the alders grew.

Cyanobacterial and heterotrophic bacterial N_2-fixation rates can add significant amounts of nitrogen to wetlands. Combined N_2 fixation by microorganisms associated with the aerobic layer of wetland hydrosoils, the anaerobic regions including the rhizosphere of non-nodulated plants, and floating mats of particulate detritus and associated microorganisms often constitute a major source of nitrogen input to wetlands (Buresh *et al.*, 1980). Nitrogen fixation by attached cyanobacteria and heterotrophic bacteria contributed a significant but small (5–10%) portion of the total nitrogen inputs on the flood plain of a tropical riverine lake (Doyle and Fisher, 1994). In another example, the nitrogen fixed annually by heterotrophic bacteria on decaying plant debris of calcareous wetlands ranged from 530 to 2100 mg N m^{-2} and was considerably less (70 mg N m^{-2}) among acidic bog vegetation (Waughman and Bellamy, 1980).

Azolla, a small (1–3 cm) aquatic fern, with global distribution, floats freely on the water surface of many natural and cultivated wetlands. All *Azolla* species contain a symbiotic heterocyst-forming, N_2-fixing cyanobacterium *Anabaena azollae* (Lumpkin and Plucknett, 1980; Peters and Meeks, 1989). These organisms are actively cultivated in rice agriculture to supplement alternative sources of nitrogen fertilization. It is estimated that as much as a quarter of the total nitrogen consumed by humankind emanates from this symbiotic N_2-fixing cyanobacterium–fern association.

II. INORGANIC AND ORGANIC NITROGEN

In addition to atmospheric nitrogen in the form of precipitation, dry fallout, and fixation of N_2 just discussed, a major source of nitrogen income to streams and lakes is from influents, both from surface land drainage and from groundwater sources. Inputs of nitrogen by ground water can be a major part of the annual nitrogen loading in many streams and lakes, especially in regions rich in limestone. In detailing the nitrogen cycle, the forms of nitrogen must be discussed individually and then integrated with rates of biogeochemical utilization and transformations as well as nitrogen losses from the lake ecosystem. An obvious loss is via inorganic dissolved and organic (both dissolved and particulate) compounds in effluents flowing out of lake basins. Further losses occur as a result of permanent interment of partially decomposed biota and inorganic and organic nitrogen compounds adsorbed to inorganic particulate matter in the sediments. Nitrogen can also be lost by volatilization of compounds from

TABLE 12-4 General Relationship of Lake Productivity to Average Concentrations of Epilimnetic Nitrogen[a]

General level of lake productivity	*Change in alkalinity in epilimnion in summer (meq liter^{-1})*	*Inorganic N (mg m^{-3})*	*Approximate average organic N (mg m^{-3})*
Ultra-oligotrophic	< 0.2	< 200	< 200
Oligo-mesotrophic	0.6	200–400	200–400
Meso-eutrophic	0.6–1.0	300–650	400–700
Eutrophic		500–1500	700–1200
Hypereutrophic	> 1.0	> 1500	> 1200

[a] Modified from Vollenweider, R. A.: *Scientific Fundamentals of the Eutrophication of Lakes and Flowing Waters, with Particular Reference to Nitrogen and Phosphorus as Factors in Eutrophication.* OECD Report No. DAS/CSI 68.27, Paris, OECD, 1968, after data of Thomas and Lueschow *et al.* 1970.

the water surface, such as ammonia at high pH and as N_2 formed in microbial denitrification of nitrate.

Combined nitrogen occurs as ammonia (NH_4^+), hydroxylamine (NH_2OH), nitrite (NO_2^-), nitrate (NO_3^-), and dissolved and particulate organic nitrogen. NH_4—N can range from 0 to 5 mg liter^{-1} in unpolluted surface waters, although concentrations are usually low, to well above 10 mg liter^{-1} in anaerobic hypolimnetic waters of eutrophic lakes. The intermediate product, NH_2OH, is rapidly oxidized and occurs only in very low concentrations. Similarly, NO_2—N levels of natural waters are generally very low, in the range of 0–0.01 mg liter^{-1}, although concentrations of up to 1 mg liter^{-1} have been found in the interstitial waters of deep (>90 cm depth) sediments of Lake Mendota (Konrad *et al.*, 1970). Concentrations of NO_2—N increase in the anaerobic hypolimnion of lakes under reducing conditions (e.g., Brezonik and Lee, 1968; Overbeck, 1968) and in streams and lakes receiving heavy organic-matter pollution. Concentrations of NO_2—N are usually low under oxygenated conditions, but significant deepwater maxima (to 10 μg liter^{-1}) have been found in the upper portions of the hypolimnion (Mortonson and Brooks, 1980). Concentrations of NO_3—N range from undetectable levels to nearly 10 mg liter^{-1} in unpolluted fresh waters but are highly variable seasonally and spatially. Organic nitrogen, much of which occurs in forms resistant to rapid bacterial degradation, commonly accounts for more than one-half of the total dissolved nitrogen.

Recently, much attention has been devoted to the importance of nitrogen concentrations of fresh waters in the regulation of algal productivity (e.g., cf. Vollenweider, 1968). Although, as we will see in Chap. 13, phosphorus-cycling rates frequently regulate high sustained productivity, the loading rates of nitrogen are of major importance to the maintenance of high flux rates within the nitrogen cycle. Although there are a number of exceptions, a positive correlation has been found between high sustained productivity of algal populations and average concentrations of inorganic and organic nitrogen (Table 12-4). Mean chemical mass, however, must be used with caution when little consideration is given to the rates of mineralization, microbial transformation, and recycling.

In comparing the distribution of organic and inorganic forms of nitrogen in oligotrophic and eutrophic lake sediments, little correlation was found between concentrations of total or organic forms of nitrogen in sediments and general productivity of the lake (Table 12-5)

TABLE 12-5 Average Distribution of Nitrogen in Some Wisconsin Lake Sediments[a]

	Sediment-N (mg kg^{-1})		*Interstitial water-N (mg liter^{-1})*			*Total organic N (%)*	*Acid hydrolyzable (% of total N)*
Lake type	*Fixed NH_4*	*Exchangeable NH_4*	*Organic*	*NH_4*	*NO_3*		
Softwater, oligotrophic	69	167	2.1	3.8	0.2	1.53	83.1
Softwater, eutrophic	44	415	2.2	9.6	0.3	3.26	80.4
Hardwater, oligotrophic	66	66	—	—	—	0.52	84.4
Hardwater, eutrophic	134	120	2.0	11.4	0.3	0.80	82.0

[a] Modified from Keeney (1973).

(Keeney *et al.*, 1970; Konrad *et al.*, 1970). The percentage of organic nitrogen as hexosamine-N decreased while amino acid-N increased with increasing lake fertility. NH_4—N of interstitial water was somewhat higher in sediments of eutrophic lakes than in those of oligotrophic lakes.

A. Ammonia

Ammonia is generated by the biological dissimilation of nitrate, as will be discussed later in this chapter. Much of the ammonia, however, arises as a primary end product of the decomposition of organic matter by heterotrophic bacteria from the deamination of proteins, amino acids, urea, and other nitrogenous organic compounds. Intermediate nitrogen compounds are formed in the progressive degradation of organic material but rarely accumulate, because deamination by bacteria proceeds rapidly. Phagotrophic protists, particularly bacterivorous flagellates, can accelerate appreciably the regeneration of ammonia by the consumption of bacteria and the release of ammonium ions (Suzuki *et al.*, 1996). Although ammonia is an excretory product of higher aquatic animals, this nitrogen source is quantitatively minor in comparison to that generated by bacterial decomposition.

Ammonia in water is present primarily as NH_4^+ and as undissociated NH_4OH, the latter being highly toxic to many organisms, especially fish (Trussell, 1972). The proportions of NH_4^+ to NH_4OH are dependent on the dissociation dynamics, which are governed by pH and temperature. The approximate ratios of NH_4 to NH_4OH are as follows (Hutchinson, 1957):

pH 6	3000:1
pH 7	300:1
pH 8	30:1
pH 9.5	1:1

Detailed dissociation relationships with pH and temperature are given by Trussell (1972) and Emerson *et al.* (1975). Ammonia is strongly sorbed to particulate and colloidal particles, especially in alkaline lakes containing high concentrations of humic dissolved organic matter.

At high pH values, NH_3 gas can be formed by the deprotonization of NH_4^+. Although few studies have addressed the evasion of NH_3 from fresh waters and littoral areas to the atmosphere, appreciable amounts (range, 10–300 $\mu g\ N\ m^{-2}\ h^{-1}$) evade from hydrosoils of lakes and littoral wetlands (cf. review of Schlesinger and Hartley, 1992). The rates of ammonia volatilization from wetlands increase with increasing concentrations of ammonium and pH of the water overlying the sediments, as well as with greater wind velocities and temperatures (Bouwmeester and Vlek, 1981; Jones *et al.*, 1982). On a global basis, volatilization of NH_3 from inland waters and associated wetlands could constitute a significant (e.g., ca. 15%) though not dominating source.

Since NO_3^- must be reduced to NH_4^+ before it can be assimilated by plants, ammonia is an energy-efficient source of nitrogen for plants. The energy necessary to assimilate nitrogen is lowest for NH_4—N and increases for NO_3—N (and N_2—N for N_2-fixing cyanobacteria). Dark assimilation of both NO_3^- and NH_4^+ was about 50% of the assimilation rates at photosynthetically saturating light intensities, which indicated that part of the energy required for inorganic nitrogen assimilation may originate from intermediary metabolism (Priscu, 1984). Among the cyanobacteria, highest growth rates always occurred with NH_4—H as the nitrogen source at many different light intensities (Ward and Wetzel, 1980a,b). Reports of better growth of some algae with NO_3—N as the nitrogen source rather than with NH_4—N may be, in part, the result of the toxicity of NH_4OH at high pH values that can prevail both in culture and *in situ* during periods of high daily photosynthesis in very eutrophic lakes (cf. Rodhe, 1948; Laan *et al.*, 1982). Inhibition of NH_4—N assimilation by natural populations of phytoplankton was observed at high concentrations of NH_4—N, but at low concentrations NH_4—N uptake rates exceeded those of NO_3—N (Toetz *et al.*, 1977; Toetz and Cole, 1980; Berman *et al.*, 1984). NO_3—N uptake can be suppressed by NH_4—N concentrations as low as 2 $\mu g\ NH_4^+$—$N\ liter^{-1}$ (Priscu *et al.*, 1989). A few algae, such as a species of *Chrysochromulina*, are apparently able to utilize only NH_4^+ as an inorganic N source (Wehr *et al.*, 1987).

The distribution of ammonia in fresh waters is highly variable regionally, seasonally, and spatially within streams and lakes and depends upon the level of productivity and the extent of pollution from organic matter. Although generalizations are difficult to make, the concentration of NH_4—N in well-oxygenated waters is usually low. In the trophogenic zone, NH_4—N is rapidly assimilated by algae and represents the most significant source of nitrogen for the plankton in many lakes (Liao and Lean, 1978). Thus, concentrations of NH_4—N are commonly low in unproductive oligotrophic waters, in the trophogenic zones of most lakes, and in most lakes after periods of circulation (Fig. 12-4). When appreciable amounts of sedimenting organic matter reach the hypolimnion of stratified lakes, NH_4—N can accumulate. The accumulation of NH_4—N greatly accelerates as the hypolimnion becomes anoxic. Under anaerobic conditions, bacterial nitrification of NH_4^+ to NO_2^- and NO_3^- ceases, as the redox potential is reduced to below about + 0.4 V.

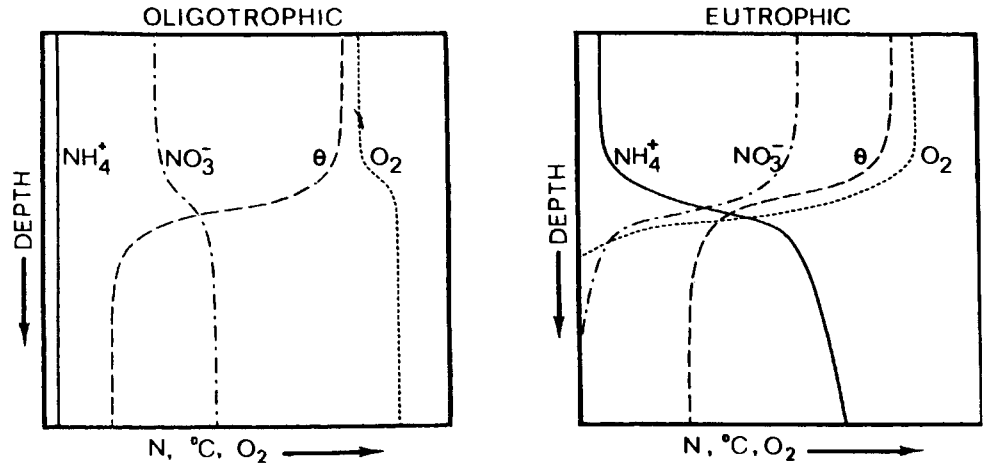

FIGURE 12-4 Generalized vertical distribution of ammonia and nitrate nitrogen in stratified lakes of very low and high productivity.

In the sediments, a large percentage of the ammonia is adsorbed on sediment particles. With the loss of the oxidized microzone at the sediment–water interface under anoxic hypolimnetic conditions, the adsorptive capacity of the sediments is greatly reduced (Kamiyama *et al.*, 1977; Verdouw *et al.*, 1985). A marked release of NH_4^+ from the sediments then occurs. Diffusion transport into the overlying water approximately equals production and release into the interstitial waters of the sediments. These diffusion rates of NH_4^+ into the overlying water can be increased severalfold by the activities of benthic invertebrates such as chironomid larvae, tubificid worms, and bivalve mollusks (Henriksen *et al.*, 1983; Fukuhara and Sakamoto, 1987; Fukuhara and Yasuda, 1989; Svensson, 1997). The ammonium enhancement apparently results more from microwater movements associated with respiratory behavior rather than from direct excretion. Excretion rates of NH_4—N of four species of chironomids and tubificids ranged from 0.33 to 2.87 μg N mg DW^{-1} d^{-1} at 15°C.

If light reaches the sediments in amounts sufficient to support benthic algae, algal and cyanobacterial growth can assimilate NH_4—N from the interstitial water and prevent the flux of NH_4—N from the sediment to the water (Jansson, 1980; Reuter *et al.*, 1986; Risgaard-Petersen *et al.*, 1994; Van Luijn *et al.*, 1995). Because the uptake rates are in part dependent upon photosynthesis, a marked diurnal variation in release rates can occur, with reduced uptake during periods of darkness. These sources of interstitial nitrogen often serve as the dominant inorganic nitrogen source, or supplement N_2 fixation, for the microbiota attached at the sediment–water interface, particularly in nitrogen-deficient lakes and streams. These attached microbial communities can release appreciable amounts of dissolved organic nitrogen to the water above the sediments.

If macrophytes are rooted in the sediments, these plants are capable of absorbing large quantities of nitrogen from the sediments. Much of the nitrogen can be immobilized in the belowground rooting tissues and in the above-sediment foliage tissues. Much of the nitrogen is assimilated as NH_4—N (e.g., Dean and Biesboer, 1985) and can remain for long periods in living tissues and particulate detritus after senescence. Thus, in littoral and wetland regions of freshwater ecosystems, the sediments are a primary storage site for nitrogen, and storage in living and senescent macrophytes is by far the most important component (e.g., Sarvala *et al.*, 1982; Reddy and Patrick, 1984; Bowden, 1987).

B. Nitrification

Nitrification may be broadly defined as the biological conversion of organic and inorganic nitrogenous compounds from a reduced state to a more oxidized state (Alexander, 1965). Of the numerous oxidation and reduction stages outlined in Figure 12-5, initial nitrification by bacteria, fungi, and autotrophic organisms involves (Kuznetsov, 1970):

$$NH_4^+ + 1\tfrac{1}{2}\,O_2 \rightleftharpoons 2H^+ + NO_2^- + H_2O$$

$$(\Delta G_0' = -66.0 \text{ kcal})^1$$

which proceeds by a series of oxidation stages through hydroxylamine and pyruvic oxime to nitrous acid:

$$NH_4^+ \longrightarrow NH_2OH \longrightarrow H_2N_2O_2 \longrightarrow HNO_2$$

[1] Gibbs energy of formation, kcal mol^{-1}.

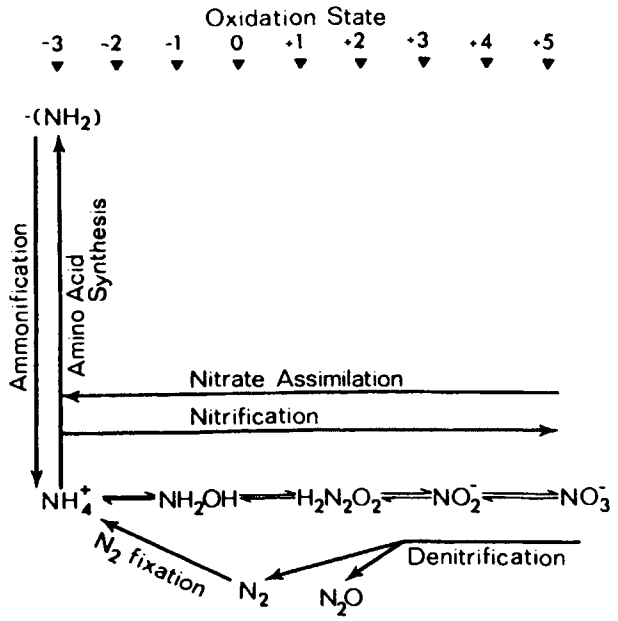

FIGURE 12-5 Biochemical reactions that influence the distribution of nitrogen compounds in water. (After Stadelmann, 1971, and Kuznetsov, 1970.)

The intermediate products are labile to physical and heterotrophic oxidation and are found only rarely in significant quantities relative to other forms of combined nitrogen (cf. Baxter *et al.*, 1973). Much of the energy (total exothermic energy = -84.0 kcal mol^{-1}) released by the oxidation series is used to reduce CO_2 in the formation of organic matter; detailed reactions are discussed by Alexander (1965a), Kuznetsov (1970), and Fenchel and Blackburn (1979).

The nitrifying bacteria capable of the oxidation of $NH_4^+ \rightarrow NO_2^-$ are largely confined to *Nitrosomonas* (Nitrobacteriaceae, order Pseudomonadales), although several other taxa, including methane-oxidizing bacteria, are known to be capable of this process (Alexander, 1965; O'Neill and Wilkinson, 1977). These bacteria are mesophilic, with a wide temperature tolerance range (1–37°C), and grow optimally at a pH near neutrality.

Oxidation of nitrite proceeds further to nitrate by:

$$NO_2^- + \tfrac{1}{2}\,O_2 \rightleftharpoons NO_3^- \qquad (\Delta G_0' = -18.0 \text{ kcal})$$

Nitrobacter is the primary bacterial genus involved in this oxidation. *Nitrobacter* is somewhat less tolerant of low temperatures and high pH, conditions that can lead to a slight accumulation of NO_2—N. The release of energy for synthesis of organic matter by the oxidation of nitrite is much lower, at -18.0 kcal per mole, than that of NH_4^+ to NO_2^-.

The overall nitrification reactions,

$$NH_4^+ + 2O_2 \longrightarrow NO_3^- + H_2O + 2H^+$$

require two moles of oxygen for the oxidation of each mole of NH_4^+. Although conditions must be aerobic in order for nitrification to occur, these processes will continue until concentrations of dissolved oxygen decline to about 0.3 mg liter^{-1}. Below this concentration, diffusion rates of oxygen to the bacteria become critical. Nitrification is greatly reduced in undisturbed sediments because oxygen is very low or absent (Chen *et al.*, 1972). Some nitrate may diffuse to the water following nitrification in the well-oxygenated surficial sediments of the littoral zone or during periods of circulation of the water and disturbance of sediments (cf. Landner and Larsson, 1972; Laurent and Badia, 1973). Oxidation of ammonia by autotrophic bacteria was found to be of relatively minor importance during the summer stratification of eutrophic Pluss See, Northern Germany (Gode and Overbeck, 1972). Several genera of heterotrophic nitrifying bacteria were found in much higher concentrations in both aerobic and anaerobic water strata. Experimental results suggested that these bacteria were most likely responsible for most of the nitrification that occurred in this lake.

Nitrification is severely inhibited by certain dissolved organic compounds, especially by tannins and their decompositional derivatives (Rice and Pancholy, 1972, 1973). Although this mechanism has been demonstrated only in soil systems, there is a strong possibility that an analogous situation exists in freshwater systems that contain relatively high concentrations of humic materials, for ammonia concentrations are often greater in highly stained lakes than in aerobic waters of other lakes. Therefore, it is likely that rates of nitrification are lower in neutral or alkaline waters containing high concentrations of dissolved humic organic matter. Such was apparently the case in several European waters (Nygaard, 1938; Karcher, 1939). Moreover, nitrification proceeds slowly in acidic waters, such as in acid bogs and acidic bog lakes, where the pH is 5 or less. Nitrate produced in such lakes is probably utilized as rapidly as it is formed, so that most of the time only very low or undetectable quantities are found.

C. Nitrate Reduction and Denitrification

As nitrate is assimilated by algae and larger hydrophytes, it is reduced to ammonia. Molybdenum is required in the enzyme systems associated with this reduction. In a few lake regions, such as granitic mountainous regions, concentrations of molybdenum are extremely low. Rates of carbon fixation by phytoplanktonic algae in lakes of these regions can be increased by

additions of molybdenum (Goldman, 1960, 1972). These circumstances are related to the rates of nitrate reduction (Axler *et al.*, 1980) and indicate the coupling of molybdenum to phytoplanktonic growth during portions of the growing season when nitrate concentrations are relatively high.

The assimilation of nitrate and its reduction by green plants are clearly dominant processes in the trophogenic zone of lakes. As much as 60% of the photoassimilated NO_3—N can be excreted as dissolved organic nitrogen compounds, some of which are simple amino acids readily utilized by bacteria (Chan and Campbell, 1978). Nitrate assimilation in oligotrophic lakes may be adequate to reduce the observed concentrations in the trophogenic zone, as depicted in Figure 12-4. Alternatively, NO_3—N assimilative losses may be counterbalanced by nitrification and inflow sources of NO_3—N. In eutrophic lakes, littoral areas, and wetlands, denitrification (see below) is a major process influencing the distribution of NO_3—N. Nitrate assimilation can, however, greatly exceed sources of income and generation, in some cases to the point of reducing NO_3—N to below detectable concentrations (Fig. 12-4).

The ratio of NO_3-N to NH_4-N in fresh waters is variable in relation to natural and pollutional sources of both forms of combined nitrogen. In regions draining calcareous sedimentary landforms, unpolluted waters can have NO_3—N:NH_4—N ratios of 25:1. In other areas where natural sources of NO_3—N are low, the ratio may approach 1:1; where slight-to-moderate sewage contamination or agricultural applications of nitrogen fertilizers influence the waters, ratios in the range of 1:10 are common.

Denitrification by bacteria is the biochemical reduction of oxidized nitrogen anions, NO_3—N and NO_2—N, with concomitant oxidation of organic matter. The general sequence of this process is

$$NO_3^- \longrightarrow NO_2^- \longrightarrow N_2O \longrightarrow N_2$$

which results in a significant reduction of combined nitrogen that can, in part, be lost from the ecosystem if it is not refixed.

Many facultative anaerobic bacteria, particularly of the genera *Pseudomonas, Achromobacter, Escherichia, Bacillus,* and *Micrococcus,* can utilize nitrate as an exogenous terminal H acceptor in the oxidation of organic substrates (Alexander, 1961). The denitrification reactions are associated with the enzyme nitrogen reductase and require, as discussed earlier (p. 209), cofactors of iron and molybdenum. Denitrification operates similarly under both aerobic and anaerobic conditions (Bandurski, 1965).

An exemplary reaction of the oxidation of glucose and the concomitant reduction of nitrate is (Hutchinson, 1957)

$$C_6H_{12}O_6 + 12NO_3^- \rightleftharpoons 12NO_2^- + 6CO_2 + 6H_2O \quad (\Delta G_0' = -460 \text{ kcal mol}^{-1}),$$

and for the reduction of nitrite to molecular nitrogen:

$$C_6H_{12}O_6 + 8NO_2^- \rightleftharpoons 4N_2 + 2CO_2 + 4CO_3^{2-} + 6H_2O \quad (\Delta G_0' = -720 \text{ kcal mol}^{-1}).$$

Approximately as much free energy results as in the aerobic oxidation of glucose by dissolved O_2 ($\Delta G_0' = -699$ kcal mol^{-1}). The denitrification reactions occur intensely in anaerobic environments, such as in the hypolimnia of eutrophic lakes (Fig. 12-4) and in anoxic sediments, where oxidizable organic substrates are relatively abundant.

High concentrations of NO_2^- can occur in large rivers in summer under warm, slow-flowing conditions as a result of dissimilatory nitrate reduction in anaerobic sediments (Kelso *et al.*, 1997, 1999). A range of organic carbon compounds, commonly found in agricultural and domestic pollutants, provide the energy sources in the NO_3^- reduction. Glucose, acetate, and particularly formate, among others, induced high NO_2^- accumulation, caused in part by partial inhibition of denitrification.

A specialized case, of much less general quantitative significance than the heterotrophic denitrification just discussed, is denitrification of nitrate concurrently with the oxidation of sulfur. The process is accomplished by denitrifying sulfur bacteria, particularly *Thiobacillus denitrificans,* that utilize S° or reduced sulfur compounds such as thiosulfate (Kuznetsov, 1970):

$$5S + 6KNO_3 + 2H_2O \longrightarrow 3N_2 + K_2SO_4 + 4KHSO_4$$

$$5Na_2S_2O_3 + 8KNO_3 + 2NaHCO_3 \longrightarrow 6Na_2SO_4 + 4K_2SO_4 + 2CO_2 + H_2O + 4N_2$$

Both processes occur chemosynthetically under dark, anaerobic conditions and yield relatively small changes in free energy. In a similar manner, a chemolithotrophic iron bacterium, *Gallionella ferruginea,* reduces nitrates to N_2 by the oxidation of ferrous ions under anaerobic conditions (Guoy *et al.*, 1984).

The rate of denitrification, as of nitrification, decreases in acidic waters (Keeney, 1973) and is very slow at low temperatures (around 2°C). Optimum rates of denitrification occur well above the temperatures of most natural fresh waters. At high temperatures, the primary product is N_2, while at lower temperatures, nitrous oxide (N_2O) predominates. N_2O is usually rapidly reduced to N_2, but its distribution is quite variable. Although N_2O has not been found in many lakes in appreciable quantities (e.g., Goering and Dugdale, 1966; Kuznetsov, 1970; MacGregor and Keeney, 1973; Kaplan and Wofsy, 1985; Mengis *et al.*, 1996), large N_2O

accumulations were repeatedly observed in strata of greatly reduced oxygen of eutrophic lakes, concomitant with large concentrations of NO_2^- (Yoh *et al.*, 1988, 1990; Yoh, 1992; Mengis *et al.*, 1997). Although nitrification contributed to the accumulations of both compounds to some extent, denitrification was the dominant process of N_2O formation in these lakes. Rates of N_2O and NO_2^- formation were maximal with very low concentrations of dissolved oxygen (ca. 0.1 mg liter^{-1}) and inhibited by reducing conditions in the lower hypolimnion sufficient to reduce iron and sulfide ions (see Chap. 14). In anaerobic littoral and wetland sediments, denitrification dominates as the process producing N_2O, but N_2O to N_2 ratios are greatest at low rates of denitrification (van Cleemput, 1994). Nitrous oxide has been found to be released from aerobic riverine sediments into the overlying water (Wissmar *et al.*, 1987). Higher evasion rates of N_2O, believed to emanate largely from nitrification, occurred from sands of pools (30–695 nM m^{-2} h^{-1}) than from gravel deposits of riffles (65–275 nM m^{-2} h^{-1}). In a series of seven amictic, permanently ice-covered lakes of Antarctica, a detailed study indicates that N_2O maxima were largely a product of nitrification and that denitrification was a sink for this gas in anoxic water (Priscu, 1997). Maxima of N_2O were common in depth gradients where oxygen concentrations and redox potentials were decreasing, and N_2O was nearly absent in anoxic zones of low redox potential. The ice barrier results in an appreciable supersaturation of N_2O, some of which evades to the atmosphere through the brief period of the summer moat of open water at the edge of the ice.

Rates of denitrification by nitrate-reducing bacteria in eutrophic Pluss See, Germany, showed marked seasonal and depth variations (Tan and Overbeck, 1973). Rates of nitrate reduction were particularly high and were correlated with cell numbers during the early portion of summer stratification, before hypolimnetic nitrate concentrations were greatly reduced. High concentrations of oxygen and low levels of nitrate depressed rates of nitrate reduction but had relatively little effect on cell numbers, especially in winter.

Nitrification and denitrification can occur simultaneously. In lake sediments, denitrification of added

[a] Note: Measurements often use $^{15}NO_3$; other approaches use mass balance techniques, but one can only calculate total lake denitrification by that approach (see text).

[b] Approximate extrapolations from values expressed as rates per weight of sediment and the area sampled by the coring device.

$^{15}NO_3$, was rapid; within 2 h up to 90% of added NO_3—N was reduced, much to $^{15}N_2$ (Chen *et al.*, 1972). Similar results were found in the sediments of several oligotrophic lakes, where denitrification in the sediments was functionally coupled to the supply of nitrate by nitrification (Klingensmith and Alexander, 1983; Dodds, and Jones, 1987). Much of the NO_3—N of lake sediments is incorporated into bacterial organic matter. Keeney *et al.* (1971) found that up to 37% of experimentally added NO_3—N (at the level of 2 mg NO_3—N liter^{-1}) became incorporated into the organic fraction. The remainder was denitrified. Denitrification rates of sediments are 3 to 4 orders of magnitude greater than those of the overlying water (Table 12-6). Denitrification activity within sediments of both lakes and streams is related to the microgradients of reducing conditions (Jones, 1979a,b; Nielsen *et al.*, 1990). In sediments of the littoral zone or those in contact with oxygenated water, denitrifying activity is depressed at the sediment surface and increases at sediment depths (10–15 mm) where reducing conditions increase (electrode potential, E_h, of 210 mV or less; see Chap. 14). Oxygen production by algae attached to the sediments in the light can increase the thickness of the aerobic layer and reduce denitrification in the sediments by as much as 70%. After darkness, oxygen is rapidly consumed by bacterial respiration at rates faster than it diffuses from overlying water, and denitrification again increases as anoxic and reducing conditions return.

D. Dissolved and Particulate Organic Nitrogen

Much of the basic understanding of major nitrogenous fractions and their distribution in lakes has evolved from the classical studies of Wisconsin lakes, especially Lake Mendota (Domogalla *et al.*, 1925; Peterson *et al.*, 1925; Birge and Juday, 1926). Although analytical methodology has improved greatly since these early investigations, their results are still generally valid for many lakes of the temperate region.

The dissolved organic nitrogen (DON) of fresh waters often constitutes over 50% of the total soluble nitrogen. Geographic variation is great, however, in relation to inputs of inorganic nitrogen from natural and artificial sources. Over one-half of the DON is in the form of amino nitrogen compounds, of which about two-thirds is in the form of polypeptides and complex organic compounds and less than one-third occurs as free amino nitrogen (Table 12-7). The qualitative nature of the numerous nitrogen compounds is incom-

pletely known (see reviews of Vallentyne, 1957, and Schnitzer and Khan, 1972). The simple amino acids are substrates that are readily utilized by bacteria; rates of decomposition are high and result in low instantaneous concentrations of free amino acids in fresh waters (Chaps. 17 and 23).

As with organic carbon, the DON of lakes and streams is from 5 to 10 times greater than particulate organic nitrogen (PON) contained in the plankton and seston (Table 12-7) (Peterson *et al.*, 1925; Barica, 1970; Stadelmann, 1971; Manny, 1972a; Manny and Wetzel, 1973, 1974; Serruya *et al.*, 1975; Takahashi and Saijo, 1981; Zehr *et al.*, 1988). The ratios of DON to PON decrease as the lakes become more eutrophic, are closer to 1:1 in the trophogenic zone, and increase in the tropholytic zones. More organic nitrogen is apparently synthesized by small phytoplanktonic algae (<10 μm) per unit cell volume than by larger forms (Manny, 1972b). A significant portion of algal intracellular nitrogen (10–20% in the cyanobacterium *Oscillatoria*) is released extracellularly, mainly as protein and ammonia nitrogen with smaller amounts of nitrite and amino acid nitrogen (Meffert and Zimmerman-Telschow, 1979). Bacterial utilization of these organic compounds, particularly the amino acids, is extremely rapid (Gardner *et al.*, 1987, 1989). Algae and especially cyanobacteria also excrete polypeptides and other organic compounds that are capable of forming complexes with metals, such as iron and copper and with phosphates, and of altering their solubility and physiological availability (Fogg and Westlake, 1955; Murphy *et al.*, 1976; Tuschall and Brezonik, 1980). Similar nitrogenous compounds have been found to be secreted by larger aquatic plants (Wetzel and Manny, 1972); in some situations where the littoral zone is extensively developed, release of DON by macrophytes can form a major source of organic nitrogen to the lake. Furthermore, as aquatic vascular vegetation decomposes, large quantities of organic nitrogen are released (Nichols and Keeney, 1973). Much of this organic nitrogen is absorbed by the sediments and is utilized by attached microbiota, where decomposition can rapidly become limited by inorganic nitrogen, especially under anaerobic conditions (cf. Chap. 23).

Certain microalgae of diverse groups are able to utilize urea as a nitrogen source. Among the phytoplankton of Lake Biwa, Japan, for example, relative assimilation rates were ammonia (average 73.8% of total) > urea (average 20.0%) > nitrate (average 6.2% of total) (Mitamura and Saijo, 1986). The turnover rate for urea varied between 2 and 21 days.

The enzyme urease requires stoichiometric amounts of nickel for catalytic activity. Urease activities and growth of the algae in culture were markedly enhanced by small enrichments of nickel at levels of 0.3–5 μg Ni $liter^{-1}$ (Oliveira and Antia, 1986; Price and Morel, 1991). How applicable these findings are to natural algal populations is unclear.

III. SEASONAL DISTRIBUTION OF NITROGEN

The seasonal changes in nitrogen vary greatly from lake to lake. Several general trends, however, do emerge from the seasonal patterns in oligotrophic and productive lakes. Although many seasonal cycles of inorganic nitrogen have been studied, the cycles of the dissolved and the biota-bound particulate organic nitrogen are often overlooked. The ensuing discussion concerns five lakes: (a) Lawrence Lake, an oligotrophic hardwater lake of southern Michigan that receives high natural inputs of inorganic nitrogen and where N_2 fixation is very low; (b) mesotrophic Vierwaldstattersee (Lake of Lucerne), Switzerland, a lake in which the hypolimnion remains aerobic throughout summer stratification; (c) moderately eutrophic Lake Mendota, Wisconsin; (d) highly eutrophic Wintergreen Lake, southern Michigan, a lake that undergoes normal dimictic circulation; and (e) Rotsee, Switzerland, an extremely eutrophic lake that circulates incompletely in spring and autumn.

The nitrogen inputs to Lawrence Lake, which is located in calcareous glacial till high in nitrates, occur largely as nitrate (Manny and Wetzel, 1982). Concentrations of NO_3—N of two small spring-fed inlet streams varied from 1 to over 20 mg NO_3—N $liter^{-1}$; groundwater inflow directly into the basin contained lower concentrations (mean 3 mg $liter^{-1}$), but contributed about 25% to the annual nitrogen income. Ammonia in the influents was much lower (between 0 to 190 μg NH_4—N $liter^{-1}$), and represented a relatively minor source of nitrogen to this lake. Nitrite concentrations were very small. The total dissolved organic nitrogen (TDON) of the surface and groundwater influents, however, was a significant source and reached levels as high as 1.5 mg $liter^{-1}$. This TDON was strongly correlated with the metabolic activity of the surrounding marsh vegetation through which the streams flow.

Figure 12-6 contrasts the concentrations of NO_3—N + NO_2—N in mg $liter^{-1}$ (*upper*) and NH_4—N in μg $liter^{-1}$ (*lower*) in seasonal depth–time diagrams. NH_4—N levels of the epilimnion and metalimnion were very low during stratification and increased conspicuously only below 11 m, where anoxic conditions existed in late summer and autumn. This increase was accompanied by a simultaneous denitrification of NO_3 in the lower hypolimnion. NO_2—N

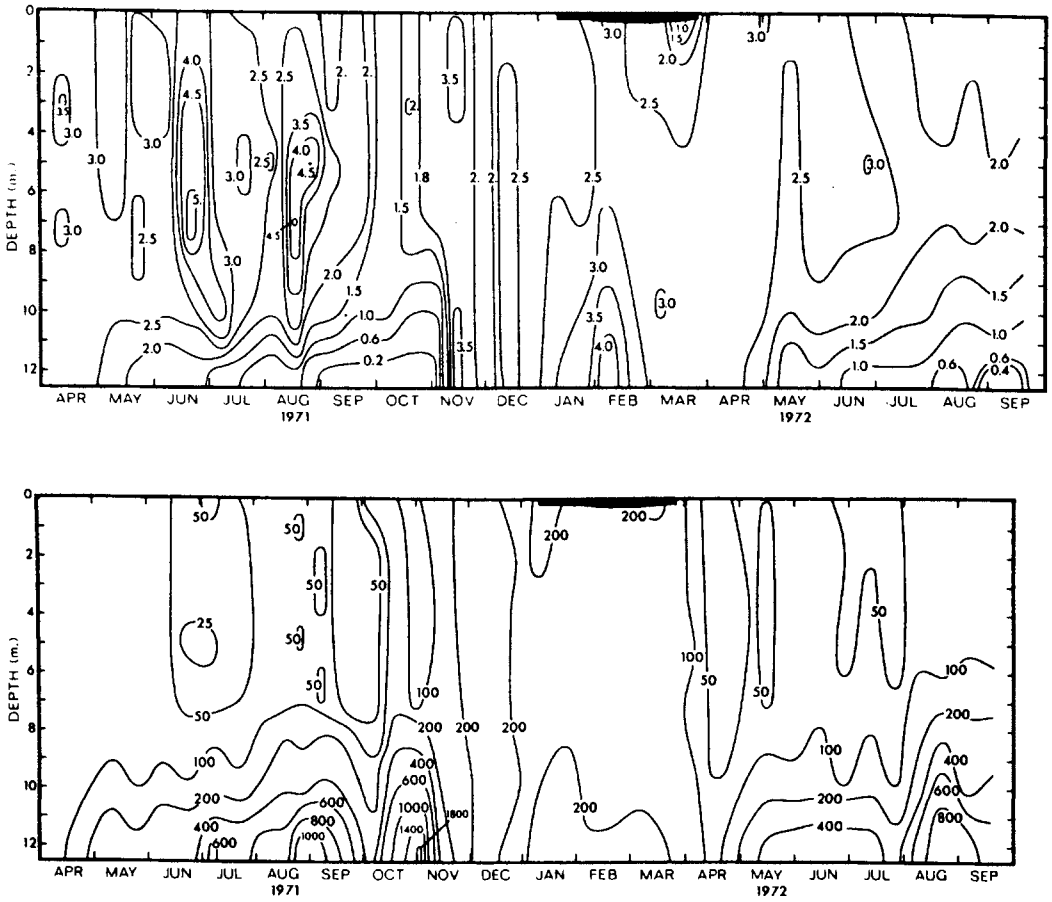

FIGURE 12-6 Depth–time diagrams of seasonal concentrations of NO_3—N + NO_2—N in mg liter^{-1} (*upper*) and NH_4—N in μg liter^{-1} (*lower*), Lawrence Lake, Michigan, 1971–1972. Opaque areas = ice cover to scale. (From Manny and Wetzel, unpublished data.)

concentrations were always very low (< 20 μg liter^{-1}). During turnover in November, and throughout much of the winter period of ice cover, NH_4 concentrations were distributed uniformly with depth at levels over 200 μg liter^{-1}. Nitrification was seen in the greater depths during the winter, and marked decreases in NO_3—N concentrations occurred immediately below the ice, consonant with intensive growth of algal populations. After the spring period of uniform circulation, the pattern was repeated.

The dissolved organic nitrogen (DON) and particulate organic nitrogen (PON) of the open water of Lawrence Lake generally were found to be about equal in concentration (50–1000 μg liter^{-1}). Concentrations of PON closely followed the dynamics of the biomass of the plankton; those of DON were maximal in the summer in the epilimnion and minimal during the winter in the hypolimnion.

The nitrogen budget of a large bay of Vierwaldstattersee was studied in detail by Stadelmann (1971). The nitrate concentrations (Fig. 12-7, *left*) of the epilimnion decreased sharply in the summer because of algal utilization, and this decrease was reflected in the amounts of planktonic particulate organic nitrogen (Fig. 12-7, *right*). NO_2—N concentrations followed a similar seasonal cycle but never exceeded 11 μg NO_2—N liter^{-1}. Ammonia concentrations were always low, usually only in trace quantities; maximum levels (70 μg NH_4—N liter^{-1}) occurred in late summer near the sediments. During this summer period when epilimnetic concentrations of inorganic nitrogen approached zero, cyanobacterial and heterocyst numbers reached their maximum, indicative of a heavy reliance on molecular N_2 fixation. Aerobic hypolimnetic waters of this lake did not undergo significant denitrification.

As lakes become more eutrophic, the processes of assimilation of nitrogen in the trophogenic zone and denitrification in the tropholytic zone intensify. Vertical gradients become extreme. As is exemplified in Wintergreen Lake (Fig. 12-8), nitrate and nitrite are reduced by algal assimilation and denitrification extremely rapidly, from over 1000 μg liter^{-1} to below detectability

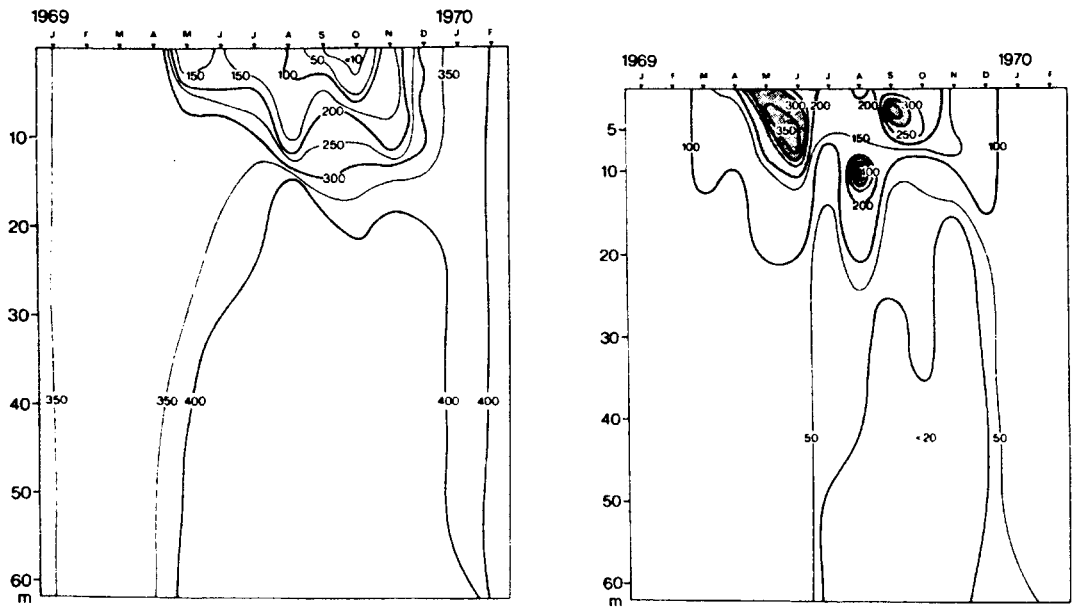

FIGURE 12-7 Depth–time diagrams of the concentrations of nitrate (*left*, in μg NO_3—N liter^{-1}) and particulate organic nitrogen (*right*, in μg N liter^{-1}) in Vierwaldstattersee, Switzerland. (After Stadelmann, P.: *Schweiz. Zeitschrift f. Hydrologie.* 33:1–65, 1971.)

in slightly over a month (Wetzel *et al.*, 1982). Fixation of molecular N_2 was limited to the 0- to 3-m depths in Wintergreen Lake, and very high rates of N_2 fixation by *Anabaena* and *Aphanizomenon* were found only during periods when levels of combined inorganic nitrogen were very low (Duong, 1972; Ward and Wetzel, 1980a). Ammonification and denitrification were particularly intensive in the anaerobic tropholytic zone below a depth of 3 m. As the name of the lake (Wintergreen) implies and as is common in hypereutrophic lakes (Wetzel, 1966a), production continues vigorously beneath the ice and the denitrification process continues, although more slowly, during winter stratification. An analogous situation occurred in the extremely hypereutrophic Rotsee, Switzerland (Stadelmann, 1971). However, in this lake, which is protected from major wind-induced water movements by the surrounding topography, circulation in the spring and autumn was weak and incomplete. The hypolimnion was anaerobic all year long, except for a slight intrusion of oxygen for a week in the spring; this condition was reflected in the high concentrations of ammonia throughout much of the lake most of the year (Fig. 12-9). Hypolimnetic concentrations of nearly 10 mg NH_4—N liter^{-1} are not uncommon near the sediments.

The seasonal distribution of the various forms of nitrogen in eutrophic Lake Mendota (Fig. 12-10) is similar to that commonly found in numerous lakes of temperate regions (Domogalla *et al.*, 1926; Domogalla and Fred, 1926; Barica, 1970). In many cases, autumnal nitrogen minima gradually increase in late fall to maxima in late winter and early summer. Looking at the seasonal processes involved in the surface and hypolimnetic strata over an annual period (Fig. 12-11), the net effects of nitrification and nitrate reduction–assimilation can be seen. In the oxygenated upper waters, nitrate decreases during the spring maximum from increased rates of assimilation by the plankton and nitrate reduction by bacteria. Nitrification decreases rapidly in the tropholytic zone after thermal stratification develops, because the hypolimnion becomes anaerobic. Additional decreases in rates of nitrification in the hypolimnion can occur when nitrifying bacteria suffer losses from grazing of zooplankton (Cavari, 1977). Nitrification ceases and nitrate reduction increases markedly until stratification is disrupted in the fall.

Similar patterns of nitrification and denitrification are found in many diverse lakes. For example, in Lake Titicaca in the high Andes Mountains of Peru–Bolivia, rates of nitrification were highest in the surface mixed layer and lowest in the uppermost portion of the hypolimnion, which is often the stratum of the water column that exhibits very high rates of pelagic decomposition (Vincent *et al.*, 1985). Nitrification activities in the hypolimnion increased somewhat with increasing depth toward the anoxic zone near the sediments, where NH_4^+ concentrations are high as long as some oxygen was present. In many mesotrophic lakes, as stratification decays into autumnal circulation of the water column the accumulated hypolimnetic nitrate-N persists

for some time, often throughout the winter, during periods of lower biotic utilization by the plankton (e.g., Boström, 1981). If the lakes are shallow and not thermally stratified, however, phosphorus can be effectively adsorbed to the sediments and nitrogen denitrified, with a reduction of the nitrogen available for production in the water column (Jansson, 1984).

IV. CARBON-TO-NITROGEN RATIOS

The carbon content of organic matter is on the average at least an order of magnitude greater than that of nitrogen. The complex mixtures of organic compounds in particulate and dissolved phases are decomposed and mineralized to inorganic carbon, primarily as CO_2, and to inorganic nitrogen compounds. The proteolytic metabolism of fungi and bacteria removes proportionately more nitrogen than carbon. The rates of decomposition become slower with the greater chemical recalcitrance of the residual organic compounds, and the selective removal of nitrogen by microbes results in a net increase in the C:N ratios.

If we look at the general distribution of organic carbon and nitrogen in many lakes, as Birge and Juday (1934) did in several hundred Wisconsin lakes, certain trends become apparent (Table 12-8). There are large seasonal and spatial variations in the particulate organic matter in lakes and streams, but most of the organic matter is in the dissolved fraction, and concentrations of dissolved organic matter are very constant (cf. Wetzel *et al.*, 1972). Lakes can be grouped into categories of increasing organic carbon and dissolved organic matter. There is a clear decrease in organic nitrogen with increasing organic carbon content, which results in increasing C:N ratios. This relationship suggests an increase in the refractory nature of the organic compounds in lakes that contain greater amounts of dissolved organic matter. Such is indeed the case when waters containing high concentrations of dissolved organic matter receive increasingly greater proportions of their organic content from organic plant material

TABLE 12-8 Approximate Composition of Organic Matter of Water from Numerous Wisconsin Lakes[a]

produced in wetland and littoral marsh areas surrounding the water (Wetzel, 1979, 1990a). Material of wetland and littoral origin dominates the dissolved organic matter pool of nearly all small lakes, streams, and particularly bogs and bog lakes.

Organic matter of terrestrial and marsh areas undergoes varying degrees of decomposition prior to and during transport to the lake or stream and during which much of the organic nitrogen can be utilized. Therefore, in general (cf. Hutchinson, 1957), allochthonous organic matter contains about 6% crude protein and has a C:N ratio from 45:1 to 50:1. The dissolved organic matter contains a high percentage of humic acid compounds that are low in nitrogen content (Shapiro, 1957; Schnitzer and Khan, 1972), and these compounds impart a stained brown color to the water. In contrast, autochthonous organic matter produced by decomposition of plankton within the lake contains about 24% crude protein and has a C:N ratio of about 12:1.

Alterations in the protein–carbohydrate–lipid ratios change the C:N ratio as a result of either phosphorus or nitrogen limitation (Vollenweider, 1985). The C:N ratio is thus not only indicative of environmental nutrient availability but also yields an approximate indication of the relative proportions of proteins and nonproteins in the organic matter. One cannot assume that all nitrogen is in proteins, but certainly a majority (ca. 85%) is proteinaceous in the plankton.

Nutrient stoichiometry is important in the regulation of both the species composition and the growth rates of phytoplankton communities. A combination of physiological assays and sestonic ratios is useful in proximate assessments of the nutrient status of phytoplankton (Healey and Hendzel, 1980; Kilham, 1990). For example, a C:N ratio of >14.6 often indicates a severe nitrogen deficiency in phytoplankton, between 8.3 and 14.6 a moderate deficiency, and <8.3 no nitrogen deficiency. The subject of C:N ratios is discussed further in concert with phosphorus in the following chapter (Chap. 13).

V. SUMMARY OF THE NITROGEN CYCLE

A diagrammatic representation of the major nitrogen inputs, transformation pathways, and outputs to a general lake system is given in Figure 12-12. Although numerous pathways are presented, it is obviously a

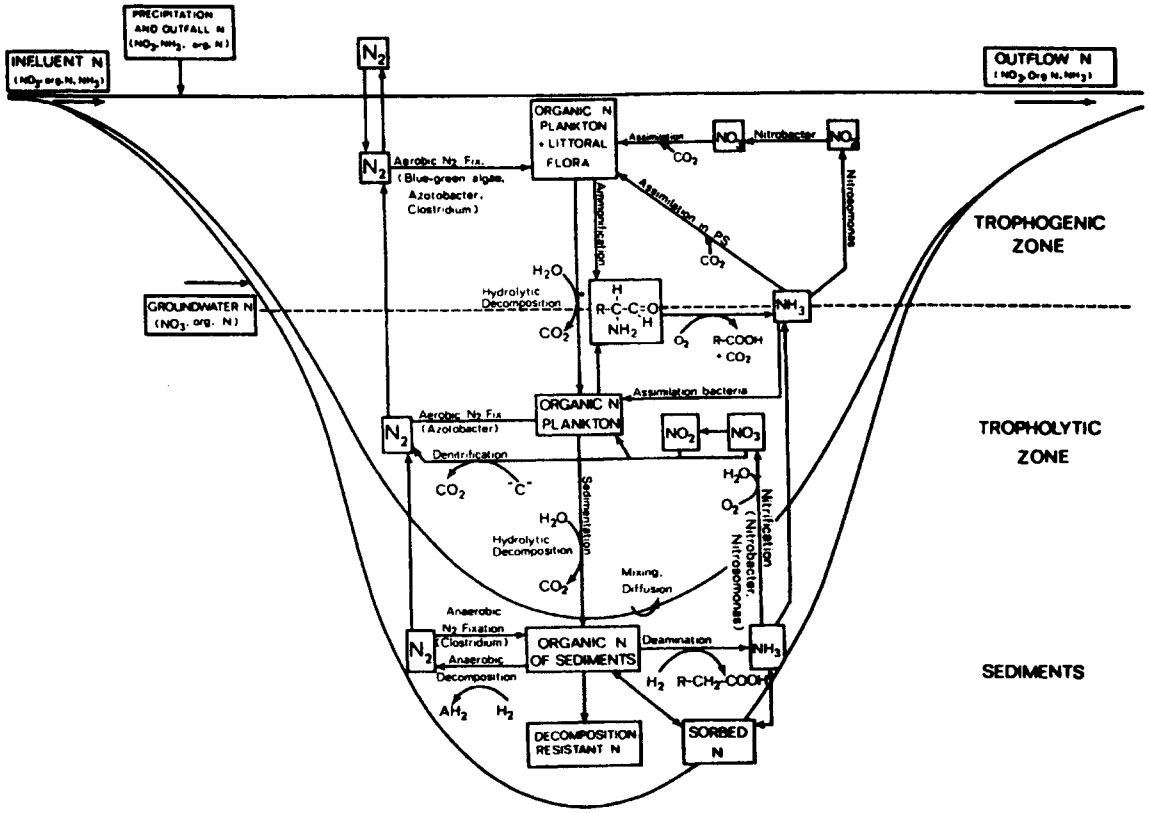

FIGURE 12-12 Generalized nitrogen cycle for fresh waters. PS = photosynthesis. (Greatly modified from Kuznetsov, 1970.)

[a] Modified from estimates of Frink (1967).

simplification of the complex mechanisms and processes. Numerous analogies in the nitrogen cycle exist between lake and river systems.

The components of the cycle have already been discussed; only a few points need to be emphasized. The processes indicated in the tropholytic zone represent a composite situation under aerobic conditions. Clearly, the obligately aerobic decomposition processes would cease in the anaerobic hypolimnia of productive lakes. The metabolism of the littoral flora, including the vascular macrophytes and their epiphytic associations of bacteria and algae, is not only a major or dominant source of organic nitrogen synthesis in many lakes but can influence significantly the flux of nitrogen from the sediments to the water as well.

Many components and processes are variable seasonally and spatially. For example, inputs of nitrogen from guano of migratory waterfowl that briefly reside on a lake in extraordinary densities (one per m^2) can represent a major input of nitrogen and phosphorus to certain lakes (Manny *et al.*, 1975, 1994; cf. also the extremely detailed review of vertebrate excreta by Hutchinson, 1950). Sewage inputs of organic N, NO_3—N, and NH_4—N to rivers and recipient lakes are often highly pulsed. Similarly, agricultural applications of fertilizers to drainage basin areas are seasonal and can alter nitrogen inputs to lakes and rivers. Nitrogen fixation, normally a minor component of the total nitrogen income, can become a significant driving source of nitrogen to the system at certain times of the year.

The nitrogen dynamics of the sediments are poorly understood. Lake sediments typically contain on the order of 50–200 kg of nitrogen per hectare to a 10-cm sediment depth (Table 12-9), much of which is immobilized and sorbed to inorganic particles (Keeney, 1973). The interstitial water in sediments usually has a much higher concentration of soluble nitrogen compounds, mainly as NH_4—N and organic N, than that of the overlying water. Diffusion rates are exceedingly slow, but mixing of surficial sediments occurs to some extent, even when the lake is strongly stratified, as a result of deepwater water movements, activities of benthic organisms, and loss of gas bubbles from the sediments. At periods of turnover, 1–10 cm of the surface sediment can be mixed and much of it resuspended in the water column (e.g., Wetzel *et al.*, 1972; Davis, 1973; Dillon *et al.*, 1990). Surface sediments are usually oxidized for only a few millimeters in depth, but an oxidized microzone is critical to the solubility and sorption properties of the sediments for ammonia and can fundamentally alter rates of microbial transformations. Nitrogen exchange between sediments and water also varies greatly with sediment composition. For example, the release of nitrogen from sediments of the Rybinsk Reservoir was greatest in silts high in organic matter (Table 12-10). In this reservoir, the anaerobic decomposition of sediment organic matter resulted in considerable loss of nitrogen in the form of N_2.

Because of the functional complexity of the many components of the nitrogen cycle, no direct measurements exist for all processes simultaneously in any lake or stream over an annual period. Where detailed experimentation has dissected individual process rates using ^{15}N isotopic techniques, results from certain times of the year emphasize the major importance of the sediments not only as a large reservoir of nitrogen but as the site of much of the nitrogen metabolism.

Lake Wingra in southern Wisconsin is a shallow, eutrophic lake in which submersed macrophytes constitute a major part of the total lake productivity. An overall average nitrogen content of the various compartments in Lake Wingra was estimated for midsummer

conditions (Table 12-11). Much (97%) of the total nitrogen occurred in the sediments as organic nitrogen (column A) but was not readily available for metabolism in the lake system (Isirimah *et al.*, 1976). Neglecting these relatively unreactive nitrogen reservoirs, about 50% of the "available" nitrogen existed in the water column, mostly in dissolved form, 20% in the macrophytes, and 30% in the interstitial water of surficial sediments (column B). Rapid turnover rates of NH_4—N occurred in the water but not in the sediments. NO_3—N turnover was slower in the water than in the sediments, where about 80% of the NO_3—N was rapidly denitrified to N_2.

VI. NITROGEN BUDGETS

Detailed evaluations of the nitrogen cycle that include close-interval quantitative measurements of inputs, metabolic dynamics, and outputs are available for only a few freshwater ecosystems. The cycle is obviously complex and requires accurate analyses of the dynamics of all components for several years. Only a few approximate mass balance analyses of the nitrogen budgets of lakes and streams are available. In these analyses, the rates of bacterial metabolism are obtained indirectly, by assumptions of microbial processing or sedimentation by differences. Nonetheless, the approximate calculated budgets are instructive in characterizing the inputs, outputs, and retention of nutrients by ecosystems.

The nitrogen budget of Lake Mendota, Wisconsin, demonstrates the roughly equivalent contributions from runoff, ground water, and precipitation (Table 12-12). Major losses of nitrogen occur via sedimentation, denitrification, and outflow. Loss by seepage out of the basin was probably small, since most lake basins are well sealed (cf. Wetzel and Otsuki, 1974). In Table 12-13, the nitrogen budget for a large reservoir of complex morphometry accounts for inflows from all river influents and losses by sedimentation and outflow. Although the total nitrogen content of this reservoir decreased in 1962 because of low water levels, inputs of atmospherically derived nitrogen amounted to roughly 10,000 tons per year. About 1300 metric tons entered with rain and snow; the remainder may be attributed largely to biological fixation. Mirror Lake, a kettle lake located in a crystalline granitic bedrock region of the White Mountains of central New Hampshire, receives appreciable (half) nitrogen loading from atmospheric sources (Table 12-14). Primary outputs are via permanent sedimentation and river outflow in approximately equal quantities of inorganic and organic forms. Some 54% of the annual gross sedimentation of organic

nitrogen was mineralized in a large, oligotrophic lake in Sweden (Jonsson and Jansson, 1997). About two-thirds of the nitrogen mineralized in the sediments, released to the overlying water, and transported out of the lake as nitrate via the outlet during turnovers in spring and autumn. Only ca. 4% of organic nitrogen remained in the sediments; the remainder was lost via denitrification at about 1 mg N m^{-2} yr^{-1}.

Analyses of nitrogen budgets of some 40 lakes of very different states of productivity indicated that the removal of nitrogen is usually dominated by denitrification, which is directly correlated to organic matter loadings (Hellström, 1996). Where nitrogen fixation is significant, the increase in total nitrogen from N_2 fixation is generally proportional to the concentration of total phosphorus minus a fraction of the estimated nitrogen concentration without any N_2 fixation. General nitrogen budgets of this type leave much to be desired because they provide relatively little insight into the dynamics of internal processing or metabolic controls mechanisms. From an applied viewpoint, however, such mass balance information is useful in relation to nitrogen loading and the effects of this loading on alterations of productivity, as will be discussed in some detail with phosphorus (cf. Chap. 13).

Annual elemental mass balance budgets have also been used to characterize the inputs, outputs, and retention (i.e., the difference between nitrogen inputs and outputs) of stream ecosystems. Hydrological variations can be great in streams and they influence the fluxes. Even among more hydrologically stable streams, interannual variations in discharge can be large (Meyer and Likens, 1979; Meyer *et al.*, 1981; Grimm, 1987). In arid regions, flooding events can cause extreme variations in annual budgets.

Examination of representative nitrogen budgets of streams indicates that total nitrogen storage was similar even though the distributions among storage

components differed (Table 12-15). Nitrogen storage was largely associated with woody debris (59–80%) in forested streams, whereas in an open desert stream as much as 93% was in algae and autochthonous detritus. Some nutrients are stored in consumer animals, although turnover rates in these organisms are relatively slow. Dissolved organic nitrogen exports are less than inputs and indicated biological utilization associated with mineralization and potentially some sorption and flocculation processes (Triska *et al.*, 1984). Most particulate organic inputs increased in nitrogen concentrations prior to export (Table 12-16).

It has been predicted that ecosystem nitrogen retention would increase as rates of net ecosystem production and biomass accumulation increase and then decline or increase at a slower rate as biomass approaches a steady state (Vitousek and Reiners, 1975; Grimm and Fisher, 1986). At steady state, nutrient inputs would equal outputs, even though the state and forms of the nutrients may change. This relationship has been generally verified in studies that evaluated the patterns of nitrogen retention during successional recovery of algal and macroinvertebrate communities after they were disturbed by flash-flooding events and reduced to virtual zero levels (Grimm, 1987). Biomass and stored nitrogen increased during the early to middle successional stages of recolonization and development and were followed by declines in late stages.

A. Nitrogen Loading: Effects of Human Activities

Enrichment of fresh waters with nutrients needed for plant growth occurs commonly as a result of losses from agricultural fertilization, loading from sewage and industrial wastes, and enrichment via atmospheric pollutants (especially nitrate and ammonia). Sufficient information exists about the general responses of many lakes to loading of major nutrients, especially phosphorus and nitrogen, to predict the potential changes in their productivity. The phytoplankton productivity of infertile, oligotrophic lakes is often limited by the availability of phosphorus. As phosphorus loading to fresh waters increases and lakes become more productive, nitrogen often becomes the nutrient limiting to plant growth. Excessive loading of these nutrients permits increased plant growth until other nutrients or light availability become limiting.

The nitrogen loading concepts in relation to increased lake productivity are best discussed simultaneously with phosphorus loading and limitations. Both will be treated in the following chapter.

VII. NITROGEN DYNAMICS IN STREAMS AND RIVERS

A. General Nutrient Dynamics in Flowing Waters

Nutrients move unidirectionally within running waters. Dissolved substances move downstream, may be bound or assimilated for a period of time, and later be released for further movement downgradient. As materials and chemical mass cycle among biota and abiotic components of the stream ecosystem, they are transported downstream, in processes that resemble spirals and have been termed ***nutrient spiraling*** (Webster and Patten, 1979; Newbold *et al.*, 1981; Stream Solute Workshop, 1990). Although upstream movements of nutrients can occur in backflows from eddies, fish migration, and flight of adult aquatic insects, net fluxes are downstream.

Hydrological processes physically move water containing dissolved and particulate components to reactive sites. Exchanges at reactive sites include chemical ionic transformations, sorption and desorption, and metabolically mediated uptake and assimilation by biota (Fig. 12-13). Materials can be transferred from the water column to the stationary streambed. Some of these materials will be retained, utilized by incorporation into living organisms, potentially transferred to other organisms, and subsequently released by excretions or decomposition to the water column and further transported downstream.

Dissolved substances in running waters may be utilized extensively by biota or be reactive abiotically and

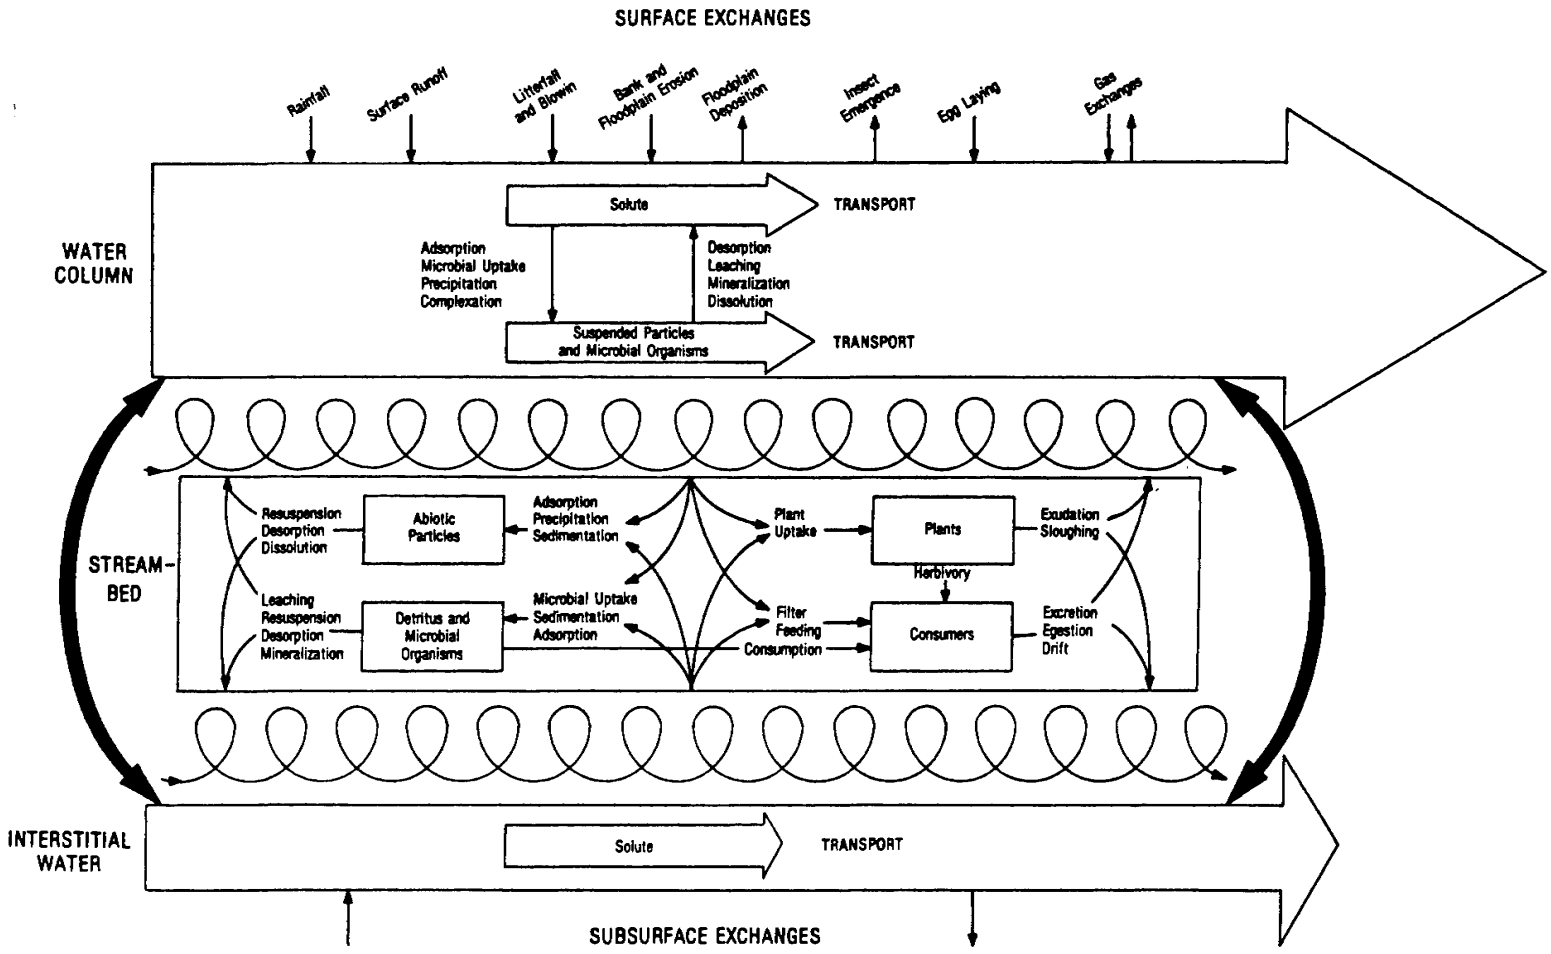

FIGURE 12-13 Solute processes in streams. The two spirals represent the continuous exchange of solutes and particle-bound chemical substances between the water column and the streambed and between the streambed and interstitial water. Materials in the water column and interstitial water are moving downstream, while the streambed materials are stationary. (From Stream Solute Workshop, 1990.)

are termed ***nonconservative.*** Other dissolved substances, termed ***conservative,*** are not generally modified chemically under normal limnological conditions or occur in such abundance that concentrations are not modified substantially by biological removal. Chloride ion is an essential nutrient that is nearly always conservative and is often used as a hydrological tracer. It should be noted, however, that differentiation between conservative and reactive solutes is relative; a solute may be conservative at one time or site and may become reactive at another place or time (Bencala and McKnight, 1987).

A nutrient atom may be used repeatedly as it passes downstream. The rate of utilization and release depends upon physical and biological retentiveness, largely by the microbiota associated with the streambed, that is, the extent to which the downstream transport of the nutrient is retarded relative to that of the water (Newbold, 1992). The objective is to quantify the average downstream distance (S, in meters) for the average nutrient atom to complete a cycle that takes an average time while it moves downstream at an average velocity. The average downstream velocity of the nutrient may be near that of the water in large rivers but is very much slower in streams and rivers where nutrients reside in the sediments and microbiota for a high proportion of the time.

Spiralling length (S) is the average distance a nutrient atom travels downstream during one cycle through the water and biotic compartment. The S equals the sum of distance traveled until uptake ("uptake length," S_W) and the downstream distance traveled within the biota until regeneration ("turnover length," S_B) (Fig. 12-14). The S can be calculated from the downstream nutrient fluxes (mass per unit width of river per unit time in the water (W) component, F_W, and in the biota (B) component, F_B) and the exchange fluxes of biotic utilization (U) of nutrients from the water compartment or regeneration (R) from the biota in mass per unit area per unit time (Fig. 12-14). Details of the methodology, particularly to evaluate the uptake flux rates and release rates by the biotic compartments by use of isotopes of nutrients, are delineated in Newbold *et al.* (1981, 1983).

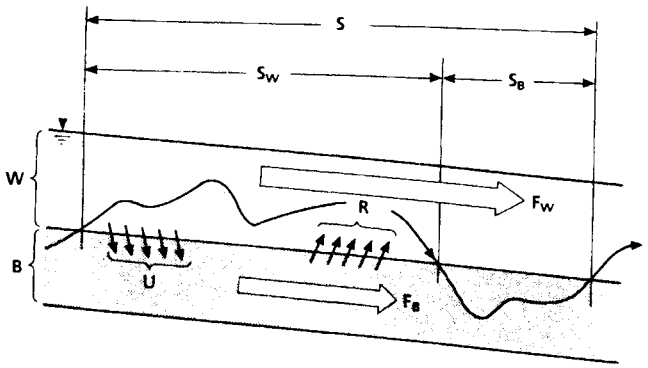

FIGURE 12-14 Spiralling in a river ecosystem of two compartments: water (W) and biota (B). The spiralling length (S) is the average distance a nutrient atom travels downstream during one cycle through the water and biotic compartments. S = the sum of the uptake length (S_W) and the turnover length (S_B) estimated from the downstream nutrient fluxes (F_W and F_B) and the exchange fluxes of uptake (U) and retention (R). (From Newbold, 1992. The Rivers Handbook, vol. 1, Blackwell Science Ltd. Reproduced with permission.)

B. Nutrient Limitations and Retention

Nutrient limitations of primary producers and heterotrophic microbiota in streams and small rivers appear to be uncommon (cf. review of Newbold, 1992). Although cases of phosphorus limitations of both attached algal growth and production and of heterotrophic microbial activities have been determined in a number of streams and rivers, concentrations of soluble reactive phosphorus were consistently < 15 μg liter^{-1} and often < 5 μg liter^{-1}. Similarly, increased microbial growth is found with inorganic nitrogen enrichments where natural concentrations were $< 50-60$ μg liter^{-1}, but rarely above this level. Evidence suggests that in lower-order streams with a greater dominance of biota attached to substrata, retention of nutrients is very high and that these nutrients are intensively recycled within the attached communities (cf. Paul and Duthie, 1989; Wetzel, 1993; Burns, 1998; Chap. 19). Removal of the attached microbial community, as was the case in a desert stream following a flood that eliminated most of the biota, reduced the retention of nitrogen to very low levels, slowed recycling rates, and increased spiralling length (Grimm, 1987). Nitrogen retention increased rapidly as the attached algal and bacterial community reestablished. As rivers become larger, nutrient retention is less and nutrient limitations can become more prevalent. Nutrient loadings to larger rivers, however, are often high because of human activities in the drainage basins. Coupled with high nonalgal particulate turbidity and light reductions, nutrient availability is usually adequate to support microbial productivity within other environmental constraints.

The spiralling length of a nutrient suggests the extent of availability and utilization rates. A shorter spiralling length of one nutrient versus another could imply that the nutrient cycling more rapidly is in greater demand and is possibly limiting the potential growth and productivity of the community. For example, the shorter spiralling uptake length of nitrate nitrogen than that of phosphorus in a small stream of southern Spain was used as evidence of nitrogen limitation under different hydrological regimes (Maltchik *et al.*,

1994). Perhaps a more functional application is to determine the spiralling rates of nutrients among different dissolved, particulate, and animal consumer groups (e.g., Newbold *et al.*, 1983b). Such analyses demonstrate the rapid recycling rates and very short spiralling lengths of the attached microbiota in comparison to abiotic particulate materials and consumer metazoans.

C. Nitrogen Cycling in Running Waters

The inputs, transformations, and cycling of nitrogen in running waters are influenced, as in standing waters, to a large extent by bacterial, fungal, and other microbial metabolism. The transformation processes include both assimilation of nitrogen sources for utilization in synthesis of organic matter and growth, as well as utilization of inorganic and organic nitrogen compounds for energy in oxidation–reduction reactions. These processes have been discussed in detail in this chapter and are largely applicable to running water ecosystems as well as to lakes. Because many of these processes require anaerobic conditions, which are found less frequently in rivers, the subsequent discussion evaluates some of the quantitative differences in flowing waters on these processes. An important initial point of emphasis is that the assumptions that moving waters are fully oxygenated is not always true at even the macrolevel of bulk water volumes in streams and rivers and is often not the case in microenvironments within communities attached to surfaces and in interstitial waters of stream sediments.

D. Dissolved and Particulate Nitrogen in Rivers

The quantities of dissolved inorganic (NO_3^-, NO_2^-, and NH_4^+) and organic nitrogen compounds are highly diverse and variable because of marked differences in the inputs from surface and groundwater sources, particularly as affected by human activities (e.g., Spalding and Exner, 1993), and because of many competing reactions occurring in the nitrogen cycle. Ammonia concentrations tend to be low (7–60 μg N liter^{-1}) in natural river waters, as is the condition in aerobic waters of reservoirs and lakes (Meybeck, 1982, 1993b). Ammonia nitrogen can constitute an appreciable portion (15 to >80%) of the total dissolved inorganic nitrogen (DIN), particularly at low and, among polluted rivers, at very high DIN concentrations. As in lakes, nitrite nitrogen concentrations are very low (<3 μg N liter^{-1}; < 1.5% of total dissolved inorganic nitrogen, DIN) among well-oxygenated, unpolluted waters.

Among major rivers, nitrate concentrations range from < 25 μg N liter^{-1} in subarctic environments and in Amazonia to ca. 200 μg N liter^{-1} in some temperate rivers (Meybeck, 1982, 1993b). Higher nitrate nitrogen concentrations are found among rivers influenced by agricultural runoff. An average NO_3—N concentration of nearly 100 μg N liter^{-1} is found in natural river waters (Table 12-17). Maximum nitrate concentrations during storm flows were directly related to the magnitude of the storms and resulting high discharge and inversely related to the frequency of storm events (Tate, 1990; Triska *et al.*, 1990a). The activity of terrestrial vegetation of the riparian zones influences the loadings of nitrate and ammonia to the streams; nitrogen concentrations are generally higher during periods of vegetation dormancy or following losses from harvesting or fire (e.g., Likens, 1985; Spencer and Hauer, 1991; McClain *et al.*, 1994). The extensive transformation reactions focused at the upland and stream margins of the riparian zone regulate and diminish transfers of inorganic nitrogen from ground water to stream water.

TABLE 12-17 Distribution of Nitrogen Species (mg liter^{-1}) in Unpolluted Rivers[a]

	Mean (min, max)
Values	
NH_4—N	0.018 (0.005–0.04)
NO_2—N	0.0012
NO_3—N	0.101 (0.05–0.2)
Dissolved organic N (DON)	0.260 (0.05–1.0)
Ratios	
DOC:DON	20 (8–41)
POC:PON	8.5 (7–10)

[a] From many sources but particularly Malcolm and Durham (1976) and Meybeck (1982, 1993b).

Dissolved organic nitrogen (DON) concentrations, although measured less frequently in natural river waters, nearly always constitutes a major part (world average ca. 40%) of the total dissolved nitrogen (Wetzel and Manny, 1977; Meybeck, 1982). In subarctic and humic tropical rivers, DON can constitute over 90% of the dissolved nitrogen. Although dissolved inorganic nitrogen concentrations and discharge can vary widely on a diurnal basis and seasonally, dissolved organic carbon and nitrogen are relatively constant (Manny and Wetzel, 1973). The ratio of dissolved organic carbon to dissolved organic nitrogen is, however, variable (8–41) and averages ca. 20 (Table 12-17).

Particulate nitrogen consists of particulate organic nitrogen (PON), adsorbed ammonia, and organic nitrogen adsorbed to particles (Table 12-17). On a weight ratio basis, the particulate organic carbon to

particulate organic nitrogen ratio is relatively constant at 8–10 (mean ca. 8.5).

E. Nitrogen Cycling in Sediments of Flowing Waters

Ammonium sorption to channel and riparian sediments can be extensive. For example, in granular sediments (0.5–2.0-mm grain size) of a third-order stream in California, exchangeable ammonium ranged from 10 μeq 100 g^{-1} of sediment where nitrification and subsurface exchange with stream water were high to 115 μeq 100 g^{-1} in the floodplain riparian sediments where channel water and groundwater mixing and nitrification potential were both low (Triska *et al.*, 1994). Sorbed ammonium was highest during summer/autumn base flow and lowest during winter storm flows. Similar results were found, with somewhat different seasonality, in a small temperate forest stream (Mulholland, 1992) and in the hyporheic zone of desert streams (Holmes *et al.*, 1994; Jones *et al.*, 1995). The riparian zone, when water-saturated, and parafluvial[2] and hyporheic zones are major sources of ammonium and dissolved organic nitrogen to the stream. Once within the stream, nitrogen uptake by attached microbes (bacteria, fungi, and algae) was the primary mechanism controlling spatial and seasonal variations in the water. Diurnal daytime reductions in stream nitrate concentrations at base flow suggest that uptake by photoautotrophs can be an important retentive process (Burns, 1998), although the coupling of photosynthetic oxygen production within the sediment microbial communities to diurnal changes in denitrification are not clear in these environments.

The physical sorption of ammonia to sediment particles is dynamically coupled to sources from ground water and ammonification and transformations of dissolved inorganic nitrogen by nitrification, denitrification, and nitrate reduction (Fig. 12-15). Experimental studies of ammonium uptake by stream sediments indicated that biotic uptake by attached microflora was quantitatively much greater than physical adsorption (Newbold *et al.*, 1983b; Richey *et al.*, 1985; Aumen *et al.*, 1995). The duration of the storage of ammonium by sorptive processes is variable. Some studies indicate that appreciable retention can occur in summer months and contribute from 12–25% of nitrate released subsequently in winter by nitrification (e.g., Richey *et al.*, 1985), but in larger eutrophic river systems much of the ammonium is rapidly nitrified and exported downstream as nitrate (Lipschultz *et al.*, 1986).

The effectiveness of the denitrification and nitrification processes in the hyporheic zone of stream sedi-

[2] ***Parafluvial zone*** refers to the part of the active stream channel without surface water that is connected hydrologically with the surface stream water.

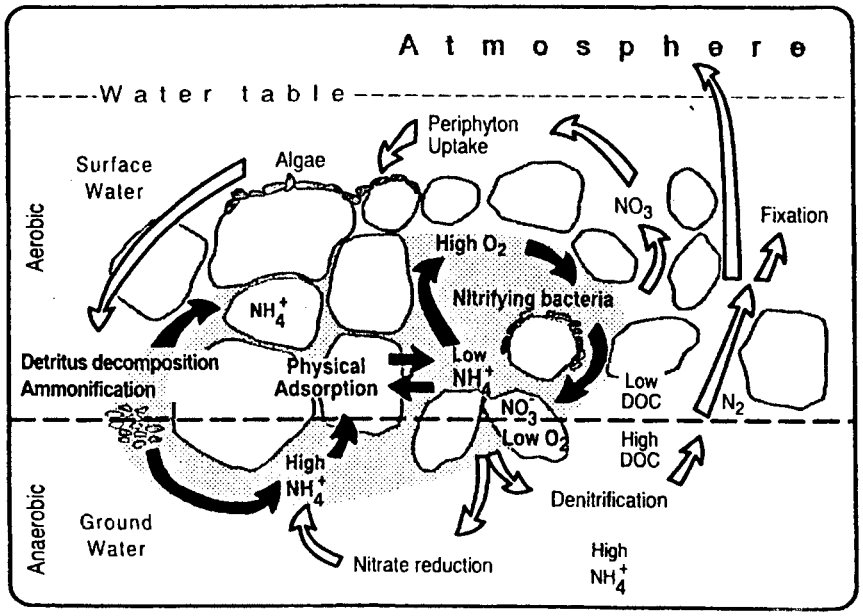

FIGURE 12-15 Linkages among physical sorption of ammonia to sediment particles, sources from ground water and ammonification, and transformations of dissolved inorganic nitrogen by nitrification, denitrification, and nitrate reduction at the groundwater–surface interface of a stream channel. (From Triska *et al.*, 1994.)

ments depends greatly upon the redox conditions within the interstitial water (Fig. 12-15). Flow conditions within the sediment interstices are quite variable spatially because of localized differences in sediment composition and textures. Internal flows also change over time between precipitation events, which lead to variations in both rates of groundwater inflow as well as rates of in-channel flows that penetrate down into the sediments (e.g., Triska *et al.*, 1990b). In organic-rich sediments, the redox profiles can be quite similar to those in lake sediments, in which the zone of nitrification can be restricted to the upper 2–3 mm and intensive denitrification occurs below the stratum of nitrifier activity (e.g., Cooke and White, 1987a,b; Birmingham *et al.*, 1994). Denitrification also occurs in shallow riparian sediments connected to the stream by the hyporheic zone (Duff and Triska, 1990). Denitrification increases with greater distance (10–15 m) from the stream channel were correlated with decreasing oxygen concentrations and increasing concentrations of reduced compounds.

Photosynthetic oxygen production by attached algae can diffuse for several millimeters into the sediments and reduce the rates of denitrification (Christensen *et al.*, 1990). Under shaded conditions or darkness, rates of denitrification increase rapidly as bacterial respiration depletes oxygen in the microzones. Clearly, the processes of nitrification and denitrification can be functioning simultaneously and reciprocally in the sediments, particularly where many microzones of steep redox gradients occur.

VIII. SUMMARY

1. Nitrogen, along with carbon, hydrogen, and phosphorus, is one of the major constituents of the cellular protoplasm of organisms. Nitrogen is a major nutrient that affects the productivity of fresh waters.
2. A major source of nitrogen of the biosphere originates from fixation of atmospheric molecular nitrogen (N_2). The nitrogen cycle is a complex biochemical process in which nitrogen in various forms is altered by nitrogen fixation, assimilation, and reduction of nitrate to N_2 by denitrification. For all practical purposes, the nitrogen cycle of lakes is microbial in nature: Bacterial oxidation and reduction of nitrogen compounds are coupled with photosynthetic assimilation and utilization by algae, photosynthetic bacteria, and larger aquatic plants. The direct role of animals in the nitrogen cycle is certainly very small; under certain conditions, however, their grazing activities can influence microbial populations and nitrogen transformation rates as well as nitrogen utilization rates by photosynthetic organisms. Although the nitrogen cycle of fresh waters is understood qualitatively in appreciable detail, the complex dynamics of quantitative transformation rates have not been clearly delineated, especially at the sediment–water interface, where intensive bacterial metabolism occurs.
3. Dominant forms of nitrogen in fresh waters include (a) dissolved molecular N_2, (b) ammonia nitrogen (NH_4^+), (c) nitrite (NO_2^-), (d) nitrate (NO_3^-), and (e) a large number of organic compounds (e.g., amino acids, amines, nucleotides, proteins, and refractory humic compounds of low nitrogen content).
4. The nitrogen cycle consists of a balance between nitrogen inputs to and nitrogen losses from an aquatic ecosystem.
   a. Sources of nitrogen include (i) nitrogen contained in particulate "dry fallout" and precipitation falling directly on the lake surface, (ii) nitrogen fixation both in the water and the sediments, and (iii) inputs of nitrogen from surface and groundwater drainage.
   b. Losses of nitrogen occur by (i) outflow from the basin, (ii) reduction of NO_3^- to N_2 by bacterial denitrification with loss of N_2 to the atmosphere, and (iii) sedimentation of inorganic and organic nitrogen-containing compounds to the sediments.
5. Microbial fixation of molecular N_2 in soils by bacteria is a major source of nitrogen. In lakes and streams, N_2 fixation by heterotrophic bacteria and certain cyanobacteria is quantitatively less significant, except under certain conditions of severe depletion of combined inorganic nitrogen compounds.
   a. The N_2 content of water is usually in equilibrium with the N_2 of the atmosphere during periods of turbulent mixing. In stratified, productive lakes, concentrations of N_2 may decline in the epilimnion because of reduced solubility as temperatures rise and increase in the hypolimnion from denitrification of NO_3—N.
   b. N_2 fixation by cyanobacteria is usually much greater than fixation by heterotrophic bacteria. In cyanobacteria, N_2 fixation is light-dependent and usually coincides with the spatial and temporal distribution of these microbes. NH_4—N assimilation requires less energy expenditure than NO_3—N, and NO_3—N less than N_2—N. N_2 fixation by cyanobacteria increases when NH_4—N and NO_3—N concentrations decrease in the trophogenic zone.

c. Bacterial N_2 fixation in wetlands surrounding lakes or adjacent to streams can add significant amounts of combined nitrogen to freshwater ecosystems.

6. Ammonia is generated by heterotrophic bacteria as the primary nitrogenous end product of decomposition of proteins and other nitrogenous organic compounds. Ammonia is present primarily as NH_4^+ ions and is readily assimilated by plants in the trophogenic zone.
   a. NH_4—N concentrations are usually low in aerobic waters because of utilization by plants in the photic zone. Additionally, bacterial nitrification occurs, in which NH_4^+ is oxidized through several intermediate compounds to NO_2^- and NO_3^-.
   b. When the hypolimnion of a eutrophic lake becomes anaerobic, bacterial nitrification of ammonia ceases. The oxidized microzone at the sediment–water interface is also lost, which reduces the adsorptive capacity of the sediments for NH_4—N. A marked increase in the release of NH_4^+ from the sediments then occurs. As a result, the NH_4—N concentrations of the hypolimnion increase (Fig. 12-4).
   c. Bacterial nitrification proceeds in two stages: (i) the oxidation of $NH_4^+ \rightarrow NO_2^-$, largely by *Nitrosomonas* but also by other bacteria, including methane oxidizers; and (ii) the oxidation $NO_2^- \rightarrow NO_3^-$, in which *Nitrobacter* is the dominant bacterial genus involved.
   d. Nitrite (NO_2^-) is readily oxidized and rarely accumulates except in the metalimnion, upper hypolimnion, or interstitial water of sediments of eutrophic lakes. Concentrations are usually very low (< 100 μg liter^{-1}) unless organic pollution is high.
7. Nitrate is assimilated and aminated into organic nitrogenous compounds within organisms. This organic nitrogen is bound and cycled in photosynthetic and microbial organisms. During the normal metabolism of these organisms, and at death, much of their nitrogen is liberated as ammonia. Additionally, organisms release a variety of organic nitrogenous compounds that are resistant to proteolytic deamination and ammonification by heterotrophic bacteria to varying degrees.
   a. Nitrate (NO_3^-) is the common form of inorganic nitrogen entering fresh waters from the drainage basin in surface waters, ground water, and precipitation. In certain oligotrophic waters in basaltic rock formations, nitrate loading from atmospheric sources, especially if contaminated by human-produced combustion emission products, can dominate nitrogen loading.
   b. Bacterial denitrification is the biochemical reduction of oxidized nitrogen anions (NO_3^- and NO_2^-) concomitant with the oxidation of organic matter: $NO_3^- \rightarrow NO_2^- \rightarrow N_2O \rightarrow N_2$. Nitrous oxide ($N_2O$) is rapidly reduced to N_2 and has rarely been found in lakes in appreciable quantities. Denitrification is accomplished by many genera of facultative anaerobic bacteria, which utilize nitrate as an exogenous terminal hydrogen acceptor in the oxidation of organic substrates. Denitrification occurs in anaerobic environments, such as in the hypolimnia of eutrophic lakes (Fig. 12-4) or in anoxic sediments, where oxidizable substrates are relatively abundant.
8. Dissolved organic nitrogen (DON) often constitutes over 50% of the total soluble nitrogen in fresh waters.
   a. Over half of the DON occurs as amino nitrogen compounds, mostly as polypeptides and complex nitrogen compounds.
   b. The ratios of DON to particulate organic nitrogen (PON) of streams and lakes are usually from 5:1 to 10:1. As lakes become more eutrophic, DON:PON ratios decrease.
9. The distribution of nitrogen in a lake can change rapidly. Examples of the depth–time distributions of the different forms of nitrogen demonstrate that as lakes become more productive from nutrient loading, concentrations of NO_3—N and NH_4—N in the trophogenic zone can be severely reduced and depleted by photosynthetic assimilation. Cyanobacteria with the capability of nitrogen fixation may then come to dominate. In anaerobic hypolimnia, NO_3—N is rapidly denitrified to N_2, which is either fixed or lost to the atmosphere. NH_4—N concentrations accumulate from decomposition of organic matter and release of NH_4—N from sediments under anaerobic conditions.
10. Organic carbon-to-nitrogen ratios (C:N) indicate an approximate state of resistance of complex mixtures of organic compounds to decomposition, because proteolytic metabolism by fungi and bacteria removes proportionally more nitrogen than carbon. Higher C:N ratios commonly occur in residual organic compounds, which are more resistant to decomposition.
    a. Organic materials from allochthonous and wetland sources commonly have C:N ratios from 45:1 to 50:1 and contain many humic compounds of low nitrogen content.
    b. Autochthonous organic matter produced by the decomposition of plankton tends to have higher

protein content and C:N ratios of about 12:1.

c. Alterations in in the protein-carbohydrate-lipid ratios alter the particulate C:N ratio as a result of phosphorus or nitrogen limitation. A C:N ratio of >14.6 often indicates a severe nitrogen deficiency in phytoplankton, between 8.3 and 14.6, a moderate deficiency, and < 8.3, no nitrogen deficiency.

11. Much of the total nitrogen occurs in the sediments in forms that are relatively unavailable for biotic utilization. Of the readily available nitrogen, a majority occurs in soluble form in the water and in the interstitial water of surficial sediments (and in littoral vegetation in shallow, productive lakes). Turnover rates of NH_4-N are rapid in water but slower in the sediments. In contrast, NO_3—N turnover is slower in the water than in sediments, where, under anoxic conditions in eutrophic lakes, NO_3—N is rapidly denitrified to N_2.
12. Increased loading of inorganic nitrogen to rivers and lakes frequently results from agricultural activities, sewage, and anthropogenic atmospheric pollution. In unproductive oligotrophic lakes, phosphorus availability is often the principal limiting nutrient for plant growth. As phosphorus loading to fresh waters increases and they become more productive, nitrogen becomes more important as a growth-limiting nutrient.
13. In running waters, nitrogen is used repeatedly as it passes downstream. The rate of utilization and release depends upon physical and biological retentiveness, largely by the microbiota attached to the streambed. The average distance a nutrient atom travels downstream during one cycle through the water, biotic, and substrata compartments is referred to as the ***spiralling length*** (Figs. 12-13 and 12-14).
14. Nutrient limitations for biotic productivity are uncommon in small rivers and streams, where nutrients are efficiently retained and recycled. As rivers become larger, nutrient retention is less and nutrient limitations can become more prevalent.
15. The processes of nitrogen cycling in the water of streams and rivers are similar to those of lakes and are influenced to a large extent by bacterial, fungal, and other microbial metabolism. Attached bacteria, fungi, and algae are the primary organisms controlling the seasonal spatial and temporal variations within the water. The processes of nitrification and denitrification often function simultaneously and reciprocally in running water sediments, where many microzones of steep redox gradients occur in the hyporheic zone of the streambed.

IX. Summary

I. PHOSPHORUS IN FRESH WATERS

No other element in fresh waters has been studied as intensively as phosphorus. A great body of quantitative data exists on the seasonal distribution of phosphorus in lakes and loading rates of phosphorus from the surrounding drainage basins. Ecological interest in phosphorus stems from its major role in biological metabolism and the relatively small amounts of phosphorus available in the hydrosphere. In comparison to the rich natural supply of other major nutritional and structural components of the biota (carbon, hydrogen,

nitrogen, oxygen and sulfur), phosphorus is least abundant and most commonly limits biological productivity.

II. THE DISTRIBUTION OF ORGANIC AND INORGANIC PHOSPHORUS IN LAKES AND STREAMS

In contrast to the numerous forms of nitrogen in lake systems, the most significant form of inorganic phosphorus is orthophosphate (PO_4^{3-}). A very large proportion, greater than 90%, of the phosphorus in fresh water occurs as organic phosphates and cellular constituents in the biota and adsorbed to inorganic and dead particulate organic materials. It is instructive to discuss first the general aspects of the forms and distribution of phosphorus that occur in fresh waters before analyzing the dynamics of exchange between the compartments.

Phosphine (PH_3) is a volatile constituent of the global biogeochemical phosphorus cycle. Generation of phosphine occurs by anaerobic enzymatic reduction of phosphate and has been found in anoxic sediments of fresh waters, wetlands of flood plains and rice fields, and in sewage treatment facilities (Dévai *et al.*, 1988; Gassmann and Schorn, 1993; Gassmann, 1994; Glindemann *et al.*, 1996). In very shallow areas of organic-rich sediments or saturated hydrosoils, phosphine can evade directly to the atmosphere. It has been estimated that very large amounts of phosphorus can be released to the atmosphere from open sewage treatment facilities. Phosphine is reactive under oxic conditions and has not been detected in water. Within sediments, however, concentrations of phosphine have been found in the nanomolar ranges (0–25 nM dm^{-3}). Although phosphine is likely a minor constituent in lake and river waters, evasion to the atmosphere from enriched shallow wetlands and sediments could result in transport to other distant drainage basins and subsequent deposition with precipitation as phosphate.

Total inorganic and organic phosphorus has been separated in various ways for chemical analyses; often, these fractions relate poorly to the way in which phosphorus is metabolized. Perhaps the most important measure is the total phosphorus content of unfiltered water, which consists of the phosphorus in the particulate and in "dissolved" compartments (Juday, 1927; Ohle, 1938). Particulate phosphorus includes (1) phosphorus in organisms as (a) the relatively stable nucleic acids DNA, RNA, and phosphoproteins, which are not involved in rapid cycling of phosphorus; (b) low-molecular-weight esters of enzymes, vitamins, et cetera; and (c) nucleotide phosphates, such as adenosine diphosphate (ADP) and adenosine 5-triphosphate (ATP) used in biochemical pathways of respiration and CO_2 assimilation; (2) mineral phases of rock and soil, such as hydroxyapatite, in which phosphorus is adsorbed onto inorganic complexes such as clays, carbonates, and ferric hydroxides; (3) phosphorus adsorbed onto dead particulate organic matter or in macroorganic aggregations. In contrast to the phosphorus of particulate matter, dissolved phosphorus is composed of (1) orthophosphate (PO_4^{3-}), (2) polyphosphates, often originating from synthetic detergents, (3) organic colloids or phosphorus combined with adsorptive colloids, and (4) low-molecular-weight phosphate esters.

Because of the fundamental importance of phosphorus as a nutrient and major cellular constituent, much emphasis has been placed on its analytical evaluation. Chemical analyses of phosphorus center around the reactivity of phosphorus with molybdate and changes in reactivity during enzymatic and acidic hydrolysis of complex forms of phosphorus compounds as they are converted to orthophosphate. Detailed analyses recognize eight forms of phosphorus, which are differentiated on the basis of reactivity with molybdate, ease of hydrolysis, and particle size (Strickland and Parsons, 1972; Wetzel and Likens, 2000). Four operational categories result: (a) soluble reactive P, (b) soluble unreactive P, (c) particulate reactive P, and (d) particulate unreactive P. However, these operational methods do not necessarily correspond to either the chemical species of phosphorus or to their role in biotic cycling of phosphorus.

Most of the phosphorus data for fresh waters refer to total phosphorus and inorganic soluble phosphorus (orthophosphate), although in more detailed studies, four general fractions have been identified (Hutchinson, 1957). These four fractions are similar to the four operational groups already cited: (a) soluble phosphate phosphorus, (b) acid-soluble suspended (sestonic) phosphorus—mainly ferric phosphate and calcium phosphate, (c) organic soluble and colloidal phosphorus, and (d) organic suspended (sestonic) phosphorus.

Total phosphorus concentrations in nonpolluted natural waters extend over a very wide range from <1 μg $liter^{-1}$ to more than 200 mg $liter^{-1}$ in some closed saline lakes. The total phosphorus concentrations of most uncontaminated surface waters are between 10 to 50 μg P $liter^{-1}$. Variation is high, however, and can be related to characteristics of regional geology. Phosphorus levels of fresh waters are generally lowest in mountainous regions of crystalline bedrock geomorphology and increase in lowland waters derived from sedimentary rock deposits. Lakes rich in organic matter, such as bogs and bog lakes, tend to exhibit high total phosphorus concentrations. A few sedimentary coastal areas, such as in the southeastern United States,

TABLE 13-1 General Relationship of Lake Productivity to Average Concentrations of Epilimnetic Total Phosphorus[a]

General level of lake productivity	*Change (reduction) in alkalinity in epilimnion during summer (meq liter^{-1})*	*Total phosphorus (μg liter^{-1})*
Ultra-oligotrophic	<0.2	<5
Oligo-mesotrophic	0.6	5–10
Meso-eutrophic	0.6–1.0	10–30
Eutrophic		30–100
Hypereutrophic	>1.0	>100

[a] Modified from Vollenweider, R. A.: *Scientific Fundamentals of the Eutrophication of Lakes and Flowing Waters, with Particular Reference to Nitrogen and Phosphorus as Factors in Eutrophication.* OECD Report No. DAS/CSI/68.27, Paris, OECD, 1968, after numerous sources.

are rich in phosphatic rock. Lakes with drainage from these deposits have abnormally high phosphorus levels.

In an extremely detailed treatment relating phosphorus and nitrogen to lake productivity, Vollenweider (1968) demonstrated by several criteria that the amount of total phosphorus generally increases with lake productivity (Table 13-1). Although there are a number of exceptions to this relationship, it demonstrates a general principle that is useful when dealing with applied questions of eutrophication. The relationships of total phosphorus content to loading rates of phosphorus from the drainage basin and from lake sediments are discussed in the concluding sections of this chapter.

Separation of the total phosphorus into inorganic and organic fractions in an appreciable number of lakes indicates that most of the total phosphorus is in an organic phase (Table 13-2). Of the total organic phosphorus, about 70% or more is within the particulate (sestonic) organic material, and the remainder is present as dissolved or colloidal organic phosphorus. Rigler (1964) and Lean (1973b) demonstrated that data of former researchers who employed centrifugation and paper filtration methods of fractionation underestimated the importance of the sestonic organic phosphorus. Soluble organic phosphorus includes a significant quantity of phosphorus in a colloidal state. Inorganic soluble phosphorus is consistently very low, constitutes only a few percent of total phosphorus, and, as will be seen further on, is cycled very rapidly in the zones of utilization. The ratio of inorganic soluble phosphorus to other forms of phosphorus of approximately 1:20, or <5%, as inorganic phosphate phosphorus is remarkably constant in a large variety of lakes and streams within the temperate zone. The percentage of total phosphorus occurring as truly ionic orthophosphate is probably considerably <5% in most natural waters (e.g., Prepas and Rigler, 1982; Tarapchak *et al.*, 1982).

The phosphorus distribution within the fractions just discussed is the picture generally observed in the trophogenic zones of lakes. Phosphate, pyrophosphate, triphosphate, and higher polyphosphate anions additionally form complexes, chelates, and insoluble salts with a number of metal ions (Stumm and Morgan, 1996). The extent of complexing and chelation between various phosphates and metal ions in natural waters depends upon the relative concentrations of the phosphates and the metal ions, the pH, and the presence of other ligands (sulfate, carbonate, fluoride, and organic species).

Because phosphate concentrations are generally low, complex formations involving these major cations and various phosphate anions will have little effect on

the distribution of metal ions but may have marked effects on the phosphate distribution (cf. Golachowska, 1971). Metal ions such as those of ferric iron, manganous manganese, zinc, copper, et cetera, are present in concentrations comparable to or lower than those of phosphates. For these ions, complex formation can significantly affect the distribution of the metal ion, the phosphates, or both. For example, the solubility of aluminum phosphate ($AlPO_4$) is minimal at pH 6 and increases at both higher and lower pH values. Ferric phosphate ($FePO_4$) behaves similarly, although it is more soluble than $AlPO_4$. Calcium concentration influences the formation of hydroxylapatite, $[Ca_5(OH)(PO_4)_3]$. In an aqueous solution lacking other compounds, a calcium concentration of 40 mg liter^{-1} at a pH of 7 limits the solubility of phosphate to approximately 10 μg liter^{-1}. A calcium level of 100 mg liter^{-1} lowers the maximum equilibrium of phosphate to 1 μg liter^{-1}. Elevation of the pH of waters containing typical concentrations of calcium leads to apatite formation (Kümmel, 1981). Moreover, increasing pH leads to formation of calcium carbonate, which coprecipitates phosphate with carbonates (Otsuki and Wetzel, 1972). Sorption of phosphates and polyphosphates on surfaces is well known, particularly onto clay minerals (cf. Stumm and Morgan, 1996), by chemical bonding of the anions to positively charged edges of the clays and by substitution of phosphates for silicate in the clay structure. In general, high phosphate adsorption by clays is favored by low pH levels (approximately 5–6).

Following from these interactions and the distribution of phosphorus in inorganic and organic fractions, the general tendency is for unproductive lakes with orthograde oxygen curves to show little variation in phosphorus content with depth (Fig. 13-1). Similarly, during periods of fall and spring circulation, the vertical distribution of phosphorus is more or less uniform. Oxidized metals, such as iron, and major cations, particularly calcium, can react with and precipitate phosphorus.

Lakes exhibiting clinograde oxygen curves during the periods of stratification, however, possess much more variable vertical distributions of phosphorus. Commonly, there is a marked increase in phosphorus content in the lower hypolimnion, particularly during the later phases of thermal stratification (Fig. 13-1). Much of the hypolimnetic increase is in soluble phosphorus near the sediments. The sestonic phosphorus fraction is highly variable with depth. Sestonic phosphorus in the epilimnion fluctuates widely with oscillations in plankton populations and loadings from littoral areas. Sestonic phosphorus in the metalimnion and hypolimnion varies with sedimentation of plankton, depth-dependent rates of decomposition, and the development of deep-living populations of bacterial and other plankton (e.g., euglenophyceans).

III. PHOSPHORUS CYCLING IN RUNNING WATERS

A. Dissolved and Particulate Phosphorus in Rivers

Dissolved inorganic phosphorus, commonly referred to as orthophosphate or more correctly as soluble reactive phosphorus (SRP) based upon methods used in chemical analyses, averages about 10 μg liter^{-1} worldwide among unpolluted rivers (Meybeck, 1982, 1993b). Total dissolved phosphorus in these waters averages about 25 μg liter^{-1}.

Total dissolved inorganic phosphorus (DIP) of river water often increases by a factor of two- to four-fold

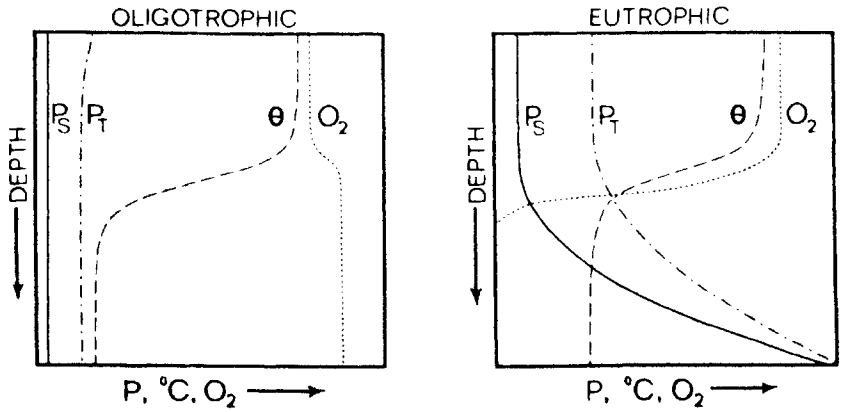

FIGURE 13-1 Generalized vertical distribution of soluble (P_S) and total (P_T) phosphorus in stratified lakes of very low (oligotrophic) and of high (eutrophic) productivity.

during and following increases in discharge from heavy rainfall events or in the early stages of snowmelt. DIP from pollutional sources often increases to levels of 50–100 μg P liter^{-1} from agricultural runoff and to over 1000 μg P liter^{-1} from municipal sewage sources (Meybeck, 1982, 1993b). Where DIP enters streams or rivers at point sources, concentrations decline downstream with net uptake rates in the range of 10–100 mg m^{-2} day^{-1}. As discussed next, uptake occurs both by physical adsorption to benthic substrata and to particulate seston, as well as by assimilation by attached biota. Although uptake of DIP by planktonic seston may be small (ca. 1% of total uptake) in small streams (Newbold *et al.*, 1983a; Mulholland *et al.*, 1990), sestonic uptake increases markedly in larger streams, particularly when dominated by phytoplankton (Newbold, 1992). Some of the seston and adsorbed phosphorus may settle out during base flows and then later be transported downstream during storm-induced high discharge. Exchange from these particles to the water may then occur in these displaced locations.

B. Biological Utilization

Biological uptake of phosphorus by algae, cyanobacteria, bacteria, and larger aquatic plants generally follows Michaelis–Menten kinetics (Chap. 17). Many algae and bacteria assimilate phosphorus at rates more rapid than used for growth. As a result, cells accumulate phosphorus and steady-state growth is saturated by concentrations much lower than the half-saturation constant (where uptake is half its maximum rate). Uptake rates of phosphorus by coarse particulate organic matter and microbiota associated with it commonly reach a maximum in 15–20 days and then decline precipitously (e.g., Mulholland *et al.*, 1984).

The rates of phosphorus uptake correlate with the metabolism of dominant organisms. In highly shaded streams with minimal in-stream photosynthesis, much (60 and 35%, respectively) of the uptake was associated with large (>1 mm) and fine (<1 mm) particles and only 5% with attached algae (Newbold *et al.*, 1983a; Mulholland *et al.*, 1985). In streams where decomposition of leaf detritus was dominant, phosphorus uptake was associated with the attached fungi and bacteria. Much of the phosphorus uptake associated with particulate organic matter is heterotrophic uptake by microbes associated with large and small particles of the benthic detritus (Gregory, 1978; Meyer, 1980; Webster *et al.*, 1991; Suberkropp, 1995). Phosphorus uptake was primarily associated with attached and planktonic algae in streams that were less shaded (e.g., Ball and Hooper, 1963; Petersen *et al.*, 1985). If other growth conditions are adequate, enrichments with phosphorus in the water often result in immediate enhancements of rates of algal photosynthesis and growth (e.g., Hart and Robinson, 1990; Burton *et al.*, 1991; Kjeldsen, 1994). Uptake by macrophytes, particularly by rooted vascular plants that rely largely upon rooting tissues for nutrient uptake, was much less than by attached algae and other microbes.

Average sestonic algal abundance has been positively correlated with total phosphorus and average phosphorus concentrations of many streams at moderate levels of nutrient loadings (Jones *et al.*, 1984; Soballe and Kimmel, 1987; Nieuwenhuyse and Jones, 1996) but becomes increasingly less responsive, as in lakes, to nutrient loadings at higher phosphorus concentrations. Summer mean chlorophyll concentration of seston among temperate streams exhibits a curvilinear relationship with summer mean total phosphorus concentrations (Fig. 13-2). The amount of nutrient loading to a river increases with greater catchment area. The analyses indicated that the phosphorus–sestonic chlorophyll relationship increased some 2.3-fold as the area increased from 100 to 100,000 km^2 (Fig. 13-2). It is important to note that the primary productivity of rivers is generally much less responsive to increased nutrient loadings than is the productivity of lakes. As will be discussed later in the sections on algal productivity, nutrient availability is generally higher in rivers than lakes. Nutrient losses in lakes are greater and large quantities are stored in parts of the ecosystem that are not readily available to the producers.

C. Adsorption and Release

The kinetics of abiotic adsorption and desorption of phosphorus onto and from organic and inorganic particles, such as natural sediment and suspensoid particles, generally comply with Langmuir isotherms. Fine particles (<0.1 mm) account for nearly all of the sorption capacity for phosphorus (0.1–1.0 μg P g^{-1} sediment per μg P liter^{-1} water; Meyer, 1979; Logan, 1982; Stabel and Geiger, 1985). The adsorption capacities of particles saturate and reach quasi-steady state in which uptake and release are about balanced.

The abundance of phosphate is also regulated by solubility reactions, particularly in relation to solid–solution associations with colloids or particles. Phosphorus concentrations in turbid rivers with low calcium concentrations are influenced by a solid ferric hydroxide-phosphate present in colloidal suspensions or on suspended particulates (Fox, 1993). In hardwater streams, the solubility of inorganic phosphorus can decrease as pH increases above 8.5, as is common in areas of intensive photosynthesis (Diaz *et al.*, 1994). Precipitation of inorganic phosphorus as calcium

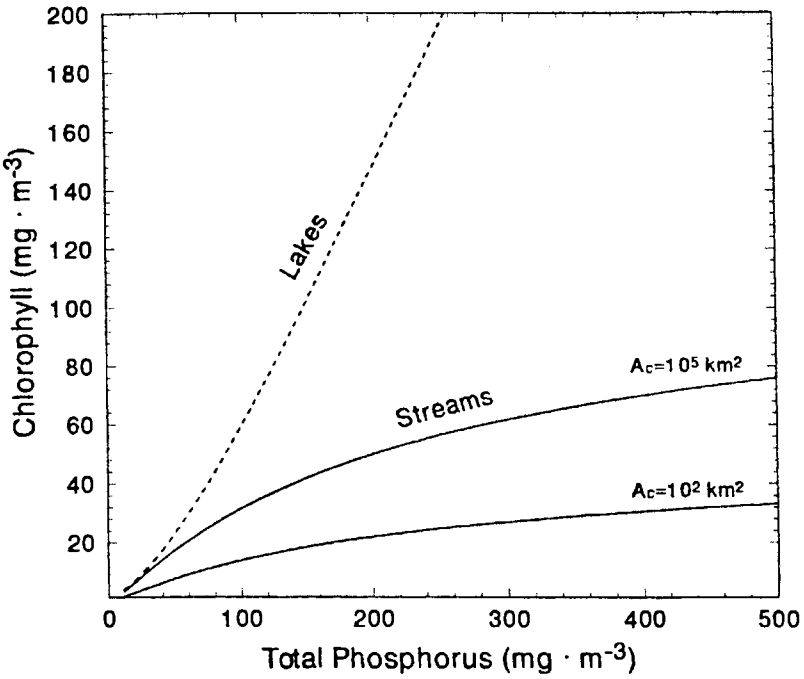

FIGURE 13-2 Phosphorus–sestonic chlorophyll relationships in temperate streams and lakes. Solid curves indicate predicted chlorophyll concentrations in rivers of differing catchment areas (A_C) of 100 and 100,000 km^2. The dashed curve depicts the trajectory of chlorophyll concentration in *P*-limited lakes in which total N:P > 25 (Forsberg and Ryding, 1980). (After Nieuwenhuyse and Jones, 1996.)

phosphate, highly stable as hydroxyapatite, increased to >60% at Ca concentrations approaching 100 mg liter^{-1} and pH values of 9.0 or greater. If calcium carbonate crystallizes under these conditions, phosphorus can be coprecipitated into the crystals and also adsorbed to the surfaces of the carbonates (Otsuki and Wetzel, 1972; cf. Chap. 11). These carbonate deposits are common in travertine encrustations in rivers that receive ground waters supersaturated with calcium and bicarbonates.

Thus, the major divalent metal ions in water, calcium and magnesium, tend to destabilize particles and enhance aggregation and sedimentation rates. In contrast, dissolved organic matter tends to stabilize colloidal particles in stream and lake water, slowing aggregation rates and thereby lowering sedimentation rates (Tipping and Higgins, 1982; Ali *et al.*, 1985). Separation distances and efficacy of van der Waals forces for attraction and aggregation, however, vary greatly with different types and concentrations of natural dissolved organic compounds and with the ionic strengths of charged colloids or particles (O'Melia, 1998).

As particulate organic matter increases, as is common from leaf-fall in late fall and winter in temperate woodland streams, phosphorus uptake can increase as the particulate organic matter increases (Mulholland *et al.*, 1985; Klotz, 1986). It is during this time as well that fungal activity is maximal on particulate organic matter (e.g., Suberkropp, 1995) and bacterial activities are maximal on dissolved organic matter leaching from the particulate organic matter (Wetzel and Manny, 1972b). Phosphorus uptake length, and hence total spiralling length, decreases in winter. These rates are counteracted at other times when detrital particulate organic matter is reduced by high discharge associated with storms.

D. Recycling of Phosphorus in Streams

As discussed earlier in terms of the biota of lakes, phosphorus can be released from biota by excretion in inorganic and organic forms from living microbiota or as the organisms senesce, die, and lyse. Phosphorus can also be released, as discussed earlier, during egestion of consuming animals. As in lakes, the dissolved organic phosphorus compounds in streams are utilized enzymatically appreciably more slowly than is dissolved inorganic phosphorus (reviewed by Newbold, 1992). Because of their slower rates of utilization, an accumulation of phosphorus compounds of high molecular weight (>5000 Daltons) occurs, and these compounds

are exported downstream for subsequent utilization (Mulholland *et al.*, 1988).

The spiralling of phosphorus has been measured in only a few streams. In a first-order woodland stream in Tennessee, the spiralling length was 190 m, most of it (165 m) associated with the water movement, and the remainder (25 m) in the particulate components, mostly coarse and fine particulate matter (Newbold *et al.*, 1983a). Less than 3% of the total passed through the invertebrate and vertebrate consumers. Phosphorus uptake lengths ranged from 21 to 165 m and varied inversely with the quantity of detritus on the stream sediments (Mulholland *et al.*, 1985). In a larger river in Michigan, phosphorus uptake lengths varied between 1100 and 1700 m (Ball and Hooper, 1963). Most streams, however, have considerable uptake capacity for phosphorus, with uptake lengths in the range of 5–200 m (e.g., Hart *et al.*, 1991).

In unshaded streams where autotrophic production constitutes an appreciable component of organic matter subsidy of streams, heavy grazing by macroinvertebrate consumers of attached algae and other microbes can reduce the uptake of phosphorus from the water (Mulholland *et al.*, 1983, 1985b). This reduction can result both from decreases in the microbiota as well as increased reduction in sizes of particles. The fine particles of organic matter and phosphorus are then scoured relatively easily and are the predominant form exported downstream (Meyer and Likens, 1979).

Long-term evaluations of phosphorus dynamics in streams are rare. Examination of an average annual phosphorus budget for a forested second-order stream ecosystem of New Hampshire illustrates some of the potential transport and transformation processes (Table 13-3). Phosphorus inputs were dominated by dissolved and fine particulate phosphorus (63%) and falling and windblown litter (23%). Subsurface inflows (10%) and precipitation (5%) were relatively small sources of phosphorus in this ecosystem. The geologic export of phosphorus in the stream water was the only removal vector of consequence. On an annual basis, no annual net retention of phosphorus occurred in the stream. However, over short periods of time, inputs exceeded exports, with phosphorus accumulation. The accumulated phosphorus was exported in large pulses during precipitation-mediated episodes of high-stream discharge. Similar exports have been observed in many other stream ecosystems (e.g., Long and Cooke, 1979; Verhoff *et al.*, 1982; Munn and Prepas, 1986; Wetzel, 1989). For example, in a detailed analysis of daily phosphorus dynamics in a small second-order stream in Michigan passing through a wetland to a lake, between 60 and 80% of the annual PO_4—P from this stream to the receiving lake occurred during three major precipitation events (Wetzel, 1989). Dissolved inorganic and organic nitrogen loadings from the stream, however, were not as strongly coupled to discharge and were controlled to a greater extent by biological retention processes.

IV. PHOSPHORUS AND THE SEDIMENTS: INTERNAL LOADING

The exchange of phosphorus between sediments and the overlying water is a major component of the phosphorus cycle in natural waters. There is an apparent net movement of phosphorus into the sediments in most lakes. The effectiveness of the net phosphorus sink to the sediments and the rapidity of processes regenerating the phosphorus back to the water depend upon an array of physical, chemical, and biological factors. The correlation between the amount of phosphorus in the sediments and the productivity of the overlying water is modest to weak, and the phosphorus content of the sediments can be several orders of magnitude greater than that of the water. The important factors are (1) the ability of the sediments to retain phosphorus, (2) the conditions of the overlying water, and (3) the biota within the sediments that alter exchange equilibria and effect phosphorus transport back to the water.

A. Exchanges across the Sediment–Water Interface: Overview

The deposition of phosphorus into lake sediments occurs by five mechanisms (Williams and Mayer, 1972;

Boström *et al.*, 1988; Wetzel, 1990a): (1) Sedimentation of phosphorus minerals imported from the drainage basin. Most of this material settles rapidly and is deposited largely in nearshore areas. (2) Adsorption or precipitation of phosphorus with inorganic compounds by three mechanisms: (a) Phosphorus coprecipitation with iron and manganese; (b) adsorption to clays, amorphous oxyhydroxides, and similar materials; and (c) phosphorus associated with carbonates. It is difficult to distinguish direct adsorption of dissolved phosphorus of lake water onto particles in the sediments from diagenetic and transfer processes within surface sediments. (3) Sedimentation of phosphorus with allochthonous organic matter. (4) Sedimentation of phosphorus with autochthonous organic matter. (5) Uptake of phosphorus from the water column by attached algal and other attached microbial communities and to a lesser extent by submersed macrophytes, with eventual transport back to the sediments by translocation and deposition with detritus.

Once the phosphorus is within the sediment in various forms, exchanges across the sediment–water interface are regulated by mechanisms associated with mineral–water equilibria; sorption processes, particularly ion exchange, oxygen and other electron acceptor-dependent redox interactions; and the physiological and behavioral activities of many biota (bacteria, algae, fungi, macrophytes, invertebrates, and fish) associated with the sediments. The sediment–water interface separates into two distinct domains. In all but the upper few millimeters of sediment, exchange is controlled by motions on molecular scales with correspondingly low diffusion rates (Duursma, 1967). In the water, exchange is regulated by much higher and more variable rates of turbulent diffusion (Mortimer, 1971). The exchange rates between various deposits of phosphorus and the interstitial water of the sediments depend on local adsorption and diffusion coefficients and their alteration by enzyme-mediated reactions of the microbiota.

Numerous processes operate, often simultaneously, to mobilize phosphorus from particulate stores to dissolved interstitial phosphorus and then to transport that dissolved phosphorus across the sediment–water interface into the overlying water (Fig. 13-3). Orthophosphate is bound to particles by physical adsorption as well as chemical binding of different strengths (complex, covalent, and ionic bonds). Physical and chemical mobilization includes desorption, dissolution of phosphorus-containing compounds, particularly assisted by microbially mediated acidity, and ligand exchange mechanisms between phosphate and hydroxide ions or organic chelating agents (Boström *et al.*, 1982; Stumm and Morgan, 1996). Microbial biochemical mobilization processes include mineralization by hydrolysis of phosphate–ester bonds, release of phosphorus from living cells as a result of changing environmental conditions, particularly redox, and autolysis of cells.

The internal phosphorus loading to a lake from the sediments depends on hydrodynamic and biotic mechanisms that transport dissolved phosphorus from the sediments to the lake water. Because of the steep concentration gradients of phosphorus between interstitial water and the overlying water, molecular diffusion is a primary transport into the overyling anaerobic water (Fig. 13-3). Currents from wind-induced water turbulence can disrupt gradients and resuspend sediment particles. Disturbance of sediments by benthic invertebrates living on or in the sediments and by bottom-feeding fishes can, when occurring in large densities, cause appreciable bioturbation of sediments. Microbial generation of gases, particularly CO_2, CH_4, and N_2, can accumulate, form bubbles, and rise to the surface. Such ebullition can disrupt gradients and accelerate diffusion of phosphorus upward. The metabolism and growth of plants living on and within the sediments can both suppress and enhance the transport of phosphorus across the sediment–water interface. Because of the major importance of the movement of phosphorus from large accumulations in the sediment to the overlying water, each of these processes is discussed in greater detail in subsequent sections.

B. Oxygen Content of the Microzone

The most conspicuous regulatory features of the sediment boundary are the mud–water interface and the oxygen content. The oxygen content at this microzone is influenced primarily by the metabolism of bacteria, algae, fungi, planktonic invertebrates that migrate to and live within the interface, and sessile benthic invertebrates. Microbial degradation of dead particulate organic matter that settles into the hypolimnion and onto the sediments is the primary consumptive process of oxygen in deepwater areas of lakes. The rate of oxygen depletion is governed by the rates of organic loading to the hypolimnion and by lake or reservoir morphology (cf. Chap. 9). For example, it has been estimated that 88% of the hypolimnetic oxygen consumption in the central basin of Lake Erie resulted from bacterial degradation of algae sedimenting from the trophogenic zone (Burns and Ross, 1971). Decomposition of more labile organic fractions, largely of plant origin, occurs while it is settling to the sediments, and, depending on rates of input and sedimentation, the sediments often receive organic residues that are relatively resistant to rapid decomposition.

Sediment demand for oxygen is high and is governed by the intensity of microbial and respiratory metabolism, slow rates of diffusion, and by the fact

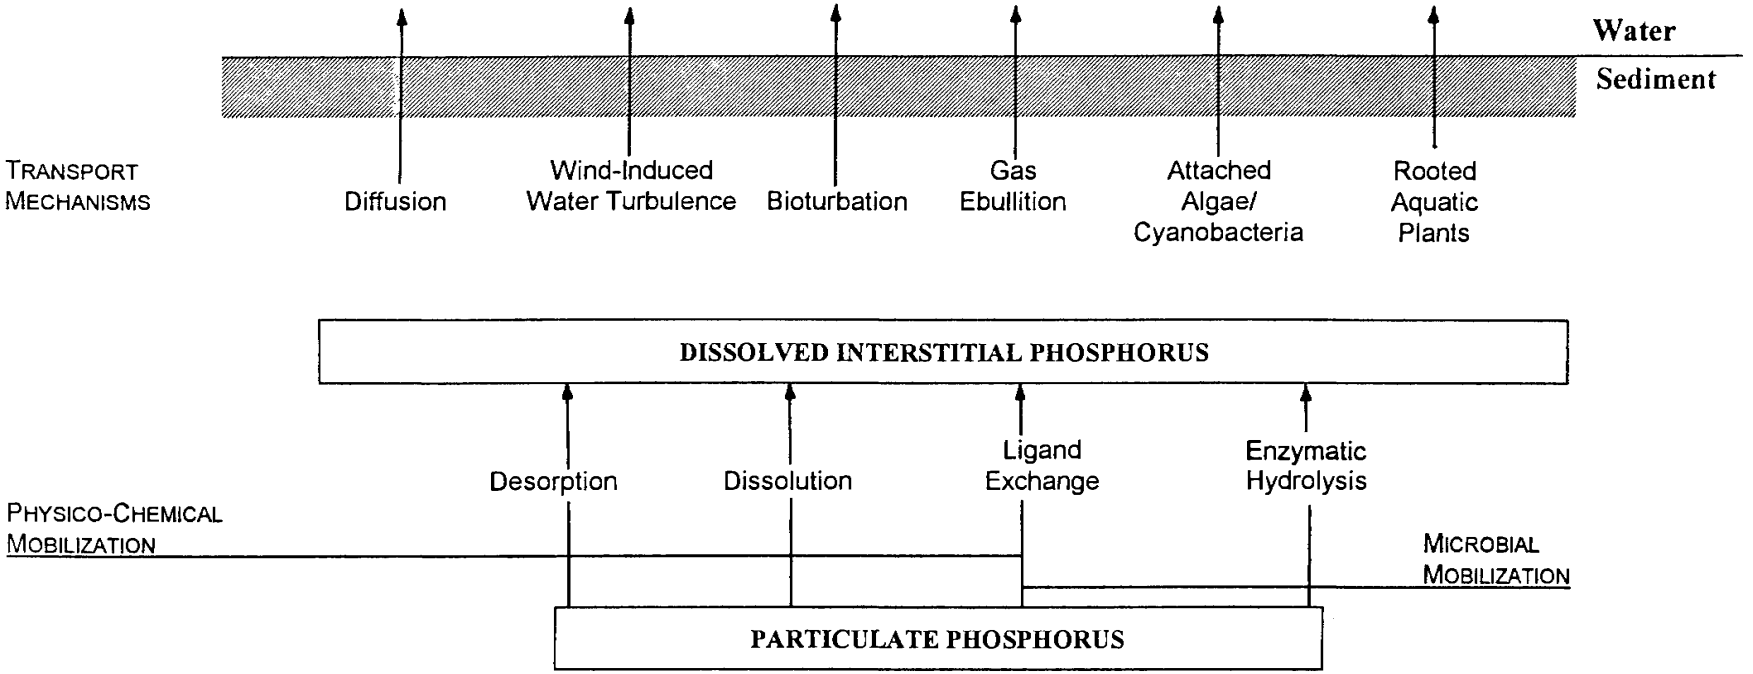

FIGURE 13-3 Processes involved in the mobilization of phosphorus from particulate stores into dissolved states of interstitial water of the sediments and transport across the sediment–water interface into the overlying water. (Modified extensively from Boström *et al.*, 1982, 1988, and Wetzel, 1999c.)

that inorganic elements, such as Fe^{++}, accumulate in reduced form when released into the sediment from decomposing biota. Diffusion regulates transport and is essentially molecular in the sediments, unless the superficial sediments are disturbed by overlying water turbulence. Oxygen from well-aerated overlying water, as in oligotrophic lakes or in more productive lakes at periods of complete circulation, will penetrate only a few centimeters into the sediments by diffusion. Oxygen penetration into the sediments is governed by the rate of oxygen supply to the sediments, turbulent mixing of superficial sediments, if any, and by the oxygen demand per unit volume of the sediment. The superb experimental and observational work of Mortimer (1941, 1942, 1971) has demonstrated the importance of an oxidized microzone to chemical exchanges, especially of phosphorus, from the sediments. At the sediment surface, a difference of a few millimeters in oxygen penetration is the critical factor regulating exchange between sediment and water. These relationships are exemplified by two lakes with organic sediments: The first lake maintained oxygen concentrations at the sediment interface >8 mg liter^{-1} throughout summer stratification, while in the second lake, oxygen levels at the interface decreased to <1 mg liter^{-1}.

In the first situation, illustrated by Mortimer's studies of Lake Windermere, England, oxygen concentration at the sediment surface did not fall below 1 or 2 mg liter^{-1}. Electrode potentials, which approximate composite redox potentials (cf. Chap. 14), of the oxygenated overlying water and surficial sediments to a depth of approximately 5 mm were uniformly high (+200 to 300 mV). Below 40–50 mm in the sediments, the potentials were uniformly low (approximately −200 mV), indicative of extreme reducing conditions and total anoxia (Fig. 13-4). The sediment remained oxidized to a depth of about 5 mm throughout the period of summer stratification. Seasonal differences were observed in the sediment depth at which the transition from high to low potential occurred, but the region of low potential never extended into the water. After five months of stratification, the point of zero mV moved toward the surface of the sediments, to −5 mm from approximately −12 mm at the time of spring turnover and moved downward to −10 mm during fall circulation. The integrity of the oxidized microzone was maintained in a thin but operationally very significant layer during stratification periods. The oxidized microzone was further maintained by diffusion and by turbulent displacement of the uppermost sediments to the overlying water during turnover periods (cf. Gorham, 1958). The effectiveness of the oxidized microzone in preventing a significant release of soluble components from the interstitial waters of the sediments to the overlying water was demonstrated in experimental chambers for over five months (Fig. 13-5, *left*). Phosphorus, in particular, was prevented from migrating upward.

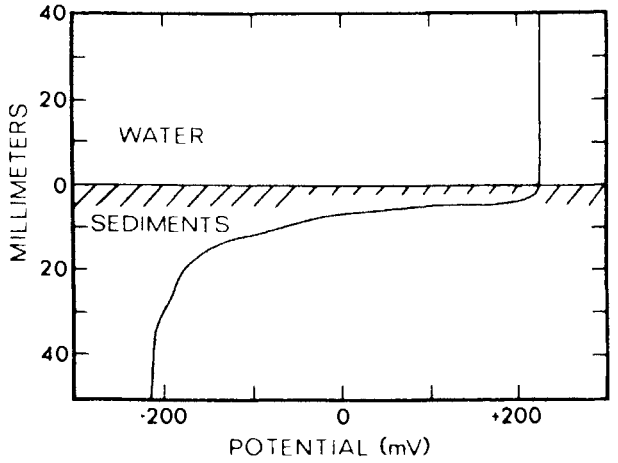

FIGURE 13-4 Diagrammatic profile of composite electrode potentials, not corrected for pH variations, across the sediment–water interface in undisturbed cores from the deepest portion of Lake Windermere before, during, and after stratification. (Based on data of Mortimer, 1971.)

The ability of sediments to retain phosphorus beneath an oxidized microzone at the interface is related to several interacting factors. Much of the organic phosphorus reaching the sediments by sedimentation is decomposed and hydrolyzed (Sommers *et al.*, 1970). Most of the sediment phosphorus is inorganic, for example, apatite, derived from the watershed, and phosphate adsorbed onto clays and aluminum and ferric hydroxides (Frevert, 1979a, b; Detenbeck and Brezonik, 1991; Andersen and Jensen, 1992; Danen-Louwerse *et al.*, 1993). Additionally, phosphate coprecipitates with iron, manganese, and carbonates (Mackereth, 1966; Harter, 1968; Wentz and Lee, 1969; Otsuki and Wetzel, 1972; Boström *et al.*, 1988). Work on Wisconsin lake sediments and the Great Lakes indicated that phosphorus was present in the sediments predominantly as apatites, organic phosphorus, and orthophosphate ions covalently bonded to hydrated iron oxides (Shukla, 1971; Williams *et al.*, 1970, 1971a–c; Williams and Mayer, 1972; Golterman, 1982, 1995). In calcareous sediments of hardwater lakes containing 30–60% $CaCO_3$ by weight, $CaCO_3$ levels were not directly related to inorganic and total phosphorus. These sediments had a lower capacity to adsorb inorganic phosphorus than noncalcareous sediments (cf. Stauffer, 1985; Olila and Reddy, 1993). The observations imply that $CaCO_3$ sorption is less important than iron–phosphate complexes in controlling the

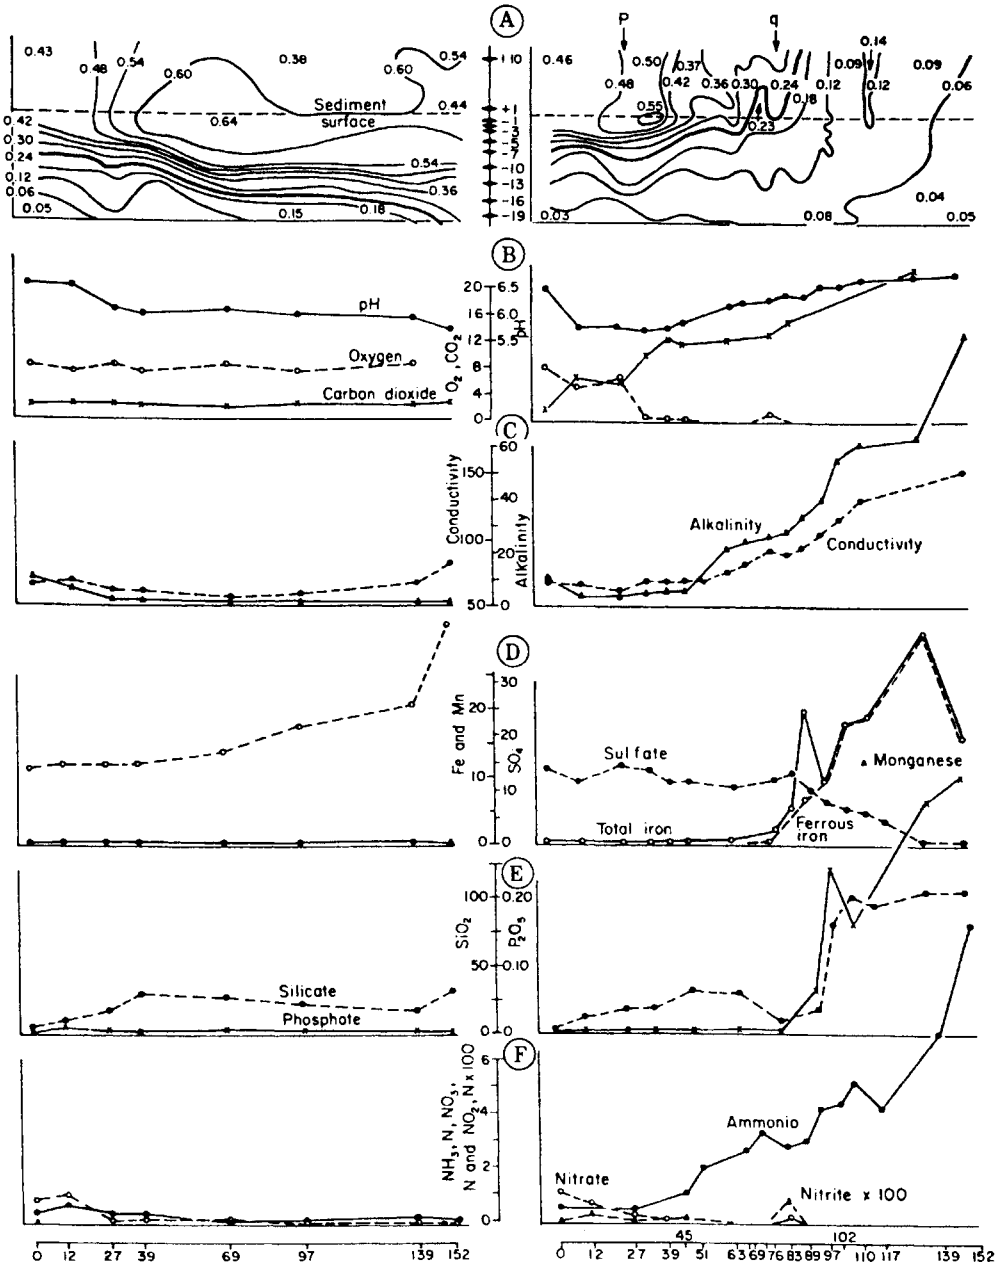

FIGURE 13-5 Variation in chemical composition of water overlying deepwater Lake Windermere sediments over 152 days in experimental sediment–water tanks. *Lefthand series:* aerated chamber; *righthand series:* anoxic chamber. (a) Distribution of redox potential (E_7; Eh adjusted to pH 7) across the sediment–water interface in mm; (b) pH, concentrations of O_2, and CO_2 in mg liter^{-1}; (c) alkalinity expressed as mg $CaCO_3$ liter^{-1} and conductivity, in μS cm^{-1} at 18°C; (d) iron (total and ferrous as Fe) and SO_4 in mg liter^{-1}; (e) phosphate as P_2O_5 and SiO_2 in mg liter^{-1}; (f) nitrate, nitrite ×100, and ammonia, all as N, in mg liter^{-1}. (Mortimer, C. H.: *Limnol. Oceanogr. 16*:396, 1971, and *J. Ecol. 29*:280, 1941.)

concentrations of phosphorus in sediments (Andersen, 1975; Frevert, 1980). Although phosphorus exchange by adsorption and desorption within the sediments between sediment particles and interstitial water can be as rapid as a few minutes (Hayes and Phillips, 1958; Li *et al.*, 1972), the rate of transfer across the sediment–water interface depends on the state of the microzone. The oxidized layer forms an efficient trap for iron and manganese (see Chap. 14) as well as for phosphate, thereby greatly reducing the transport of materials into the water and scavenging materials such as phosphate from the water.

As the oxygen content of water near the sediment interface declines, the oxidized microzone barrier weakens. As seen from Mortimer's experiments (Fig. 13-5, right-hand series), the release of phosphorus, iron, and manganese increased markedly as the redox potential decreased. With the reduction of ferric hydroxides and complexes, ferrous iron and adsorbed phosphate were mobilized and diffused into the water. The same general reactions were observed in the hypolimnetic water just overlying the sediments in eutrophic Esthwaite Water (Fig. 13-6), a pattern that has been observed repeatedly in productive dimictic lakes since its initial detailed description by Einsele (1936). A sudden release of ferrous iron and phosphate into the water occurs at the time when the +0.20 isovolt (E_7 = +200 mV) emerged above the interface surface. This event is preceded by nitrate reduction and the slow release of bases (alkalinity), CO_2, and ammonia. As long as an abundance of nitrate remains and nitrate reduction continues in the overlying water (ca. >0.1–1 mg NO_3—N liter^{-1}), no release of iron-bound phosphate occurred from the sediments to the anoxic hypolimnion (Andersen, 1982; Tirén and Pettersson, 1985; Foy, 1986). Manganese is reduced and mobilized at a higher redox potential than iron.

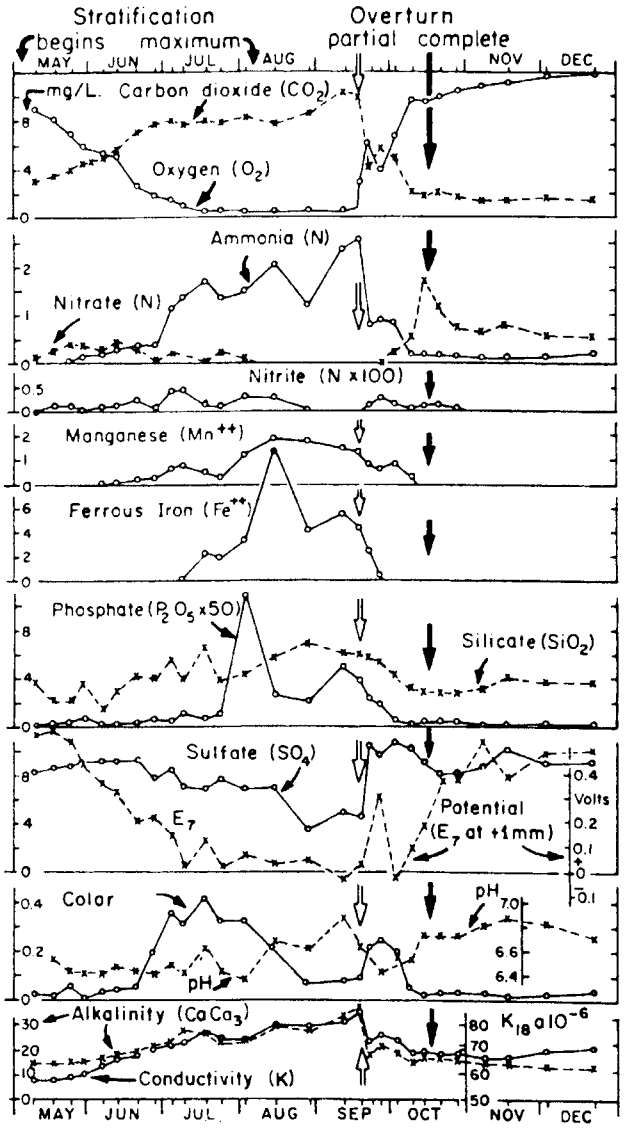

FIGURE 13-6 Seasonal distribution in composition (mg liter^{-1}) and properties of water within 30 cm of the sediments at 14 m in Esthwaite Water, England. Components as in Figure 13-5; color in arbitrary units. (From Mortimer, C. H.: *Limnol. Oceanogr.* 16:387, 1971.)

The introduction of oxygen during autumnal circulation[1] causes ferrous iron to be oxidized and produces a simultaneous reduction of phosphate, part as ferric phosphate, which is less soluble than ferric hydroxide, and part by adsorption onto ferric hydroxide and $CaCO_3$. Although manganese is oxidized more slowly than iron, it nonetheless is effectively precipitated at the time of overturn. Ferrous iron released from the sediments is always in excess of phosphate, and when oxidized, it precipitates much of the phosphate. Some of the ferric phosphate in particulate form may slowly hydrolyze and restore some phosphate to the upper waters and littoral areas (Hutchinson, 1957). Although most phosphate is returned eventually to the sediments, much (>50%) of the hypolimnetic phosphorus upwelled during autumnal circulation is available biologically (Nürnberg, 1985). Often, however, other growth conditions (temperature, light) are not optimal at that time of year.

In very productive lakes where hypolimnetic decomposition of sedimenting organic matter produces anoxic conditions and hydrogen sulfide, some ferrous sulfide (FeS) is precipitated. Ferrous sulfide, like many other metal sulfides, is exceedingly insoluble and forms at a redox potential of about + 100 mV. If large quantities of FeS precipitate, sufficient iron can be removed to permit some of the phosphate accumulated in the hypolimnion to remain in solution during autumnal circulation. The addition of sulfate to a lake in order to increase the bacterial production of hydrogen sulfide (H_2S) and to accelerate the loss of iron has been suggested as a method of fertilizing lakes by regenerating phosphate from the sediments (Hasler and Einsele, 1948).

[1] The normal seasonal erosion in the autumn of the epilimnion and metalimnion with progressive oxygenation of the upper portion of the hypolimnion can be periodically intensified during storm periods, particularly in reservoirs (e.g., James *et al.*, 1990). Stratification can be reestablished subsequently for short periods until the next intensive wind period occurs.

Iron interacts with dissolved humic substances (cf. Chap. 23) to bind phosphorus at acidic to near-neutral pH values, irrespective of redox conditions, in the surficial sediments of certain softwater lakes (Jackson and Schindler, 1975; Francko, 1986). This process should enhance sediment retention of phosphorus in lakes with high loading of iron and humic substances.

C. Phosphorus Release from the Sediments

Because of the obvious importance of phosphorus as a nutrient that often accelerates the productivity of fresh waters, much interest has been devoted to the phosphorus content of sediments and its movement into the overlying water. Lake sediments contain much higher concentrations of phosphorus than the water (Olsen, 1958, 1964; Holden, 1961; Hepher, 1966; Holdren *et al.*, 1977; Boström *et al.*, 1982; and many others). Under aerobic conditions, the exchange equilibria are largely unidirectional toward the sediments. Under anaerobic conditions, however, inorganic exchange at the sediment–water interface is strongly influenced by redox conditions (Frevert, 1979b). The depth of the sediment involved in active migration of phosphorus to the water is considerable (e.g., Carignan and Flett, 1981). In undisturbed anoxic sediments, given sufficient time (2–3 months), phosphorus moved upward readily from a depth of at least −10 cm to the overlying water, regardless of whether the sediments were calcareous eutrophic muds or acidic and peaty in nature (Hynes and Greib, 1970). Comparison of movement in sterile sediments and sediments with anaerobic bacteria showed no significant difference; thus, diffusion predominated.

Phosphorus-mobilizing bacteria, especially of the genera *Pseudomonas, Bacterium,* and *Chromobacterium,* were abundant to at least 15 cm in reservoir sediments (Gak, 1959, 1963). Their abundance and vertical distribution varied with the type of sediments. Low numbers occurred in sandy sediments with small amounts of silt, and the bacteria were concentrated near the interface. Their numbers increased more uniformly with depth in sandy sediments with moderate amounts of organic matter and silts. The greatest numbers of bacteria were found in silts high in organic matter. Hayes and Anthony (1958, 1959) and Anthony and Hayes (1964) examined the relationship of bacterial densities and organic content of sediments in detail and found only a weak correlation in a large number of lakes. Bacterial numbers in the sediments increased proportionally, especially at the interface, with several indices of increasing lake productivity in lakes of neutral or alkaline pH and with low concentrations of humic compounds. In general, however, bacterial production rates are correlated with phosphorus and carbon in the sediments (Eckerrot and Pettersson, 1993). Bacterial biomass in sediments of organically stained acidic bog lakes was also high.

Although bacteria are of major importance in the dynamics of phosphorus cycling in the water, as will be discussed in the following section, their role in expediting phosphorus exchange across the sediment interface is relatively minor in comparison to chemical equilibria processes (Hayes, 1964). Bacterial decomposition is proportional to bacterial densities at the interface and directly related to the general productivity of the lake (Hayes and MacAuley, 1959; Hargrave, 1972). The sediment microflora is important in increasing the concentrations of phosphorus dissolved in the interstitial water of the sediments (Fleischer, 1978). Bacterial metabolism at the interface, however, has relatively little effect on biogenic fixation and removal of phosphate from the overlying water. Using sterilized and natural sediments, it was found that microbial fixation and transport of phosphorus from the water to the sediments amounted to <5% of the total movement under anaerobic reducing conditions (Hayes, 1955; Macpherson *et al.*, 1958; Olsen, 1958; Pomeroy *et al.*, 1965). Under aerobic conditions, bacteria of the interface did significantly increase the microbial transport of phosphorus to the sediments (Hayes, 1955; Hayes and Phillips, 1958), and this loss was related to the amount of microbial phosphorus sedimenting to the interface (cf. also Frevert, 1979a).

Mobilization of sediment-associated P to the overlying water has therefore been ascribed largely to PO_4^{3-} release from Fe(III) oxide as these compounds are reduced by anoxic conditions in surface sediments and the overlying water (Mortimer, 1941; Boström *et al.*, 1982). When release of PO_4^{3-} is compared on a molar ratio to PO_4^{3-} liberated per unit of organic carbon mineralized by bacterial metabolism, the availability of alternate electron-acceptor compounds, such as sulfate (SO_4^{2-}), becomes as important within the interstitial waters of the sediments as the oxidative conditions of the overlying water (Hasler and Einsele, 1948; Sugawara *et al.*, 1957; Caraco *et al.*, 1989, 1990; Roden and Edmonds, 1997). The relative PO_4^{3-} release from sediments can be significantly higher as sulfate concentrations increase from natural or anthropogenic sources, particularly in oligotrophic, softwater lakes.

Iron sulfide formation coupled to sulfate reduction can reduce the abundance of Fe compounds that can complex PO_4^{3-} and thereby promote release of PO_4^{3-} into sediment porewater. When sulfate content is low or absent in anaerobic sediments, microbial reduction generates Fe(II) compounds from microbial reduction of Fe(III) oxide. PO_4^{3-} can be retained effectively with

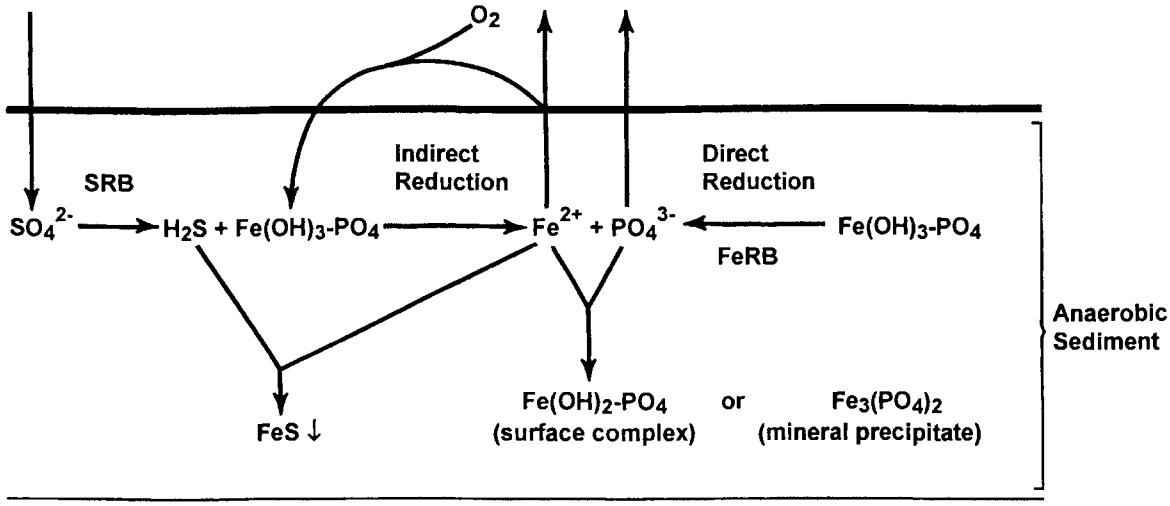

FIGURE 13-7 Interactions of sulfate on the reduction of Fe(III) and release of Fe(II) and phosphate. SRB = sulfate-reducing bacteria; FeRB = iron-reducing bacteria. (Modified from Roden and Edmonds, 1997.)

Fe(II) compounds but Fe-associated PO_4^{3-} is quantitatively released when amorphous Fe(III) oxide of the sediment is converted to iron sulfides (Roden and Edmonds, 1997). Conversion of reactive sediment Fe compounds to iron sulfides by sulfate-reducing bacteria leads to more efficient release of Fe-associated PO_4^{3-} than does direct microbial Fe(III) oxide reduction (Fig. 13-7).

Other processes can contribute to the composite release of Fe-associated PO_4^{3-} from sediments. For example, the uptake of excessive amounts of P by aerobic bacteria (e.g., Fleischer, 1986) and storage as polyphosphates could be rapidly degraded and released with the onset of anaerobic conditions (DeMontigny and Prairie, 1993; Gachter and Meyer, 1993). Because organic sediments are aerobic for only one or a few millimeters, this contribution is likely small in comparison to other mechanisms.

The sorption capacities of Fe(III) oxide decrease as pH levels increase above 6.5 (Stumm and Morgan, 1996). Large increases in pH values can occur within the sediments for several millimeters as a result of diurnal fluctuations in photosynthesis by epipelic algae (Fig. 13-8) and by submersed aquatic macrophytes and associated epiphytic algae. Simultaneous increases in oxygen concentrations (Fig. 13-8) and adsorption to or with photosynthetically induced precipitation of $CaCO_3$ (e.g., Mickle and Wetzel, 1978a) can counteract the availability of desorbed PO_4^{3-}.

The rate of phosphorus release from lake sediments increases (about doubles) markedly if the sediments are disturbed by agitation from turbulence (Zicker *et al.*, 1965). Covering anaerobic sediments with sand or polyethylene sheeting greatly impedes the loss of oxygen in the overlying water and decreases sediment release of phosphorus, iron, and ammonium (Hynes and Greib, 1970).

Algae growing on sediments are able to effectively utilize phosphorus from the sediments (Golterman *et al.*, 1969; Björk-Ramberg, 1986). Moreover, algae suspended in water with various particulate inorganic compounds of extremely low solubility were capable of extracting sufficient phosphorus for growth; without sediment phosphorus sources, the phosphorus content of the water limited algal growth under experimental conditions. The presence or absence of bacteria had little effect on algal utilization of phosphorus. These results stress the importance of extractable phosphates in the sediments if they are agitated into the water column, as in shallow lakes, even though their solubilities may be extremely low.

Some phosphorus release occurs under aerobic conditions from littoral sediments, particularly as temperatures warm above 10–15°C, as concentrations in the overlying water decline below equilibrium levels and as pH increases from intense photosynthetic activity of submersed macrophytes and attached algae (Twinch and Peters, 1984; Drake and Heaney, 1987; Boers and van Hese, 1988; Carlton and Wetzel, 1988; Boers, 1991; James and Barko, 1991). Because the volume of the littoral water is often small in comparison to that of the total lake, the littoral water often cools more rapidly at night than the pelagic zone. Convective flows from the littoral as interflow to the base of the epilimnion can move appreciable quantities of phosphorus from the littoral areas to the pelagic zone.

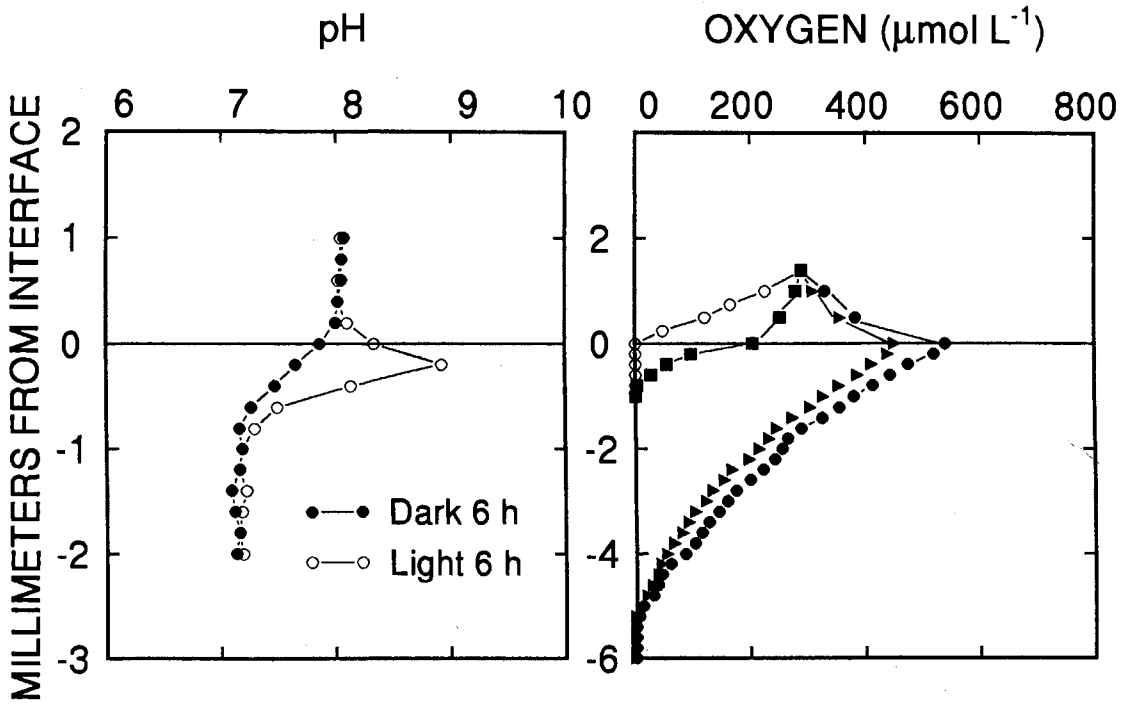

FIGURE 13-8 Distribution of pH (*left*; illumination 30 μmol quanta m^{-2} s^{-1}) and dissolved oxygen (*right*) immediately above and within sediments colonized by epipelic microalgae and bacterial communities. Oxygen microprofiles (*right*) during darkness (○—○), and after 1 h (■—■), 8 h (△—△), and 10 h (●—●) illumination with 10 μmol quanta m^{-2} s^{-1}. (Extracted from data of Carlton and Wetzel, 1987, 1988.)

D. Benthic Algae and Phosphorus Release from Sediments

Thus, oxygen is a primary factor influencing the release of phosphorus from sediments. If the sediments receive light, even at very low intensities (<50 μmol quanta m^{-2} s^{-1}), photosynthesis of epipelic algal communities growing on the sediments can quickly (minutes) produce high, often markedly supersaturated, concentrations of oxygen within the community usually <2 mm in thickness (Fig. 13-8) (Revsbech *et al.*, 1983; Carlton and Wetzel, 1987). This oxygen can diffuse several millimeters into the interstitial water of the supporting sediments at rates greater than it is consumed by bacterial respiration and chemical oxidations. By this mechanism, diurnal changes occur in the oxidized microzone of the sediments from fully oxidized in the daylight hours to fully reducing at nighttime. It was shown experimentally that the rate of phosphorus efflux from sediments is inversely related to the extent of sediment oxygenation and the magnitude of epipelic algal photosynthesis (Carlton and Wetzel, 1988). Although much of the reduced phosphorus efflux is caused by direct chemical redox changes, the microbial community also assimilates and complexes nutrients in organic compounds (cf. Kelderman *et al.*, 1988; Hansson, 1989).

E. Phosphorus Translocation by Migrating Phytoplankton

Several algae and cyanobacteria of lakes exhibit vertical migrations from nutrient-rich sediments or lower water strata to the euphotic trophogenic zone on a seasonal or daily basis. For example, a motile cryptomonad alga and a dinoflagellate migrate vertically from phosphorus-rich strata below the metalimnion at night to surface waters in early morning in sufficient quantities to enrich the epilimnion (Salonen *et al.*, 1984; Taylor *et al.*, 1988). Migrations of a large part of certain benthic-inhabiting cyanobacteria to the epilimnion have been implicated in translocation of benthic phosphorus sufficient to increase phytoplanktonic productivity (Barbiero and Welch, 1992).

F. Phosphorus Cycling Mediated by Aquatic Plants and Epiphytic Microflora

Lakes, reservoirs, and rivers are coupled with their drainage basins by intervening wetlands and littoral zones, the ***land–water interface zones,*** through which much runoff and seepage water flows before entering the main water bodies. The aquatic plants of the interface zones are major biotic components in many, if not most, lakes and in the flood plains of river ecosystems.

These plants often occupy much of the epilimnion and trophogenic zone, both of which extend virtually to the same depth in many small lakes. The littoral macrophytes and their attached microflora function mutualistically as conservative retainers of phosphorus and can modify greatly phosphorus loadings and budgets among aquatic ecosystems (Wetzel, 1990a).

1. Aquatic Plants

Emergent, rooted, floating-leaved and submersed higher aquatic plants take up most of their phosphorus from the interstitial waters of the sediments, where the concentrations are several orders of magnitude greater than in the overlying water (Denny, 1972; Barko and Smart, 1981; Brock *et al.*, 1983). Even though the structural and vascular systems of submersed aquatic angiosperms are simplified and reduced, nutrient uptake is largely by the root–rhizome system from the sediments (cf. Chap. 18). Early studies provided conflicting results. For example, the presence of the macrophytes *Eriocaulon* or *Utricularia* in experimental sediment–water systems increased the movement of radiophosphorus from the water to the sediments (Hayes, 1955). Absorption and translocation of phosphorus, studied in bacteria-free cultures of the macroalga *Chara* common to hardwater lakes, showed all parts of the plants could absorb ^{32}P about equally (Littlefield and Forsberg, 1965). About the same proportion of adsorbed phosphorus was translocated from the apices or from rhizoids to other parts of the plants. Similar results were obtained for other freshwater plants (e.g., Schwoerbel and Tillmanns, 1964; DeMarte and Hartman, 1974).

Rates of phosphorus uptake and excretion by the roots and leaves of submersed macrophytes were found to be dependent on the phosphorus concentrations of the medium (McRoy *et al.*, 1972; Kussatz *et al.*, 1984; Brix and Lyngby, 1985). Because the interstitial sediment phosphorus concentrations are very much greater than those of the water, uptake from the sediments predominates (e.g., Gabrielson *et al.*, 1984; Smith and Adams, 1988). Critical experimental studies of phosphorus uptake both from the sediments and from the water by submersed macrophytes that possessed their normal epiphytic microflora showed, however, that nearly all phosphorus was obtained from the sediments (e.g., Moeller *et al.*, 1988). Nearly all of the nutrient uptake from the water was by the attached microbiota and very little was transferred to the supporting macrophyte.

As foliage matures, a gradual, partial senescence of leaves often occurs, particularly among submersed macrophytes, from which nutrients leach. Some senescing leaves slough off of the living plants and collect among detrital accumulations of the sediments. For example, the leaching of phosphorus from dead macrophytes under sterile conditions was rapid and resulted in a loss of from 20 to 50% of total phosphorus content in a few hours and 65–85% over longer periods (Solski, 1962; Nichols and Keeney, 1973; Landers, 1982). Rates of leaching were greater from roots than from leaves.

Most aquatic angiosperms are herbaceous perennials with multiple cohorts (see Chap. 18). Upon completion of a growth cycle, a major portion (25–75%) of phosphorus of the foliage is translocated to the rooting tissues (cf. review of Granéli and Solander, 1988). Some of this phosphorus store can be permanently interred in senescing root tissues that decompose very slowly in anaerobic sediments.

2. Epiphytic Microbiota

The surfaces of submersed vegetation are colonized with epiphytic microflora. The physiology and growth of attached microflora are coupled to the physical and physiological dynamics of the living substrata upon which they grow. The productivity of epiphytic bacteria and algae is very high (cf. Chap. 19). This community acquires nutrients both from the water within and passing through the littoral zone and from the supporting "host" macrophyte tissues. Although relatively little of the total phosphorus pool within actively growing macrophytes is released, this release can be important to the epiphytes. For example, certain algal species that grow adnate to the macrophyte can obtain over 60% of their phosphorus from the macrophyte (Moeller *et al.*, 1988). Even when phosphorus concentrations are very high in the water, some nutrients are obtained from the macrophyte simply because diffusion within the complex epiphytic community is too slow to meet demands.

The phosphorus of the littoral water is very actively assimilated by the loosely attached epiphytic periphyton, incorporated into the periphyton, and intensively recycled (e.g., Riber and Wetzel, 1987; Wetzel, 1993a). The periphyton, rather than the submersed macrophytes, function as the primary scavenger for limiting nutrients such as phosphorus from the water.

During dormancy phases and senescence of aboveground macrophyte tissues, releases of phosphorus are readily utilized by the periphytic community, which tends to develop profusely during autumn and winter periods. As the senescing macrophytes with their epiphyte communities collapse to the detrital mass near the sediments, much of the released phosphorus is rapidly retained and recycled by epiphytic bacteria and algae (Fig. 13-9) (Wetzel, 1990a, 1993a). Therefore, the attached microflora, particularly that epiphytic on

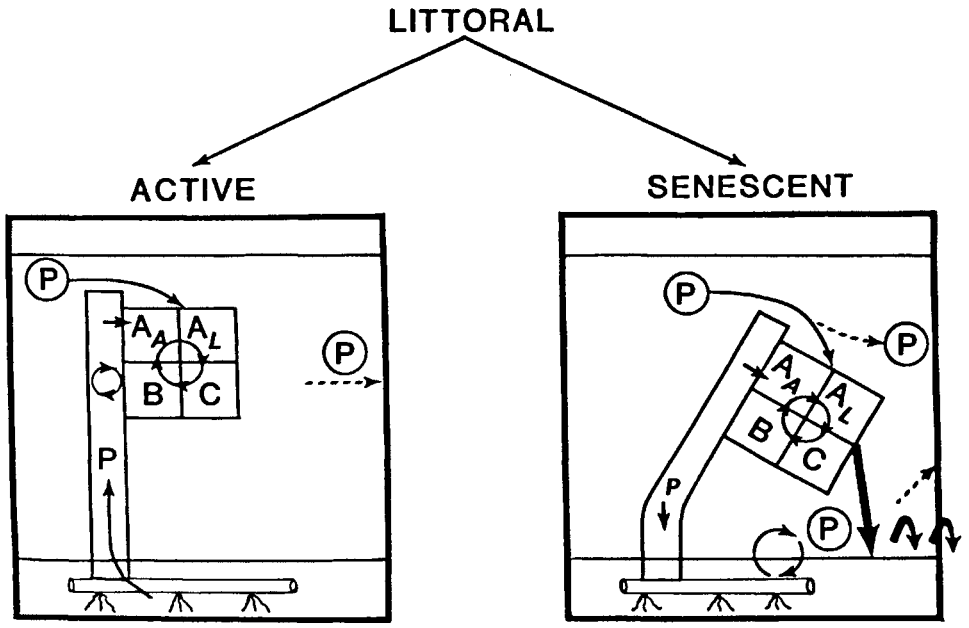

FIGURE 13-9 Fluxes of phosphorus (P) from the sediments to submersed littoral macrophytes and among the epiphytic microflora of the periphyton. A_A = adnate algae; A_L = loosely attached algae, B = bacteria; and C = inorganic or organic particulate detritus, such as calcium carbonate. (From Wetzel, 1990a.)

submersed macrophytes, can function as an effective phosphorus scavenger from the water (e.g., Howard-Williams and Allanson, 1981). The retention capacity is regulated by many environmental parameters and can be exceeded if the loading of phosphorus is very high or the rates of water flushing through this biological sieve is too rapid to allow time for uptake and retention. Rapid water movements through littoral zones, such as by natural storm events (Kairesalo and Matilainen, 1988) or from artificial human-induced runoff (e.g., Adams and Prenkte, 1982), can result in flushing movements of nutrients into the receiving open waters at rates too fast to be retained biologically. Once phosphorus is cycling within the submersed macrophyte–periphyton community, however, it is improbable that much of it will be exported to the open waters.

G. Littoral Phosphorus Fluxes and Loadings

Major sites of phosphorus fluxes in lakes has been examined by dividing them into three general compartments: (a) the pelagic open water and organisms of the epilimnion, (b) the littoral macrophytes and attached microorganisms, and (c) the hypolimnion and sediments. Early tracer experiments employing such compartmental analyses indicated that phosphorus in the epilimnion is extremely mobile (Rigler, 1964). The turnover time of phosphorus in the epilimnion (i.e., the time in which an amount of phosphorus equivalent to the total amount in a compartment leaves that compartment and a similar amount enters it) of a small lake was found to be 3.6 days (Rigler, 1956). Within 20 min of the time it entered, over 95% of the added phosphorus was taken up by the plankton; it had a turnover time of <20 min. In Toussaint Lake, a small acidic lake with a well-developed littoral zone of rooted aquatic plants, the littoral region was the most important contributor to the turnover and retention of phosphorus in the epilimnion; phosphorus was lost to this compartment 10 times more rapidly than to the hypolimnion and sediments and 50 times more rapidly than its loss through the outlet. In comparable experiments in an acidic bog lake in Nova Scotia with extensive developments of littoral *Sphagnum* moss, nearly all of the tracer phosphorus was taken up by the *Sphagnum* and plankton (Coffin *et al.*, 1949; Hayes and Coffin, 1951). Essentially no phosphorus reached the hypolimnion in the short term.

Rate constants of phosphorus loss from the epilimnion cannot be derived from these data. However, reanalyses of the results of several studies indicated that the turnover time of phosphorus in the epilimnion ranged from 20 to 45 days and was inversely correlated with areas of the lakes and estimates of development of the littoral vegetation (Table 13-4). In experimental pond systems with regulated steady-state inputs of phosphorus to and outputs from the epilimnion,

TABLE 13-4 Calculated Rate Constants of Phosphorus Transport in Three Lakes of Differing Littoral Development[a]

Lake	Area (*ha*)	Littoral vegetation (*rank*)	P turnover time (*days*)	Rate constants	
				k (*out of epilimnion*)	*k* (*sedimentation from epilimnion*)
Toussaint	4.7	1	20	0.05	0.01
Upper Bass	5.8	2	27	0.04	—
Linsley Pond	9.4	3	45	0.02	0.02

[a] Modified from Rigler (1973); lakes are ranked in order of decreasing amount of littoral vegetation, subjectively estimated.

filamentous algae of simulated littoral zones were major sites of phosphorus uptake before it reached the epilimnion (Confer, 1972). The equilibrium exchange between phosphorus inputs to or releases from the littoral flora and from or to the epilimnetic water varies with the amounts of phosphorus input from the drainage basin (Chamberlain, 1968).

Phosphorus uptake by and release from senescing littoral macrophytes and attached algae will vary with the physical constraints of littoral development determined, in part, by basin morphometry and water-exchange patterns. This relationship can shift with seasonal changes in active growth of the littoral macrophytes (e.g., Sarvala *et al.*, 1982). The physiology and growth of attached microflora are coupled to the physical and physiological dynamics of the living substrata upon which they grow. By means of intensive recycling of limiting dissolved nutrients and gases to maintain high sustained growth and biomass, losses are minimized and imported external nutrients can be directed primarily to net growth (Wetzel, 1990a, 1993a). Most aquatic plants are perennial with numerous cohorts and continuous growth and turnover, particularly in regions of moderate climate, and littoral growth is more or less continuous (cf. Chap. 18). Thus, the littoral complex of macrophytes and attached microbiota is often a major component of phosphorus retention and exchange with epilimnetic water, but it is constantly changing in the effectiveness of nutrient retention and loading.

H. Benthic Invertebrates and the Transport of Phosphorus

Evidence for how effectively benthic invertebrates can influence the rates and directions of phosphorus exchange between sediments and the water has been controversial. Clearly, these organisms can enhance rates of transport of phosphorus from the interstitial waters of sediments under certain environmental conditions. In other cases, their influences are minor. Examination of the transport mechanisms related to benthic invertebrate activities on phosphorus fluxes need to address (a) feeding activities of the invertebrates, intestinal decomposition, and excretion; (b) feeding and respiratory behavioral activities that alter redox gradients in sediments and phosphorus solubilities; and (c) movement of organisms from the sediment habitat to other habitats with displaced phosphorus release.

Benthic macroinvertebrates are extremely diverse in their feeding, respiratory, growth, and reproductive behaviors. This diversity contributes to the conflicting, inconclusive, and occasionally uncritical conclusions drawn on the effects of organisms on phosphorus and nitrogen fluxes (cf. reviews of Kamp-Nielsen *et al.*, 1982; Andersson *et al.*, 1988). Simply because phosphorus may be transported from interstitial waters to water immediately above the sediments does not necessarily mean that these compounds will be transported in available chemical forms for use in the trophogenic zones of lakes or rivers. One must retain an ecosystem scale perspective in evaluating these fluxes.

Dominant macroinvertebrate groups include the oligochaete worms, amphipods, bivalve mollusks, and immature chironomid midges. All inhabit and feed in the sediments differently (cf. Chap. 22). Oligocheate worms feed shallowly on surface sediments and do not burrow extensively. Amphipods inhabit and feed on the rich microbiota and detrital particles at the sediment–water interface. Bivalve mollusks move through and disturb surficial sediments and filter particles from the water. The chironomid larvae feed on surficial detrital particles or filter particles from water as they inhabit tubes within the sediments. Their undulating body movements transport water in and out of these tubes.

As populations of benthic invertebrates develop, phosphorus is incorporated into the fauna from the organic material fed upon in the sediments. Adsorption or direct assimilation of inorganic phosphorus is

quantitatively insignificant, at least among the microcrustacea (Rigler, 1964). Ingested materials, however, are partially digested and released feces can accelerate the microbial regeneration of nutrients. Direct excretion of dissolved phosphorus, largely as inorganic phosphorus, occurs in small quantities; rates decrease markedly at temperatures below 15°C (e.g., Nalepa *et al.*, 1983; Fukuhara and Yasuda, 1985).

The movement of water by the respiratory and feeding activities of macroinvertebrates is often invoked as a primary means of transporting interstitial water of higher nutrient content from microbial remineralization activities in the sediments to the overlying water. Considerable experimental evidence supports such advective movements of water and particles mediated by benthic animals [***bioturbation*** (Aller, 1982)]. For example, chironomid midge larvae can cause increases in the phosphorus content of the overlying water (Gallepp *et al.*, 1978; Gallepp, 1979; Fukuhara and Sakamoto, 1987). Larger species cause a greater effect. The release of total phosphorus increased approximately linearly (0.3–9.4 mg P m^{-2} d^{-1}) over a range of 0–6585 larvae m^{-2}. In contrast, Davis *et al.* (1975) showed that tubificid worms only slightly influenced phosphorus release and may actually enhance phosphorus deposition at the sediment–water interface. Most of the phosphorus released to the overlying water was as soluble reactive phosphorus, which is readily inactivated chemically under oxidizing conditions or is readily assimilated by bacteria (Johannes, 1964a,b) or algae if light is available. Under oxygenated conditions of the sediment–water interface, only when larval invertebrate densities reach extreme levels (e.g., >100,000 m^{-2}; Lindegaard and Jnasson, 1979; Wisniewski, 1991) do their activities influence the transport of phosphorus across the sediment–water interface.

The role of macroinvertebrate activity at the sediment–water interface is unclear in relation to the transport of phosphorus to the water. Ciliates associated with the sediments are capable of hydrolyzing dissolved organic acids and releasing inorganic phosphate to the water (Hooper and Elliot, 1953). Low oxygen concentrations, however, not only produce an unfavorable environment for most ciliates but also inhibit the release of phosphate by the cells.

Negatively phototactic cladoceran and mysid zooplankton, which migrate to the sediment interface region during daylight, presumably feed actively on the rich microbiota of that region (e.g., Kasuga and Otsuki, 1984). The extent of phosphorus transport to the epilimnion during their subsequent nighttime migration is unknown but worthy of further investigation. Although the experimental addition of snails and ostracod microcrustacea to the sediments altered plankton abundance in ponds, these benthic organisms produced no corresponding changes in uptake rates of phosphorus in open water (Confer, 1972). When benthic invertebrates emerge as adults, they may emigrate from the sediments, thereby transporting phosphorus to other compartments of the ecosystem. For example, in streams a significant upstream migration of phosphorus by fish and invertebrates has been found (Ball et al., 1963a, 1963b). However, this displacement of phosphorus by invertebrates plays only a small part in the overall quantitative cycling of phosphorus in aquatic ecosystems.

I. Contributions of Birds and Fishes to Nutrient Loadings and Cycling

Vertebrate excreta, particularly of birds, are well known to import large quantities of nutrients, especially nitrogen and phosphorus, to inland waters. A particularly comprehensive treatise on the biogeochemistry of vertebrate excretion and global deposits and fluxes has been prepared by Hutchinson (1950). Clearly, nutrient loadings from waterfowl can be large as well as highly variable seasonally in relation to behavioral and migratory patterns of the use of rivers, wetlands, and lakes. A few examples illustrate the potential magnitude of nutrient loadings. In Wintergreen Lake, southwestern Michigan, Canada geese and ducks contributed 69% of all carbon, 27% of all nitrogen, and 70% of all phosphorus that entered the lake from external sources (Manny *et al.*, 1975, 1994). In a small kettle seepage lake of Massachusetts, nearly half the annual loading of phosphorus resulted from two species of gulls (Portnoy and Soukup, 1990). Up to 37% of the annual inputs of nitrogen and 95% of phosphorus of the largest natural lake in France, Grand-Lieu, emanate from large concentrations of resident and migratory birds (Marion *et al.*, 1994). Many other examples exist, but eutrophic conditions uniformly result from such high external loadings. Waterfowl loadings must be incorporated into nutrient load–response models, as proposed by Manny *et al.* (1994), in order to accurately evaluate levels of eutrophication under high bird-use environments.

Fish can impact the distribution of phosphorus and nitrogen in aquatic ecosystems in several ways. As we will see in subsequent discussions, the total amount of phosphorus in fish communities is small in comparison to other inorganic and organic pools in the lake ecosystem (water, littoral zone, sediments, and dissolved and particulate organic matter). However, fish activities can promote and accelerate the transport of phosphorus and nitrogen from sediments to overlying water.

Particularly, the feeding activities by benthic fishes, such as carp and bullheads (*Ictalurus*), can disturb sediments and increase diffusion to overlying waters (e.g., Lamarra, 1975; Keen and Gagliardi, 1981; Schaus *et al.*, 1997). Some phosphorus and nitrogen, obtained from food and detrital sources in the sediments, can be transported into upper strata of lakes and a portion released as soluble phosphorus and ammonia and urea nitrogen with urine and feces. When external loadings to lakes are small, as in dry summer periods, these internal redistributions can be important for planktonic algae and other microbiota (Brabrand *et al.*, 1990). Similarly in streams, fish-derived nitrogen and phosphorus can be moved upstream for large distances by migrating fishes and subsequently released and recycled for use by microbiota, algae, and macroinvertebrates (Schuldt and Hershey, 1995). Feeding history affects the N:P ratios of fish excrements. For example, rates of phosphorus excretion decreased more rapidly after feeding than those of nitrogen, and hence the N:P ratio of excrement increased with time from feeding (Mather *et al.*, 1995).

As discussed earlier, fish predation-induced shifts in the size structure of zooplankton communities can alter rates of sedimentation of seston from the epilimnetic trophogenic zone. Thus, loss rates of phosphorus via sedimenting seston can decline somewhat with a shift by predation to smaller-sized plankton (Mazumder *et al.*, 1989, 1992; cf. also Kairesalo and Seppälä, 1987; Pérez-Fuentetaja *et al.*, 1996). These effects appear to be significant only in very oligotrophic lakes.

Other large vertebrates can influence phosphorus and other nutrient loadings to small waters. For example, hippopotamuses graze on land at night and defecate considerable amounts of leachable phosphorus into lakes during the day (Kilham, 1982).

V. PHOSPHORUS CYCLING WITHIN THE EPILIMNION

The classical studies of Einsele (1941) and many subsequent theoretical and applied analyses of the circulation and fate of phosphorus in the open water of the epilimnion have shown that phosphorus is very rapidly incorporated into planktonic algae and bacteria. Recent study has focused on rates of movement of phosphorus among biologically important forms in lake water. Two broad classes of investigations have resulted: (1) biotically mediated phosphorus-transfer mechanisms and (2) abiotic complexation reactions. The former includes studies on the transfer of phosphorus among seston and various forms of dissolved phosphorus, including the biotically mediated formation of colloidal phosphorus and the enzyme-mediated utilization of dissolved phosphate esters. The latter category includes studies on the sorption and desorption of phosphorus to dissolved humic compounds, colloidal calcium carbonate, and other particles.

The analyses of Rigler and his co-workers have generated a framework that has stimulated considerable further study of phosphorus dynamics (Lean, 1973a, b; Lean and Rigler, 1973; Rigler, 1973). Lean proposed a quantitative, steady-state model of phosphorus exchanges in epilimnetic water in the summer, with the following composition (Fig. 13-10): (a) *particulate phosphorus,* the fraction removed when the water is filtered through a 0.5-μm pore-size filter, which contains the bulk of the phosphorus; (b) reactive inorganic *soluble orthophosphate* (PO_4^{3-}), which has an extremely short turnover time; (c) a *low-molecular-weight* (approximately 250 D) *organic phosphorus compound* (XP); and (d) a soluble macromolecular *colloidal phosphorus* of a molecular weight >5,000,000 D. An exchange mechanism predominates between the inorganic phosphate and the particulate fraction, but some phosphorus is excreted by the microorganisms in the form of the low-molecular-weight compound (XP). Polycondensation of the low-molecular-weight compound (XP) produces the high-molecular-weight colloidal compound. Both fractions, but primarily the latter, release phosphate in the soluble inorganic fraction, which then becomes available to the plankton.

The rate constants shown in Figure 13-10 demonstrate the rapidity of phosphorus dynamics in this algal–bacterial compartment for an exemplary lake in midsummer:

(a) k_1, the uptake of PO_4 = 0.9 relative mass units min^{-1} or 0.002 μg $liter^{-1}$ min^{-1} of total biologically active phosphorus. Some PO_4 is adsorbed to sestonic particulate detritus by physical–chemical processes (Rijkeboer *et al.*, 1991).

(b) k_2, the release of XP, and k_3, the binding of XP by condensation to colloidal P = 0.022 min^{-1}. The excretion of extracellular organic phosphorus compounds is well known among marine and freshwater algae during periods of rapid growth and during senescence (Kuenzler, 1970; Fogg, 1971; Lean, 1973a; Tarapchak and Herche, 1985).

(c) k_4, hydrolysis of colloidal P to PO_4 = 0.0017 min^{-1}. After the rapid formation of colloidal P via XP, in <2 min, subsequent additions of XP displace P from the colloid, again making the soluble inorganic PO_4 form available for uptake. Both colloidal P and XP fractions are not readily utilized as direct phosphorus sources by microorganisms, and they resist rapid attack from enzymes capable of hydrolyzing the most com-

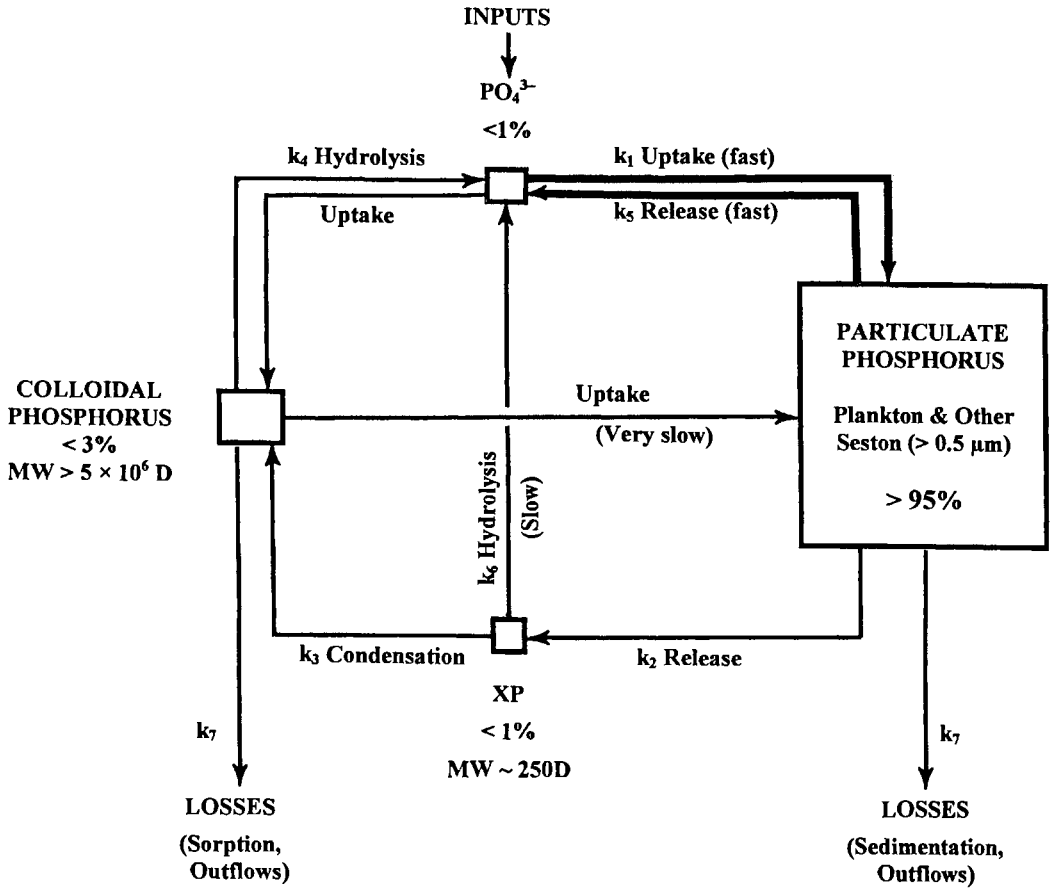

FIGURE 13-10 Phosphorus movement within the epilimnetic openwater zone of lakes, elucidating the exchange mechanisms between the phosphate and the particulate fractions. (Modified and expanded from Lean, 1973a,b.)

mon organic phosphorus compounds (Olsson and Jansson, 1984).

(d) k_5, the release of inorganic PO_4 by the particulate seston, was found to be very much greater than excretion of soluble organic phosphorus (XP). Mass balance calculations showed that k_5 is about 70 times k_2.

(e) k_6, the direct hydrolysis of XP to PO_4, was insignificant in comparison to release via the colloidal form.

(f) k_7, the rate constant for the loss of colloidal phosphorus, is small relative to the other rate constants. However, further aggregation of the colloidal fraction to particulate form or sorption to particulate matter followed by sedimentation represents a phosphorus sink from the epilimnion. Similarly, sedimentation of particulate phosphorus represents a slow but continuous loss from the epilimnion. Thus, during active growth of algae and heterotrophic bacteria, phosphorus must be continuously replaced through input from influents or from the littoral zone or recycled by zooplankton ingestion and subsequent excretion (see following discussion). In experimental systems, much of the colloidal fraction settles out and becomes biologically unavailable after one to five days. Other workers, however, have shown that high-molecular-weight colloidal phosphorus compounds can be used directly as a phosphorus source by algae possessing alkaline phosphatase enzymatic activity (Paerl and Downes, 1978). These rates of particulate loss are congruous with those found in natural waters to which phosphorus additions have been made.

From these initial insights and subsequent studies into the cycling of phosphorus in the open water, it is apparent that sestonic organic phosphorus must be separated into at least two fractions: (a) A rapidly cycled fraction, which is exchanged with soluble forms. In this fraction, phosphate is transferred rapidly through the particulate phase to low-molecular-weight compounds. (b) A fraction of the sestonic phosphorus that is released more slowly. The transfer of colloidal phosphorus material from the phytoplankton to the water

appears within minutes after uptake of soluble phosphate by bacteria and algae (Lean and Nalewajko, 1976; Paerl and Lean, 1976; Cembella *et al.*, 1984). In addition to the formation of high-molecular-weight fibrillar and amorphous particles of colloidal size (0.05–0.1 μm), bacteria and algae excrete significant amounts of dissolved organic phosphorus compounds. As discussed later, the uptake of phosphate is greater by bacteria than algae, but since algal biomass is greater than bacterial biomass, algal phosphate incorporation usually dominates uptake and release pathways in the epilimnion.

The uptake and turnover kinetics of phosphorus have been studied in a number of lakes of low to high productivity and at different seasons of the year (Table 13-5). Phosphorus turnover rates are extremely rapid in the summer periods of high demand and relatively low loading inputs but become as much as two orders of magnitude slower during the winter periods. Phosphorus turnover rates are faster under more oligotrophic conditions of greater phosphorus deficiency (e.g., Peters, 1979; Cembella *et al.*, 1983, 1984).

Phytoplankton contain many complex phosphorus esters (e.g., sugar phosphates, nucleotide phosphates, and polyphosphates). These low-molecular-weight phosphorylated compounds can be released to fresh water upon cell death or by active release by microorganisms (Berman, 1970; Kuenzler, 1970). A very large portion (>50%) of the phosphorus content of algal cells can be lost during sedimentation over a period of several days (Otto and Benndorf, 1971). In the Lean model (Fig. 13-10), direct enzymatic hydrolysis of low-molecular-weight XP fractions is presumed to be negligible. In reality, more complex phosphorus regenerative mechanisms likely exist.

Enzyme-mediated hydrolysis of naturally occurring phosphate esters is one of the most plausible mechanisms for phosphorus regeneration in the epilimnion.

TABLE 13-5 Turnover Times of Phosphate in Fresh Waters[a]

Lake	*Turnover times (min)*	*Source*
Lago Maggiore, Italy		
Epilimnion, summer	10–200	Peters (1975)
Epilimnion, winter	200–10,000

Summer	60–4800	
Winter	100–72,000	

[a] The turnover time is the reciprocal of turnover rate, which is the fraction of phosphate incorporated by the seston per unit time.

Direct enzymatic breakdown of dissolved inorganic phosphorus compounds and polyphosphates to dissolved inorganic phosphorus by relatively nonspecific phosphatase (phosphomonoesterase) activity has been the subject of intensive study. Numerous investigations demonstrate that membrane-bound algal phosphatase activity increases as phosphorus deficiency becomes acute. Increases in alkaline phosphatase activity (APA) under conditions of phosphate limitation, either from increased rates of enzyme synthesis or from derepression of preexisting enzyme, can enhance algal competitive ability by permitting algae to utilize organophosphate or inorganic polyphosphate substrates as alternative phosphorus sources (e.g., Berman, 1970; Jones, 1972; Heath and Cooke, 1975; Jansson, 1976; Stevens and Parr, 1977; Pettersson, 1980; Wetzel, 1981; Jansson *et al.*, 1988; Wynne and Rhee, 1988; Boon, 1994; Newman *et al.*, 1994). Although free, dissolved, alkaline phosphatase is short-lived (Reichardt *et al.*, 1967; Pettersson, 1980), substantial quantities of APA (often in excess of 50% of the total) can be found in dissolved phase (Pettersson, 1980; Wetzel, 1981; Stewart and Wetzel, 1981b; Cotner and Heath, 1988; Rai and Jacobson, 1993). The importance of phosphatase activity to phosphorus cycling in lakes is further confounded because bacterial production of alkaline phosphatase occurs in pelagic environments (Jones, 1972) but need not be induced strictly by phosphate limitation (e.g., Wilkins, 1972; Christ and Overbeck, 1987; Jansson et al., 1988). Several different types of phosphatases are released by higher organisms, such as zooplankton (Wynne and Gophen, 1981; Boavida and Heath, 1984). Their functions, particularly in phosphorus recycling and growth alterations of food sources, are unclear.

The enzyme 5′-nucleotidase catalyzes the hydrolysis of phosphoryl groups from 5′-nucleotides, such as ATP, from the dissolved organic phosphorus pool in natural waters (Ammerman and Azam, 1985, 1991a,b; Tamminen, 1989; Cotner and Wetzel, 1991b; Bentzen and Taylor, 1991). Although the synthesis of the external enzyme alkaline phosphatase, just discussed, is often repressed in high phosphate environments, 5′-nucleotidase is not. Greater 5′-nucleotidase activity has been associated with bacterial-size small microbiota (<1 μm), particularly in environments low in dissolved organic phosphorus concentrations. In high-phosphate environments, most of the phosphate regenerated by 5′-nucleotidase is not assimilated immediately. In comparisons of the different enzyme activities and rates of hydrolysis of different organic compounds, 5′-nucleotidase activity was found to have greater relative importance to phosphorus cycling in an oligotrophic lake than in a moderately eutrophic lake (Cotner and Wetzel, 1991b). The data suggested that nucleotidase activity may be more important to phosphorus regeneration in oligotrophic habitats than phosphatase activity.

Soluble APA and APA associated with algae and nonalgal particulate matter are highly variable seasonally and spatially (Wetzel, 1981; Stewart and Wetzel, 1981b; Cotner and Wetzel, 1991a; Wetzel, 1991). Epilimnetic APA is commonly high during the spring and summer periods of maximal phosphorus demand. During years when spring circulation is incomplete or a lake experiences temporary meromixis, extremely high APA and phosphorus limitations were found in the phytoplankton during spring and summer months (Wetzel, 1981).

Phosphomonoesters (PME) were found in lake water in substantial quantities (up to 55 μg PME-P liter^{-1} in eutrophic Twin Lakes, Ohio; Heath and Cooke, 1975). An inverse relationship was found between PME concentrations and APA during summer stratification. Potential hydrolysis rates of PME of >0.05 mmol per hour by APA were found. These values are similar to those found in marine systems using algal alkaline phosphatase as the hydrolytic enzyme (Rivkin and Swift, 1980). These results, in addition to widely differing chemical analyses of the complex phosphorus pool in lake water (e.g., Lean, 1973a, b; Lean and Nalewajko, 1979; Paerl and Downes, 1978; Downes and Paerl, 1979; Francko and Heath, 1979, 1981, 1982; Boavida and Marques, 1995), suggest that the composition of the soluble phosphorus pool varies greatly among different lake types. Although some lakes may approach the model of phosphorus cycling presented in Figure 13-10, other lakes may possess a phosphorus cycle dominated by the production and biotically mediated hydrolysis of PME.

Physicochemical mechanisms can also influence the cycling of phosphorus and, as a result, affect primary productivity. Certain complex humic materials of both low and high molecular weights contain phosphorus, such as phosphate esters and inositol hexaphosphate (e.g., Anderson and Hance, 1963; Koenings and Hooper, 1976). High-molecular-weight humic compounds can be photoreduced by low-intensity ultraviolet light such as occurs in sunlight (Francko and Heath, 1979; Stewart and Wetzel, 1981a). Orthophosphate adsorbed to ferric-humic compounds can be released by UV-induced photoreduction of ferric iron (Francko and Heath, 1982; Jones *et al.*, 1988). Low-molecular-weight humic compounds can release orthophosphate upon exposure to alkaline phosphatase.

Phosphorus–humic complexes can interact with phytoplankton and bacterioplankton in complex ways. For example, rates of carbon assimilation by

phytoplankton were reduced when the algae were exposed to low concentrations of dissolved humic materials of littoral and wetland origin (Stewart and Wetzel, 1982). The effects were species-selective and greatest among smaller (1–5 μm) phytoplankton growing under low light conditions. The production of alkaline phosphatase activity was greatly stimulated by low concentrations of dissolved humic compounds of low molecular weight. Evidence indicates that these humic materials can act as sequestering agents for phosphate ions, organophosphorus compounds, and iron, thereby reducing phosphorus and possibly iron availability to phytoplankton (Jackson and Hecky, 1980; Chow-Fraser and Duthie, 1983; Jones *et al.*, 1988, 1993; de Haan *et al.*, 1990; Münster, 1994; Shaw, 1994). These relationships can be important to both phosphorus cycling and phytoplankton productivity, for major rain events can simultaneously introduce substantial quantities of phosphorus and dissolved humic materials into the pelagial areas of small and moderate-sized lakes.

Additionally noteworthy is that in acidified lakes where aluminum [Al(III)] and iron [Fe(III)] concentrations can be markedly increased, production of acid phosphatases is enhanced (Jansson, 1981). Although the Al(III) and Fe(III) at low pH do not affect the enzymes directly, the metal ions combine with the phosphate group on the substrate and inhibit enzymatic hydrolysis. The organisms may compensate, at considerable energetic cost, for these losses by increased production of phosphatases.

A. Phosphorus Losses by Outflow, Inactivation, and Sedimentation

Accurate nutrient budgeting in a lake or river ecosystem requires quantification of routes of reduced availability for utilization by biota as well as direct losses. Direct ***losses*** by movement with water ***in outflows*** from lakes and rivers occurs in inorganic and organic dissolved and particulate forms. Knowledge of concentrations and discharge volumes allows reasonably accurate evaluations of losses by outflow. Losses by seepage through the sediments, particularly sediments near the shore line, are quite variable (cf. Chap. 4). However, in most lakes, the basin seal is relatively complete and seepage outflows are small in relation to surface outflow. Most of the losses of phosphorus by seepage is via dissolved inorganic and organic compounds.

Sedimentation of nutrients occurs in settling (a) living and dead biota and (b) inorganic particles that are imported to the water from the catchment or are formed within the water and sorb nutrients. As particles settle to the bottom, they can experience partial decomposition and microbial recycling of nutrients to the water or encounter altered chemical conditions that change nutrient sorptive properties of the particles. Once at and within the sediments, periodic resuspension occurs, particularly at times of complete water circulation, during which several centimeters of the surficial sediments can be resuspended into the water column (e.g., Davis, 1973; White and Wetzel, 1975).

Most surface waters of the world are bicarbonate-dominated and many, perhaps a quarter of lakes, are very hard waters with sufficient bicarbonate and calcium to experience periodic precipitation of $CaCO_3$ (cf. chaps. 10 and 11). Precipitation is induced and accelerated by high pH, and these conditions are often associated with microzones adjacent to rapidly photosynthesizing cells of the phytoplankton, attached algae, and submersed macrophytes (Otsuki and Wetzel, 1972, 1974; House and Donaldson, 1986). Much of the phosphorus associated with the $CaCO_3$ is adsorbed onto the crystals; a small portion is incorporated by coprecipitation into the growing crystals. Inhibitors of $CaCO_3$ growth such as magnesium and iron reduce the amount of phosphorus coprecipitated on calcite (House *et al.*, 1986).

The morphology of calcite crystals can change markedly under different environmental conditions (Koschel, 1990, 1997; Raidt and Koschel, 1993). In particular, the complexity of the crystals increases with increasing supersaturation, and they shift from rhombohedral to complex dendritic and columnar crystals (Fig. 13-11). As the crystal complexity increases, the adsorptive surfaces also increase and are potentially more effective in the removal of nutrients and dissolved organic compounds.

Because phosphorus is coprecipitated with and adsorbed to nucleating $CaCO_3$, the process of formation and sedimentation of $CaCO_3$ can markedly alter phosphorus availability to biota. For example, about 35% of the annual total phosphorus removal from the epilimnion of Lake Constance in southern Germany was associated with autochthonous calcite precipitation (Kleiner, 1988), some 25% in eutrophic Wallersee of Austria (Jäger and Röhrs, 1990), and about 30% in hypereutrophic Onondaga Lake of central New York (Effler *et al.*, 1996). In hypereutrophic prairie lakes, very high concentrations of phosphorus are stripped from the epilimnetic waters by periodic precipitation of $CaCO_3$ (Murphy *et al.*, 1983).

B. Phosphorus and Nitrogen Uptake and Recycling by Protists and Zooplankton

As we have seen, the phosphorus content of bacteria is about 10 times that of the algae. Bacteria are

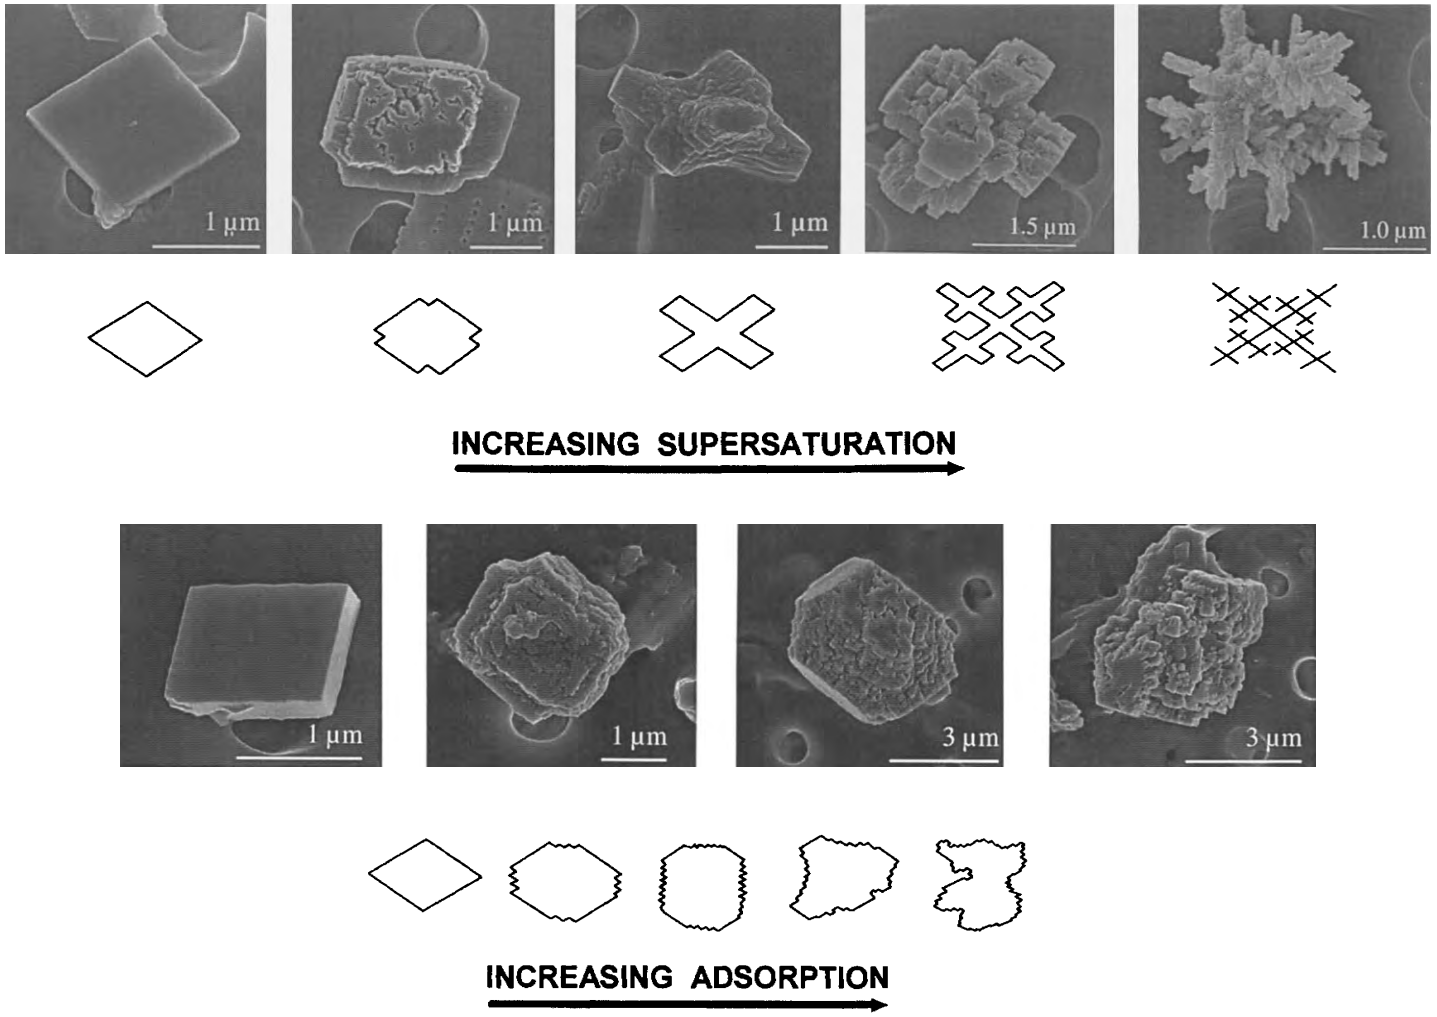

FIGURE 13-11 Calcite crystals from hardwater lakes under differing conditions of chemical saturation. Marked alterations of surface areas and adsorption also occur with changing morphology of the sedimenting crystals. (Photomicrographs courtesy of Prof. R. Koschel, Neuglobsow, Germany.)

commonly responsible for 80% or more of the net uptake of phosphorus (Hessen and Andersen, 1990; Jürgens and Güde, 1990; Vadstein *et al.*, 1993, 1995). Bacteria are often unable to achieve phosphorus saturation and thus compete vigorously with algae for inorganic phosphate.

Many studies have examined the ingestion of algal and bacterial particles by macrozooplankton and the potential regeneration of phosphorus by the feeding activities and from excreted feces, as discussed next. It should be emphasized that such uptake and excretion of phosphorus and other nutrients is a *recycling* process, not a *de novo* source of nutrients. The digestive and metabolic processes alter the storage time of the nutrients already in the ecosystem and potentially render it more available for reuse by other organisms.

Where the uptake and recycling by heterotrophic microflagellates were compared to the large zooplankton, the heterotrophic flagellates feeding on phosphorus-rich bacteria regenerated two-thirds or more of the phosphorus released by grazers (Jürgens and Güde, 1990; Vadstein *et al.*, 1993, 1995). Phosphorus and nitrogen regeneration rates varied, however, among fast- and slow-growing species of heterotrophic flagellates (Eccleston-Parry and Leadbeater, 1995) and were much higher during exponential growth phases than during stationary growth phases (Andersen *et al.*, 1986; Nakano, 1994a; Ferrier-Pagès *et al.*, 1998). A portion of the bacteria senesce and lyse and thereby release nutrients. However, many of the bacteria function as consumers of phosphate, because of their high requirements for phosphorus, and thus serve as phosphorus-rich particles for feeding by flagellates, other protista, and larger zooplankton. The release rates of phosphorus from the bacterivorous feeding of flagellates can account for major recycling sources for phytoplanktonic primary production (e.g., Miyajima, 1992; Rothhaupt, 1992; Nakano, 1994b; Sterner *et al.*, 1995). This recycling by planktonic consumers can be a significant source for the growth of bacteria and algae, particularly late in the summer period of stratification.

The uptake of nutrients, particularly phosphorus and nitrogen, by ingestion of food particles by herbivorous zooplankton and protists can be large at certain times of the year (cf. Chap. 16). During egestion and subsequent leaching from feces, nutrient release occurs in the form of soluble phosphate ions (>70% of dissolved P), ammonium nitrogen (>80% of dissolved N), and some organic phosphorus and nitrogen compounds, particularly urea (usually <10% of dissolved N) (Vargo, 1979; Lehman, 1980a; Mitamura and Saijo, 1980; Madeira *et al.*, 1982; Lenz *et al.*, 1986; Urabe, 1993; Ferrier-Pagès and Rassoulzadegan, 1994; Nakano, 1994a, b; Goma *et al.*, 1996; Ferrier-Pagès *et al.* 1998). The release rates are highly variable, but the rates of N release from crustacean zooplankton (range, 0.2–2 μg N mg DW^{-1} h^{-1}) increased with increasing food abundance, whereas the rates of P release (0.05–0.3 μg mg DW^{-1} h^{-1}) and N:P release ratios were affected directly by the N:P ratio of the food. Release rates of ammonium N were similar per unit biomass for ciliates and phagotrophic flagellates.

When prey food organisms were saturated with phosphorus, release rates from grazing zooplankton were in the range of 1.1–1.5 μg P (mg DW)$^{-1}$ h^{-1} (Olsen and Østgaard, 1985; Lehman and Naumoski, 1985; Jürgens and Güde, 1990; van Donk *et al.*, 1993). When planktonic bacteria and algae are phosphorus-starved and contain less phosphorus, however, release rates from grazers are about 0.05 μg P (mg DW)$^{-1}$ h^{-1}, <5% of the rates under P-sufficient conditions. Detrital particles were also found to contain very low concentrations of phosphorus (Olsen *et al.* 1986).

Appreciable quantities of phosphorus, nitrogen, and carbon remain in the particulate fecal materials and dead zooplankton that settle out of the water column. Loss rates of nitrogen or phosphorus from molting or dead crustacean and rotifer zooplankton were the most rapid (>2% per hour) during the first 24 hr following death (Krause, 1961, 1962; Scavia and McFarland, 1982; Ravera and Gatti, 1993). Thereafter, rates of nutrient and carbon losses decreased but usually >75% was lost in the subsequent six days. Release rates were somewhat faster in the warmer water strata than in the hypolimnion.

The quantitative significance of these sources of nutrient from micro- and macrozooplankton to phytoplanktonic productivity is unclear. Where examined carefully, zooplanktonic excretion of nitrogen likely constitutes only a few percent (<5%) of that required for gross production on an annual basis. Recycling of phosphorus could be appreciably higher, particularly during certain periods of extensive zooplanktonic grazing. The difficulty is that very few quantitative measurements of rates of nutrient regeneration by bacteria, protists, and other processes (e.g., photolysis) have been examined simultaneously with the estimates of release from zooplankton. For example, in eutrophic Lake Loosdrecht in summer, <30% of the phosphorus required by phytoplankton emanated from zooplankton excretion (Oude and Gulati, 1988). Most regeneration of phosphorus resulted from excretion and release from bacteria and algae.

To ignore nutrient regeneration by rotifers and protists as insignificant in comparison to cladocerans is not warranted. Although the individual biomass of the smaller organisms is less by two-thirds to an order of magnitude or more, densities are often several orders of magnitude greater than those of cladocerans. Specific excretion rates are generally higher as biomass de-

creases (Taylor, 1984). Estimates indicate that microconsumer protists and rotifers can regenerate 50% or more of the total phosphorus and nitrogen that is regenerated by the total zooplankton community (Ejsmont-Karabin, 1983; Lenz *et al.*, 1986; Gulati *et al.*, 1988; Oude and Gulati, 1988; Taylor and Lean, 1991).

Nutrients released by zooplankton are rapidly reassimilated by phytoplankton. Under certain circumstances, when the concentrations of phosphorus in the trophogenic zone are low, phosphorus and nitrogen regenerated by the herbivorous zooplankton can constitute a significant portion of the phosphorus and nitrogen requirements of the algae (reviewed by Lehman, 1980a,b; Gulati *et al.*, 1995). For example, based on nutrient budgets and *in situ* measurements, epilimnetic zooplankton in Lake Washington recycle 10 times more phosphorus and 3 times more nitrogen to the surface-mixed layer during the summer months (June to September) than enters from all external sources combined. Examples of the rates of regeneration of phosphate and ammonia by zooplankton are given in Table 13-6.

The magnitude of nutrient uptake and recycling depends on the nutritional status of the algal cells (Lehman, 1980a; Blažka *et al.*, 1982). Compared with

nutrient-sufficient cells, nutrient-deficient algal cells assimilated phosphate and ammonia more rapidly and exhibited lower rates of remineralization.

Zooplankton grazing accelerates rates of phosphorus and nitrogen regeneration. It is also probable that planktonic bacteria, particularly less than 1 μm in size, and very small algae immediately sequester released phosphorus (Dodds *et al.*, 1991). Even though average phosphorus (and often combined nitrogen) concentrations in the epilimnion can be low, the release of nutrients from zooplankton can cause a microheterogeneous patchiness of nutrient concentrations, since the zooplankton distribution is far more clumped than the phytoplankton distribution.

Less clear is the importance of nutrient recycling to the overall rates of algal productivity on an annual basis. Removal of algae and bacteria by grazing zooplankton fluctuates widely on a seasonal and spatial basis (Chap. 16). Moreover, grazing of algae is often size-selective. This selectivity may enhance the availability of nutrients to those algae that are not as effectively grazed. For example, assimilation rates of phosphorus by various dissolved and particulate fractions and different zooplankton species were examined in a mesotrophic lake (Lyche *et al.*, 1996). The microconsumers (<20 μm) exhibited the largest specific phosphorus assimilation (0.28 day^{-1}) and regenerated about 45% ***of assimilated*** phosphorus. The larger microcrustacea, such as *Daphnia,* acted largely as sinks for phosphorus, whereas the cyclopoids regenerated rapidly the small amounts of phosphorus assimilated because of their active feeding on the microconsumers. The zooplankton contributed significantly to sedimentation of phosphorus at this time of the year (late summer) (ca. 1% day^{-1}).

The interactions are furthermore complicated by seasonal patterns of selective predation on zooplankton by planktivorous fishes. As indicated in Chap. 15, planktivorous predation often results in reductions in zooplankton size and therefore grazing rates on phytoplankton. The smaller zooplankton can have higher biomass-specific excretion rates of phosphorus than larger zooplankton (Vanni and Findlay, 1990). Although fish excretion of phosphorus is large per unit biomass, the collective biomass is very small (see Chap. 16). In other studies, rates of phosphorus release from pelagic zooplankton were reduced during June and July when fish predation reached its seasonal maximum and allochthonous supplies were at seasonal lows (Bartell and Kitchell, 1978; Schindler *et al.*, 1993).

Finally, it must be recalled that most of the phosphorus is bound in particulate matter: algae, bacteria, and detritus. Rates of nutrient regeneration from these sources as the phytoplankton senesce and die are poorly understood. Certainly, these organisms with short generation times rapidly recycle nutrients in the trophogenic zone before they settle to lower depths. The relative magnitude of their recycling to that of the zooplankton is not clear, but is variable both spatially, seasonally, and diurnally (Schindler *et al.*, 1993). Zooplankton grazing and concomitant nutrient recycling can enhance rates of primary productivity and algal growth during periods when heavy nutrient demands exceed loading inputs to the trophogenic zone from external sources.

VI. ALGAL REQUIREMENTS FOR PHOSPHORUS

Compounds containing phosphorus influence nearly all phases of metabolism, particularly in the energy transformation of phosphorylation reactions during photosynthesis (Rao, 1997). Phosphorus is required in the synthesis of nucleotides, phospholipids, sugar phosphates, and other phosphorylated intermediate compounds. Further, phosphate is bonded, usually as an ester, in a number of low-molecular-weight enzymes and vitamins essential to algal metabolism.

The importance of phosphorus in algal physiology is of special interest to the limnologist because phosphorus is the least abundant element of the major nutrients required for algal growth in a large majority (ca. 75%) of fresh waters. Furthermore, the most important form of phosphorus for plant nutrition is ionized inorganic PO_4. Although algae can utilize organic phosphate esters, such as glycerophosphates, this ability is variable among species, as is their ability to obtain phosphate groups enzymatically or by release of exoenzymes to the water for catalytic dissociation (see reviews of Krauss, 1958, Provasoli, 1958, and Overbeck, 1962a, 1963; Cembella *et al.*, 1984). Most phosphorus released to the water during active growth of algae is inorganic soluble phosphate and organic esters, which are, in turn, very rapidly recycled. During cell lysis and decomposition, most of the algal phosphorus released is organic and undergoes bacterial degradation (Kraus, 1964).

A. Phosphate Uptake and Light

The uptake of phosphate from the water is influenced by numerous external factors. Among many algae studied in culture, the initial absorption of phosphate and subsequent uptake are greater in the light, especially under CO_2 limitation. The result is a reversible accumulation of cellular phosphate, much of which can be released to the medium. Natural algal populations are more or less synchronized in their pro-

ductive and growth cycles, and protein synthesis predominates in the initial portion of the daily light cycle (Soeder, 1965). In the green alga *Scenedesmus,* release of phosphate from the algae has been found to be greatest during the latter portion of the light period, both prior to and during cell division in the dark (Overbeck, 1962).

Absorption of phosphate per cell in the light is generally dependent on phosphorus concentration in the medium, within a range that is rather specific for a given algal species. Natural algal and bacterial populations, however, adapt to phosphorus-limited environments by synthesizing uptake enzymatic systems (half-saturation constants) of at least an order of magnitude below those detected in culture conditions (Tarapchak and Herche, 1986). Uptake by phosphorus-deficient cells in the dark is independent of phosphate concentrations (Kuhl, 1962, 1974). When phosphate is supplied in excess, the phosphorus content per cell remains nearly constant; the amount in excess of physiological needs is often incorporated and stored as polyphosphates (Zaiss, 1985). Nitrogen and carbon limitation can lead to intensive polyphosphate production, and such phosphate accumulation is stimulated by calcium (Siderius *et al.,* 1996). When phosphate concentrations become limiting, production of the polyphosphate-forming enzyme, polyphosphate kinase, decreases and the phosphate stores can be degraded in the light.

Phosphorus absorption rates are quite specific to groups of algae and often to species within a genus. Whereas nitrate absorption is independent of phosphate concentrations, optimal growth of many algae occurs at higher concentrations of phosphate when nitrate, rather than ammonia, is the nitrogen source. For example, studies of growth of the natural phytoplankton communities under gradients of nutrients indicated that diatoms were superior competitors for phosphorus and dominated at high silica-to-phosphorus ratios (Kilham, 1986; Tilman *et al.,* 1986). Green algae dominated at low Si:P ratios. In another example, phosphate uptake and transport through the cell membrane, the rate-limiting step, by cyanobacteria is strongly regulated by cation concentrations, particularly Ca^{+2} and Mg^{+2} (Falkner *et al.,* 1980; Budd and Kerson, 1987). Thus, phosphate uptake by cyanobacteria should be favored in hard waters with an abundance of divalent cations.

B. Phosphate Uptake and pH

Many species of algae exhibit optimal growth and uptake of phosphorus within a distinct range of pH of the medium. The pH may alter rates of phosphate absorption by direct effects on the activity of enzymes, on the permeability of the cell membrane, or by changing the degree of phosphate ionization. For example, uptake of phosphorus by the diatom *Asterionella* is greatest at pH values between 6 and 7 (Mackereth, 1953). Uptake rates of phosphorus have been correlated directly with the presence of numerous ions and compounds in the water, such as potassium, availability of micronutrients, and organic compounds. The mechanisms involved are not clearly understood.

C. Phosphorus Concentrations Required for Growth

From an ecological standpoint, the growth of algae in both natural and laboratory cultures exhibits dependency on the amount of available phosphorus and the rate at which it is cycled. Extensive investigations of minimal and maximal phosphorus concentrations, especially by Chu (1943) and Rodhe (1948), grouped freshwater algae into categories according to whether their tolerance ranges fell below, around, or above 20 μg PO_4—P liter^{-1}:

a. Species whose optimum growth and upper tolerance limit is below 20 μg PO_4—P liter^{-1} (e.g., *Uroglena*) and some species of the macroalga *Chara*
b. Species whose optimum growth is below 20 μg PO_4—P liter^{-1} but whose tolerance limit is well above that level (e.g., *Asterionella* and other diatoms)
c. Species whose optimal growth and upper tolerance limit is above 20 μg PO_4—P liter^{-1} (e.g., green algae such as *Scenedesmus, Ankistrodesmus,* and many others)

In these studies, phosphorus concentrations of the culture media required for optimal growth were almost always higher than those of the water in natural habitats where the algae were growing. Many explanations were offered for this difference, such as the presence of unknown organic growth factors in the lake but not in the artificial media of the bacteria-free cultures. It is now apparent that the chemical mass of inorganic phosphorus in the water has relatively little relation to growth kinetics. Of overriding importance is the rapidity with which phosphorus is cycled and exchanged between the particulate phosphorus and soluble inorganic and organic phases, as discussed in detail earlier. Secondly, it is of great ecological importance that many algae, when provided with a sufficient supply of phosphorus, can absorb phosphorus in quantities far in excess of their actual needs (Kuhl, 1974). A portion of this phosphorus is lost in normal active growth both as inorganic and organic compounds and is recycled rapidly, at least in part. A large

TABLE 13-7 The Minimal Phosphorus Requirements per Unit Cell Volume of Several Algae or Cyanobacteria Common to Lakes of Progressively Increasing Productivity[a]

Oscillatoria	>0.5
Microcystis	>0.5

[a] From data of Vollenweider, R. A.: *Scientific Fundamentals of the Eutrophication of Lakes and Flowing Waters, with Particular Reference to Nitrogen and Phosphorus as Factors in Eutrophication.* OECD Report No. DAS/CSI/68.27, Paris, OECD, 1968, after numerous sources.

majority (>95%) of the phosphorus is in the particulate phase of algae and dead organic seston. Assimilation of surplus amounts of phosphorus by algae, often referred to as "luxury" consumption, can provide sufficient phosphorus to maintain algal growth in the epilimnion, even though the external concentration of phosphorus may be very low.

Of course, this recycling and utilization of stored phosphorus reserves cannot persist for very long. Losses continually occur from the colloidal phosphorus component, as well as from sedimentation from the particulate phosphorus component and with outflows of both dissolved and particulate components. Inputs of phosphorus to the system are needed continually, either from the littoral zone and turbulent transfer from lower-depth strata and sediments or externally, in order to sustain growth for extended periods. The amount of phosphorus input or loading, then, is important to the sustenance of algal growth and is one of many factors influencing the types of algae that are growing in a particular lake at a particular time of year.

It is therefore more relevant to the question of increasing algal productivity to view phosphorus concentrations in terms of total phosphorus, since most of the phosphorus is bound in the particulate component at any given time. From the few studies available in which common algal species of lakes of differing productivity were studied in relation to phosphorus requirements, the minimum phosphorus required per cell volume can be evaluated (Table 13-7). The colonial diatom *Asterionella formosa* is often found in oligotrophic waters, has a low phosphorus requirement, and can reach maximum cell densities at very low phosphorus concentrations. The quantity of phytoplankton, expressed as cell volume, that may be produced by 1 μg P liter^{-1}, is 2–5 mm^3 liter^{-1} (Vollenweider, 1968). This quantity of algae is common in lakes of low productivity. *Tabellaria* and *Fragilaria* are diatoms that reach maximum population densities at concentrations of approximately 45 μg PO_4—P liter^{-1}, while *Scenedesmus* needs higher concentrations of around 500 μg liter^{-1}. The cyanobacterium *Oscillatoria rubescens* does not reach its maximum phosphorus content until the initial phosphate concentration of the media used is about 3000 μg PO_4—P liter^{-1}. It is of ecological interest to note that cations stimulate phosphate uptake by the cyanobacterium *Synechococcus* (= *Anacystis*). Calcium ions in particular cause a pronounced reduction in the half-saturation concentration for orthophosphate uptake by increasing the active transport of phosphorus into the cells (Rigby *et al.*, 1980; cf. also Lehman,1976).

Studies on the kinetics of phosphate uptake and growth of *Scenedesmus* in continuous culture have shown that phosphorus uptake velocity is a function of both the concentrations of internal cellular phosphorus compounds and the concentrations of the external substrate (Rhee, 1973). The apparent half-saturation constant (K_m) of phosphorus uptake was 0.6 μM (approximately 18 μg P liter^{-1}), whereas the apparent half-saturation constant for growth was less than K_m by an order of magnitude. Growth was a function of cellular phosphorus concentrations. Internal polyphosphate content appeared to regulate growth rate, particularly in the initiation of cell division. The activity of alkaline phosphatase, the primary enzyme involved in the release of phosphates from polyphosphates, exhibited a relationship that was inversely related to growth rate and was correlated to both polyphosphates and internally stored surplus phosphorus. During phosphate limitation, polyphosphates are mobilized for the synthesis of cellular macromolecules (protein, RNA, and DNA). Similar results were found for species of diatoms (Fuhs *et al.*, 1972) and for green algae and cyanobacteria (Healey and Hendzel, 1975; Senft, 1978).

D. Phosphorus Uptake and Competition by Algae vs. Bacteria

Early studies on the uptake kinetics and competition for phosphorus between planktonic algae and bacteria were inconclusive. For example, bacteria were found to have a lower affinity, in contrast to several other studies, for phosphate than did algae (Table 13-8), but could potentially outgrow the algae because of a more favorable surface-area-to-volume ratio (Fuhs *et al.*, 1972). Competition for phosphate between the alga *Scenedesmus* and the bacterium *Pseudomonas* indicated

[a] Modified from Fuhs *et al.*: Characterization of phosphorus-limited plankton algae. In Likens, G. E. (Ed.): *Nutrients and Eutrophication,* Milwaukee, American Society of Limnology and Oceanography, 1972.

a_0 = minimum P content per cell.

μ_m = growth rate during unrestricted growth at 22°C, other conditions at or near optimum.

K_m = Michaelis half-saturation constant of uptake mechanism.

V_m = maximum uptake rate for orthophosphate P per unit area of cell surface.

that algal growth was limited in the presence of the bacteria but that growth of the bacteria was little affected by the algae (Rhee, 1972). Competition, seen as cessation of exponential algal growth, was observed some time after the external phosphate concentrations were exhausted. The concentrations of stored internal polyphosphates within the algae decreased to a near-zero critical value at the time of suppressed algal and much faster bacterial growth.

A plethora of recent studies have examined the phosphorus uptake kinetics and specific growth rates of bacterioplankton in comparison to those of phytoplankton. Correlation analyses (Currie and Kalff, 1984a; Currie, 1990) and direct measurements of specific growth rates in relation to phosphorus availability and competition among bacteria and algae (Currie and Kalff, 1984b; Vadstein *et al.*, 1988, 1993; Toolan *et al.*, 1991; Cotner and Wetzel, 1992; Coveney and Wetzel, 1992) indicated the primary points: (a) Bacterioplankton have substantially higher phosphorus requirements than do phytoplankton; (b) Bacterial net consumption of phosphorus is larger (4–10 × higher) than that of the phytoplankton; (c) Bacteria contain much greater amounts of phosphorus (ca. 10×) than algae; (d) Phosphorus as well as or rather than organic carbon commonly limits bacterioplankton; and (e) Bacterioplankton can outcompete algae for phosphorus under a wide range of phosphorus supply rates.

Phosphate is the preferred substrate for uptake into both algae and bacteria (Cotner and Wetzel, 1992). Phytoplankton use both phosphate and dissolved organic phosphorus compounds, particularly at high substrate concentrations. At most natural concentrations, however, uptake of phosphate is completely dominated (>50 to nearly 100%) by bacteria (Currie and Kalff, 1984b; Güde, 1991; Cotner and Wetzel, 1992; Vadstein *et al.*, 1993). The phosphorus contained in the bacteria is then regenerated by death and autolysis of the cells or by feeding activities of heterotrophic flagellates. Because bacteria have high requirements for phosphorus, much of the phosphorus occurs in and is regenerated from these phosphorus-rich particles.

VII. HUMANS AND THE PHOSPHORUS CYCLE IN LAKES

A. Sources of Phosphorus

1. Atmospheric Precipitation

Phosphorus in atmospheric precipitation and particulate material fallout originates from fine particles of soil and rocks, from living and dead organisms, primarily as volatile compounds released from plants and from natural fires and the burning of fossil fuels (Newman, 1995). Phosphorus loadings from the ocean to the atmosphere are very small. Prevailing winds and the water of storms traveling from oceans onto land are usually low in phosphorus content but can be higher in coastal regions (Graham *et al.*, 1979). Generally, the amount of phosphorus in precipitation is less than that of nitrogen. In inland regions, the major source of phosphorus in precipitation is from dust generated over the land from soil erosion and from urban and industrial contamination of the atmosphere. In heavily fertilized agricultural regions, the phosphorus content of precipitation is much higher during the ac-

tive growing season than in winter. Even in mountainous regions much higher loadings of phosphorus from atmospheric sources were observed in the summer periods (Chapin and Uttormark, 1973; Lewis *et al.*, 1985; Cole *et al.*, 1990). It should be noted additionally that nutrients accumulate in snowpacks and on the ice during winter and can be released rapidly in large amounts during the spring thaw (e.g., English, 1978; Adams *et al.*, 1979).

The phosphorus content of precipitation is generally low (ca. <30 μg P liter^{-1}) in unpopulated regions over land but increases considerably to well over 100 μg P liter^{-1} around urban–industrial aggregations. Atmospheric contributions of phosphorus in rain and dry deposition range from approximately 0.01–0.65 g m^{-2} yr^{-1} (0.1–6.5 kg ha^{-1} yr^{-1}), with most values in the lower portion (ca. 0.2) of that range (Kortmann, 1980; Gibson *et al.*, 1995; Newman, 1995). Atmospheric inputs can represent highly significant loadings when compared for example with the 0.07 g m^{-2} yr^{-1} value that Vollenweider (1968) estimated as a general permissible phosphorus loading rate for lakes. Values of 0.13 g m^{-2} yr^{-1} or higher are considered dangerous from the standpoint of eutrophicational control in lakes with a mean depth of <5 m. Atmospheric loadings of phosphorus can constitute 40% or more of the annual loadings (e.g., Kowalczewski and Rybak, 1981; Psenner, 1984).

2. Ground Water

The phosphorus content of ground water is generally low; average concentrations are about 20 μg P liter^{-1}, even in areas where soils contain relatively large quantities of phosphorus. The low phosphorus content is a result of the relatively insoluble nature of phosphate-containing minerals and the scavenging of surface phosphate by biota and soil particles.

3. Land Runoff and Flowing Waters

In general, the regional chemical characteristics of surface waters are closely related to the soil characteristics of their drainage basins (Keup, 1968; Vollenweider, 1968; Lal, 1998). Soils reflect the regional geological and climatic characteristics. Surface drainage is often a major contributor of phosphorus to streams and lakes. The quantities of phosphorus entering surface drainage vary with the amount of phosphorus in soils, topography, vegetative cover, quantity and duration of runoff flow, land use, and pollution.

The parent rock material from which soil evolves by weathering is extremely variable in phosphorus content, and this variability increases with the thickness and heterogeneity of the stratified soil layers. Basic igneous rock contains relatively little phosphorus as apatite; phosphorus percentages of other rocks are as follows: sandstone is approximately 0.02, gneiss 0.04, unweathered loess 0.07, andesite 0.16, and diabase 0.03. Limestone containing approximately 1.3% P and rare deposits of rock phosphate (10–15% P), in which biotic accumulations either from the organisms themselves or from guano were concentrated, are largely of sedimentary origin (cf. Hutchinson, 1950). Surface layers of soil are relatively rich in organic phosphorus from plant detritus in various stages of decomposition by soil fungi and bacteria. The exchange capacity of soils for phosphorus depends on the composition of the soil and increases with greater quantities of organic and inorganic colloids. Phosphorus is most available and easily leached from soils having a pH of 6–7. At lower pH values, phosphorus combines readily with aluminum, iron, and manganese. Therefore, where drainage basins are acidified from atmospheric pollutional sources, inputs of phosphorus in runoff from acidified soils are reduced (Jansson *et al.*, 1986). At pH 6 and above, progressively greater amounts of phosphate are associated with calcium as apatites and calcium phosphates.

The topography of the catchment basin influences the extent of erosion and subsequent export of nutrients. Flat lands with little runoff and relatively high infiltration rates contribute less nutrient load to runoff than similar lands with steeper gradients (Table 13-9). Further, the relative erosion is influenced markedly by the type of vegetation and use to which the land is put (Table 13-10). Disturbances to the land cover can also have marked effects on nutrient releases to runoff water. For example, phosphorus and nitrogen concentrations of stream waters increased from 5- to 60-fold over background levels within the first two days after forest wildfires impacted the stream catchments (Spencer and Hauer, 1991). Much of the nutrient loading leached from ash. Returns to background concentrations of nutrients required several weeks. The literature on this subject is large, and the reader is referred to the reviews examining phosphorus inputs from runoff by Vollenweider (1968), Biggar and Corey

(1969), Cooper (1969), Keup (1969), Griffith *et al.* (1973), Dillon and Kirchner (1975), Meyer and Likens (1979), Loehr *et al.* (1980), Beaulac and Reckhow (1982), Grobler and Silberbauer (1985), Likens (1985), Lewis (1986), Stibe and Fleischer (1991), Likens and Bormann (1995), and Lal (1998).

An attempt has been made to classify natural and agricultural areas on the basis of the quantity of nitrogen and phosphorus in runoff (Table 13-11). Applications of fertilizers and land management practices, both in agriculture and forestry, will modify and generally increase these values considerably (see, e.g., Clesceri *et al.*, 1986; Skaggs *et al.*, 1994; Jordan and Weller, 1996). Urbanization results in increases in the amount of phosphorus discharged to surface waters in approximately direct proportion to population densities (Weibel, 1969). Phosphorus originating from heavy residential fertilization, storm sewer drainage, and leaves (Cowen and Lee, 1973) can increase phosphorus inputs to surface drainage. For example, in the largest lake of southwestern Michigan, Gull Lake, approximately 24% of the total phosphorus entering this eutrophicating lake was from fertilization of lakeside lawns. The soils of 75% of the lawns, however, were saturated with phosphorus, making additions unnecessary (Moss, 1972b; Moss *et al.*, 1980). In contrast, loadings of phosphorus to a large, undisturbed arctic lake were nearly entirely from stream inputs, largely as dissolved P (Table 13-12). Over two-thirds of the phosphorus left the lake in surface outflows, also largely as dissolved P.

The land–water interface zone where terrestrial ecosystems meet rivers and lakes can alter loadings of both water and nutrients to receiving waters. For example, a land–water "buffer zone" of wetland and littoral vegetation of 20–30 m in width can remove nearly all imported nitrate by denitrification. Rates of denitrification depend on rates of nitrate loadings, carbon availability, and hydrology (Kadlec and Knight, 1996; Fennessy and Cronk, 1997). Plant communities provide a carbon source for denitrifying bacteria, can

immobilize many nutrients by assimilation and storage in tissues, and influence nitrification rates by creating oxidized rhizospheres where nitrification can occur (see Chap. 12). Plant removal of nutrients is often, but not universally, seasonal, but denitrification can proceed throughout the year in subsurface hydrology.

Surface runoff receives very large quantities of phosphorus from domestic sewage. Of course, loading of these waters varies greatly with population density, treatment of the sewage for nutrient removal, and points of discharge of effluents. Average values are given in Table 13-13. Industrial inputs, especially those associated with food processing, can be exceedingly high.

Ironically, cleaning detergents are major sources of phosphorus that contribute marked fertilization effects to many fresh waters. Where legally permitted, synthetic detergents include phosphate builders as a major constituent, mainly sodium pyrophosphate and polyphosphates, to complex and inactivate cations of water supplies and permit more effective cleaning action. Until very recently, when detergent phosphorus content was reduced or eliminated, from 7 to 12% of the weight of detergents was phosphorus. The amount of phosphorus used in the production of detergents is staggering; well over 2 million tons are produced annually in the United States alone. Although the percentage of phosphorus in detergents has been reduced somewhat, the phosphorus loading to many water treatment facilities is still extremely high and originates from a source that could be eliminated with relative ease. In a majority of existing treatment facilities, phosphorus has been reduced significantly, but not sufficiently to prevent accelerated productivity in many recipient

lakes. Practical technology for nearly complete removal of phosphorus is available (cf. Vollenweider, 1968; Rohlic, 1969). Where phosphates are banned as a constituent of detergents, the phosphorus loadings to treatment facilities and surface waters decline by 50 to >80% (e.g., Maki *et al.*, 1984; Pallesen *et al.*, 1985; Hoffman and Bishop, 1994).

B. General Eutrophication

The word ***eutrophy*** (from the German adjective *eutrophe*) in general signifies to nutrient-rich and is greatly misused in contemporary dialogue.[2] Naumann (1919) introduced the general concepts of oligotrophy and eutrophy and distinguished them on the basis of phytoplanktonic populations. Oligotrophic lakes contained few planktonic algae and were common in regions dominated by primary rocks. Eutrophic lakes contained more phytoplankton and were common among more naturally fertile lowland regions in which human activity provided an increased supply of nutrients. Although at that time chemical methodology was crude or nonexistent for certain substances, Naumann emphasized that chemical factors, particularly phosphorus, combined nitrogen, and calcium, were primary determining factors. Limnological evidence since that time has shown a strong relationship between the biological dynamics of a lake and its nutritional level (concentrations of nutrients).

Shortly after the turn of the present century, Thienemann (summarized in 1925) found that in alpine and subalpine lakes, midge larvae, largely of the genus *Tanytarsus,* were characteristic of unproductive, deep lakes in which the hypolimnetic water lost little of its oxygen content during summer stratification. Eutrophic lakes (he later adopted Naumann's terms) were shallower and richer in plankton, and the oxygen-reduced hypolimnetic water was dominated by fauna, such as the midge *Chironomus,* which can tolerate very low oxygen concentrations. The extensive studies and conceptualizations of these earlier workers, when coupled with those of numerous others, formed a foundation upon which much regional limnology of the 1930s was based.

A plethora of subsequent limnological studies were directed toward evaluation of the characteristics of different lake types. The terminology for different lake types that developed in the ensuing two decades was indeed phenomenal. Many lake types were differentiated on the basis of indicator species. The basis for many of these descriptive classifications was founded in controlling physical and chemical parameters, while the basis for others was not. The terminology and dichotomies of classification that developed, while instructive, were excessive. Lakes were categorized in nearly every limnological aspect—geomorphological, physical, and chemical—and by indicator species or aggregations of nearly every group of organism from bacteria to fish. Lake types have been based even on the waterfowl that commonly are associated with them. As more lakes were studied, exceptions were found, which led to further splitting and name generation. Early integrative analyses, such as those of Thienemann (1925) and Naumann (1932), became less common as the terminology became more complex. If the details of classifying are carried to an extreme, lakes are so individualistic that one would soon require taxonomic keys for the many lake types (which in fact was proposed by Zafar, 1959).

The concept of trophic state was further elaborated by Naumann (1919, 1929) in which he emphasized the importance of the drainage basin to the functioning of a lake as an ecosystem. He stressed that the quantity, and later production, of phytoplanktonic algae was determined by several factors, particularly phosphorus and nitrogen. This production was translated to greater productivity of the higher trophic levels of the lake biology. Naumann also pointed out the importance of regional variations in algal production in relation to the geology of the drainage basins.

The terms *oligotrophy* for lakes of low production and *eutrophy* for lakes of high production evolved from similar concepts developed for bogs (Weber, 1907; Naumann, 1929, 1932; Hutchinson, 1969; Carlson, 1992; Carlson and Simpson, 1996). Naumann coupled trophic lake types to physical (temperature and light) and chemical (calcium, humic content, nitrogen, phosphorus, iron, pH, oxygen, and CO_2) factors that affected production. The criterion used for classification was production of organic matter, not the factors determining that production (Naumann, 1929). The rationale underlying this criterion was that production of phytoplankton in some of these "disharmonic lake types" was affected to a greater extent by factors other than the primary nutrients phosphorus and nitrogen (Table 13-14). The primary production criteria were combined with a classification system based on hypolimnetic oxygen concentrations in stratified lakes and the presence of benthic macroinvertebrates developed by Thienemann (1921; cf. Rodhe, 1975). Exceptions to the general classification scheme emerged quickly, particularly in relation to the rates of hypolim-

[2]Hutchinson (1973) has written an excellent general review of the subject and the development of the term in limnology. The semipopular book The *Algal Bowl-Lakes and Man* by Vallentyne (1974) complements collections of studies on eutrophication: *Eutrophication: Sources, Consequences, Correctives* (National Academy of Sciences, 1969), and *Nutrients and Eutrophication,* edited by Likens (1972).

TABLE 13-14 Lake Types Based upon Production of Organic Matter by Phytoplankton and Primary Physical and Chemical Determinants of That Production[a]

Lake type	*Characteristics*
Oligotrophy	Low production, associated with low phosphorus and nitrogen
Eutrophy	High production, associated with high phosphorus and nitrogen
Acidotrophy	Low production, associated with low phosphorus and nitrogen, but also with pH values <5.5
Alkalitrophy	High production, associated with high calcium concentrations
Argillotrophy	Low production, associated with high clay turbidity
Siderotrophy	Low production, associated with high iron content
Dystrophy[b]	Low production, associated with high humic color

[a] After Naumann (1929).
[b] The dystrophic lake type of low P and N but moderate to high humic organic content was described by Thienemann (1921).

netic oxygen depletion that are strongly coupled to temperature and differences in basin morphometry (cf. Chap. 6).

These problems can be avoided if the classification of lakes is made on the basis of production (biomass) rather than trying to incorporate all of the causal variables of limitation and biological structure, as well as biological and abiotic consequences of that production. A more recent development is to use single variables to define the trophic state of lakes. As we see throughout the topical discussions of this book, many variables are evaluated in the context of algal productivity (e.g., phosphorus loadings and concentrations, chlorophyll concentrations, algal productivity, algal biomass, hypolimnetic oxygen deficits, et cetera).

Combinations of many physical and biological variables as regulating trophic state have clouded true cause-and-effect relationships of rates of primary production. As Carlson (1984, Carlson and Simpson, 1996) emphasized, the trophic state concept is important as a critical organizing concept in limnology. The concept represents a continuum of trophic levels that is difficult to quantitatively delineate into subgroups. Organization along a trophic continuum is but one facet of lake typology and uses biomass or rates of production as the original, simplest, and most useful definition of trophic state. Biomass of phytoplankton can be estimated by a number of techniques from pigment concentrations to transparency (Secchi disk analyses). The annual mean rate of production is a much better criterion (cf. Chap. 15) but requires intensive and sophisticated methods for determination. ***Eutrophication*** is simply the alteration of the production of a lake along a continuum in the direction from low to high values, that is, from oligotrophy to eutrophy. The reverse process is termed ***oligotrophication.*** In contrast to annual mean production rate, which is relatively stable for a given lake ecosystem, biological food-web structure is highly susceptible to change along dynamic environmental gradients other than nutrients. No portion of the biological structure other than primary production is recommended as a criterion of the trophic concept.

The grouping of lakes must be left as a spectrum of states of lake metabolism between oligotrophy and eutrophy. Historical studies show that in many small lakes of temperate, glaciated areas, a succession is common from more inorganic sediment, containing oligotrophic-indicator fossils, to a more organic sediment, containing eutrophic-indicator fossils (Hutchinson, 1973). Evidence indicates that once organic sedimentation has become established after the initial oligotrophic phase, a type of trophic equilibrium or reasonably stable steady state occurs. This implies that nutrient inputs from the drainage basin are relatively constant over long periods of time and undergo only minor changes with oscillations in climate and inputs from vegetative cover and erosion. The systems can, and commonly do, regress in productivity (oligotrophication) as the surficial soils become reduced in nutrient content by leaching (cf. Chap. 23). Conversely, productivity can be greatly accelerated by increased nutrient inputs, particularly associated with human activities.

C. The Importance of Nutrient Loading to Aquatic Ecosystems

Great emphasis has been placed on nutrient availability in regulating aquatic productivity. As will be discussed later in treatments of biological productivity, many nonbiological factors other than phosphorus and nitrogen can regulate productivity. The early analyses of differences in productivity among aquatic ecosystems focused upon differences in nutrient concentrations. Increased information gradually demonstrated the rapid dynamics of exchange of nutrients among algae as nutrients were assimilated, utilized, and released during and following growth, reproduction, and death. Still among these studies, however, a prevailing concept was to treat lakes as closed, self-sustained entities. The most rapid change in these viewpoints arose, largely in the late 1960s and 1970s, with full recognition that rivers and particularly lakes are open systems critically dependent upon couplings with their drainage basins.

Phosphorus and nitrogen had been recognized for several decades in agriculture as critical nutrients that

often limit plant growth and productivity, and they were similarly recognized in algal productivity. The importance of phosphorus and nitrogen in eutrophication of surface waters was also long recognized, but with the understanding that lakes are open systems it became apparent that the *rates* of loading (i.e., importation) of these nutrients from the drainage basin were critical to trophic conditions. From a management viewpoint, one could also define loadings of nutrients in terms of whether they were acceptable or excessive in terms of the algal productivity generated under the lake conditions of morphometry and water retention times (Vollenweider, 1990). The trophic categories of oligo- , meso- , and eutrophy were gradually analyzed in increasingly quantitative ways, in terms of nutrient concentrations, phytoplankton biomass, chlorophyll concentrations, and water transparency in addition to the classical characterization of hypolimnetic oxygen conditions. These data from many lakes allowed the development of dynamic quantitative modeling for the prediction of probable biotic conditions as a result of nutrient loadings from the drainage basin. A summary of some of these relationships, developed and extensively tested in the 1980s, is presented later.

In more recent times, much attention has been directed to the internal recycling of nutrients within lakes and streams. In particular, internal loadings of nutrients from accumulations in sediments have been examined to determine how this recycling of nutrients supplement those allochthonous sources from the drainage basin and atmosphere. In addition, as is summarized in this chapter, much attention is directed to the recycling of nutrients through food ingestion and alteration by animals. Unfortunately, there has been very little study of the rates of microbial nutrient regeneration, processes that certainly dominate in all aquatic ecosystems. This area of research, though difficult, is a dominant frontier in limnology and is fundamental to effective management of inland aquatic resources.

D. Effects of Phosphorus and Nitrogen Concentrations on Lake Productivity

Although many definitions of lake eutrophication exist, based on an array of conditions associated with increased productivity, the consensus among limnologists is that the term *eutrophication* is synonymous with increased growth of the biota of lakes and that the rate of increasing productivity is accelerated over that rate that would have occurred in the absence of perturbations to the system. The most conspicuous, basic, and measurable criterion of accelerated productivity is an increased quantity of carbon assimilated by algae and larger plants per given area.

Under most lake conditions, the most important nutrient factors causing the shift from a lesser to a more productive state are phosphorus and nitrogen. Typical plant organic matter of aquatic algae and macrophytes contains phosphorus, nitrogen, and carbon approximately in the ratios (Vallentyne, 1974):

1P:7N:40C per 100 dry weight, or

1P:7N:40C per 500 wet weight

If one of the three elements is limiting and all other elements are present in excess of physiological needs, phosphorus can theoretically generate 500 times its weight in living algae, nitrogen 71 (500:7) times, and carbon 12 (500:40) times.

A comparison of the relative amounts of different elements required for algal growth with supplies available in fresh waters illustrates the general importance of phosphorus and nitrogen (Table 13-15). Similar proportional ratios were demonstrated by comparison of the demand among terrestrial plants with the accessible supply of elements from the lithosphere (Hutchinson, 1973). Even though variations in conditions of solubility or availability may at times make very abundant elements (e.g., silicon, iron, and certain micronutrients) almost unobtainable, phosphorus, and secondarily nitrogen, are generally the first to impose limitation on the system. This relationship is emphasized further by consideration of average demand–supply ratios in late winter prior to the spring algal maximum common in lakes of temperate regions and in midsummer during maximum sustained algal productivity (Table 13-16).

Oligotrophic lakes are often limited by phosphorus and contain nitrogen in quantities in excess of demand from growth supported by available phosphorus. As the lakes become more productive, the primary effecting agent is increased loading of phosphorus. As discussed earlier, the instantaneous concentrations of phosphorus usually decrease and are quite variable, but the turnover rate increases markedly. Rates of loss increase, and high algal productivity requires sustained phosphorus loading of the system from allochthonous and littoral sources.

Some studies have indicated that nitrogen rather than phosphorus is limiting to phytoplanktonic productivity of lakes, at least in certain water strata and at certain times of the year (e.g., Elser *et al.*, 1990). Arguments are moot that these findings contradict the general tenet of phosphorus as the foremost macronutrient to limit algal photosynthesis. Combined nitrogen, although found in large quantities in the lithosphere, is largely unavailable to plants. Nitrogen supplies to fresh waters are augmented more readily from external sources (Chap. 12) than are those of phosphorus.

TABLE 13-15 Proportions of Essential Elements for Growth in Living Tissues of Freshwater Plants (Requirements) in the Mean World River Water (Supply) and the Approximate Ratio of Concentrations Required to Those Available[a]

When phosphorus is available in quantities adequate to support metabolism, nitrogen availability can become limiting, particularly to phytoplankton. This limitation is often observed in the two extremes of the trophic spectrum. Under eutrophic conditions of high phosphorus loading, planktonic utilization of combined nitrogen can exceed inputs and literally deplete combined nitrogen supplies in the trophogenic zone in a few days or weeks (cf. Chap. 12). When this occurs, molecular nitrogen fixation by heterocystous cyanobacteria can augment the income of nitrogen, but only at a high metabolic cost. In tropical lakes of low latitudes nitrogen limitation to phytoplanktonic growth can occur (cf. reviews of Salas and Martino, 1991, and of Lewis, 1996). Phytoplanktonic productivity of tropical waters is generally higher than at temperate latitudes (cf. Chap. 15), and higher temperatures can accelerate rates of denitrification and losses of nitrogen to the atmosphere.

TABLE 13-16 Comparisons of the Ratios of Required Concentrations of Inorganic Nutrients to Average Supplies Available in Fresh Waters[a]

	Ratio of demand to available supplies	
Element	*Late winter*	*Midsummer*
Phosphorus	80,000	Up to 800,000
Nitrogen	30,000	Up to 300,000
Carbon	5000	Up to 6000
Iron, silicon	Generally low, but variable	
All other elements	<1000	<1000

[a] After Vallentyne, J. R.: *The Algal Bowl—Lakes and Man*, Miscellaneous Special Publication 22, Ottawa, Dept. of the Environment, 1974.

Under oligotrophic conditions, particularly in lakes of mountainous regions and high-latitude waters, phosphorus availability may be adequate to support modest levels of phytoplanktonic productivity, but sources and loadings of combined nitrogen are insufficient to support such productivity. Increasing the availability of nitrogen can result in increased algal photosynthesis until phosphorus again becomes limiting. Enrichments with both nitrogen and phosphorus can stimulate algal productivity markedly (e.g., Holmgren, 1984; White *et al.*, 1986; Elser *et al.*, 1990).

Phytoplanktonic productivity of reservoirs often fluctuates to a much greater extent than in natural lakes (cf. Chap. 15). Because of the frequent variations in inorganic turbidity in reservoirs, the limiting effect of light penetration on photosynthetic activity is more severe than that of nutrients (e.g., Henry *et al.*, 1985).

Nutrient loading to reservoirs from external sources can vary with long-term precipitation patterns and water inflows in comparison to the volumes of the productive zones. If flushing rates are high, turbidity can increase but also nutrient loading and availability can increase (e.g., Hoyer and Jones, 1983; Turner *et al.*, 1983). The availability of combined nitrogen and particularly phosphorus can be shown to intermittently weakly limit photosynthesis of phytoplankton in reservoirs, but light is generally of much greater limitation.

The potential for limitation of eutrophication by inorganic carbon availability has been a subject of much discussion (cf. Chap. 11). In a few exceedingly productive situations, such as sewage lagoons, in which phosphorus and nitrogen compounds are available in excess of any demands, carbon can become limiting to algal growth (Kerr *et al.*, 1972). While there is some evidence for inorganic carbon limitation in exceedingly soft lakes (see, e.g., Allen, 1972), diffusion of atmospheric CO_2 is generally adequate to sustain the carbon requirements of phytoplanktonic populations. It is extremely unlikely that carbon limitation is of significance in the limitation of algal populations in a majority of harder waters, in which dense algae develop under eutrophic conditions.

The importance of phosphorus in comparison to nitrogen and carbon has been particularly well illustrated by large-scale fertilization experiments (Schindler, 1974). Lake 226, located in northwestern Ontario in Precambrian Shield bedrock, was chemically and biologically similar to >50% of the waters draining to the northern Laurentian Great Lakes. The trophogenic zone of Lake 226 was partitioned into two lakes at a constriction in the basin (Fig. 13-12). One basin was fertilized with phosphorus, nitrogen, and carbon, and the other with equivalent concentrations of nitrogen and carbon.[3] The phosphate-enriched basin quickly became highly eutrophic, while the basin receiving only nitrogen and carbon remained at prefertilization conditions (Fig. 13-12). In this phosphate-enriched basin and in several other lakes receiving analogous treatments over a period of several years, algal biomass increased to 2 orders of magnitude over that of lakes receiving only nitrogen and carbon enrichment. Recovery to near prefertilization levels was very rapid when phosphate additions were discontinued.

The amount of evidence for these relationships is so overwhelming, both from experimental and applied investigations, that it is difficult to appreciate how the bitter controversy over the importance of carbon rather than phosphorus as a limiting nutrient in fresh waters developed in Canada in the late 1960s. As a result of a combination of the magnification of a few findings from cyanobacterial cultures and a few rare cases of discovered low carbon availability in natural habitats in which excessive amounts of nitrogen and phosphorus occurred, phosphorus was implied to be of less importance in the acceleration of eutrophication than carbon. So convincing was the misinterpretation of results by a few scientists, and so effective was the exploitation of the situation by the detergent industry and irresponsible journalists, that urgently needed legislation to reduce the effluent loading of surface waters with phosphorus was seriously impeded.

FIGURE 13-12 Lake 226 of northwestern Ontario, which was partitioned at the constriction of the basin, 4 September 1973. The far northeastern basin, fertilized with phosphorus, nitrogen, and carbon, was covered by a dense algal bloom within two months. No increases in algae or species changes were observed in the near basin, which received similar quantities of nitrogen and carbon but no phosphorus. (From Schindler, D. W.: Eutrophication and recovery in experimental lakes: Implications for lake management. *Science, 184:* May 24, 897–899, 1974. Copyright 1974 by the American Association for the Advancement of Science. Photograph courtesy of D. W. Schindler.)

[3]Additions were equivalent to 3.16 g of NO_3—N and 6.05 g of sucrose C per m^2 per year in both basins, made in 20 equal weekly increments. The northeast basin additionally received 0.6 g m^{-2} yr^{-1} of PO_4—P. The N/P and C/P ratios were greater than in treated sewage, but the quantity of P added was not exceptionally high for lakes that commonly receive pollution from domestic sources.

The matter was finally put to rest by the rebuttal of Vallentyne (1970), numerous subsequent investigations, and a national symposium on the subject (Likens, 1972). The effects of the controversy, however, continue to be felt both in research on the subject and in the efforts to reduce the loading of fresh waters with millions of tons of phosphorus each year, so that ultimately lakes will not become, in the words of J. R. Vallentyne, algal bowls.

E. Stoichiometry of Carbon, Nitrogen, and Phosphorus in Particulate Organic Matter

The elemental chemical composition of planktonic particulate organic matter reflects both the planktonic community structure as well as biochemical processes, such as nutrient supply ratios and turnover rates, that occurred in formulation of the composition of the biomass (reviewed in Tilman *et al.*, 1982; Kilham, 1990). For example, phosphorus or nitrogen limitation can lead to alterations in the ratios of protein, carbohydrate, and lipid content of cells, as well as the C:N ratio (cf. discussion in Chap. 12). Hence, the C:N ratio indicates not only characteristics of the nutrient availability but also an approximate evaluation of the relative proportions of cellular proteins and nonprotein structural elements (cf. Vollenweider, 1985).

A relative constancy in the molar ratio of C:N:P of 106:16:1 (or 41:7.2:1 by weight) among marine plankton, termed the Redfield ratio, is generally supported by numerous studies (Redfield *et al.*, 1963; Hecky *et al.*, 1993). The variance in this ratio is small, usually <20%. This constancy has been attributed to the relatively nutrient-sufficient growth conditions of marine plankton and the more homogeneous and stable nature of oceans (J. C. Goldman *et al.*, 1979). In contrast, marked deviations in the sestonic C:N:P proportions occur in lakes. These particulate composition ratios have been coupled to physiological indicators, such as rates of growth and productivity, to estimate the nutrient conditions to which phytoplankton of lakes have been exposed. Such relationships of nutrient stoichiometry can also give insights into species composition, growth rates, and successional patterns of phytoplankton (Kilham, 1990; Sommer, 1990).

Elemental cellular stoichiometries of natural phytoplankton communities and the seston can reflect the type and extent of nutrient limitation and availability. Ratios of elements being loaded to a lake are reflected in the elemental composition of the phytoplankton community. For example, N:P ratios in phytoplankton (seston) are strongly correlated with N:P loading rates to lakes (Table 13-17). The C:P and N:P ratios of lake seston are generally higher than the Redfield ratio for marine waters. Phosphorus limitation of algal productivity in lakes tends to be much greater than nitrogen limitation (Healey and Hendzel, 1980; Hecky *et al.*, 1993). Streams, shallow lakes, and reservoirs with short residence times have C:P ratios <350 and N:P ratios <26, whereas lakes with longer residence times (>6 months) differentiate from their inflows typically with C:P >400 and N:P >30. Tropical lakes tend to have relatively high C:N ratios, indicative of potential nitrogen limitations, although the number of lakes sampled was relatively small (Hecky *et al.*, 1993).

TABLE 13-17 Stoichiometric Ratios of Phytoplankton-Dominated Seston of Lakes as Approximate Indicators of Relative Nutrient Limitations[a]

		Degree of nutrient limitation[b]		
Ratio	*Deficiency*	*None*	*Moderate*	*Severe*
C:N	N	<8.3	8.3–14.6	>14.6
N:P	P	<23	—	>23
C:P	P	<133	133–258	>258
Si:P	Si	<20	—	>100
C:Chl *a*	General	<4.2	4.2–8.3	>8.3
APA:Chl *a*	P	<0.003	0.003–0.005	>0.005

[a] After Healey and Hendzel (1980), Kilham (1990), and Hecky *et al.* (1993).

[b] Composition ratios of C:N, N:P, C:P in μmol μmol1^{-1}; C:Chl *a* ratios as μmol μg^{-1}; and physiological ratio of alkaline phosphatase activity (APA):Chl *a* in (μmol μg^{-1})h^{-1}.

Cellular elemental stoichiometry is affected by the availability of nutrients and therefore can be correlated with the extent of nutrient limitations (Table 13-17). An excellent example is observed in the spatial and temporal differences in cellular stoichiometry. Epilimnetic ratios, particularly of N:P, are often higher, indicative of high phosphorus demands in proportion to total inputs, than those of the hypolimnion, and C:P as well as N:P ratios decrease with depth (e.g., Jones, 1976; Gächter and Bloesch, 1985; Tezuka, 1985; Gálvez *et al.*, 1991). These differences with depth are usually related to high phosphorus use in relation to supply, increased nutrient pool size with depth, and respiration of organic carbon as the seston settles.

The ratio of fluxes of nutrients into the dissolved nutrient resource pool (i.e., the supply rates of essential nutrients) can markedly influence the community structure of the phytoplankton (Tilman, 1982). As correctly pointed out by Sterner *et al.* (1992), external sources of nutrient loading can be and have been evaluated with some degree of accuracy, but rates and controls of internal regeneration of nutrients by physical (e.g., resuspension and mixing) and biological (e.g., nitrogen fixa-

tion, denitrification, food web regeneration by all heterotrophs, including viruses) processes are much less quantified to levels that allow effective use of predictive models. For example, denitrification was the most important mechanism for reducing N:P ratios in the water column, whereas both nitrogen fixation and sediment resuspension raised N:P ratios (Levine and Schindler, 1992). Sediments tend to be a major nitrogen source, particularly in littoral areas.

The N:P and Si:P supply ratios are fundamental axes along which phytoplanktonic community structures vary (Hecky and Kilham, 1988; Kilham, 1990). Diatoms and some chrysophyte algae have absolute silica requirements. Although total algal biomass is not limited by silica availability, the algal community composition, interspecific competition, and succession can be altered markedly (cf. Chaps. 15 and 19). Species of diatoms with low Si:P requirements, for example, often develop maximally during seasonal periods of lowest Si:P ratios (Kilham, 1984). In another example, many cyanobacteria are capable of nitrogen fixation, which allows these species to maintain high growth rates in habitats low in available combined inorganic nitrogen. The relative competitive capacities and proportions of cyanobacteria in epilimnetic phytoplankton communities are thus indicated by the N:P ratio; cyanobacteria tend to be rare at N:P >29 (Smith, 1983).

Zooplankton and higher animals usually constitute small portions of the total dissolved and seston pools of nitrogen and phosphorus. For example, in an alpine lake in California, zooplankton always constituted <5% and <10% of the pelagic storage compartments for nitrogen and phosphorus, respectively (Elser and George, 1993). However, during brief periods of high zooplankton biomass, the zooplanktonic contributions to total sestonic elemental stoichiometry can be significant. Although the N:P and C:P ratios do not vary greatly intraspecifically among zooplankton, considerable differences occur interspecifically (Watanabe, 1990; Gulati *et al.*, 1991; Sterner *et al.*, 1992; Elser and George, 1993; Urabe, 1995). Zooplanktonic N:P ratios may be altered by the N:P ratio of seston as certain individual species populations of zooplankton, which grow and reproduce most efficiently at a given N:P supply ratio, come to dominate the zooplankton community. Because the biochemical requirements of crustacean zooplankton for a N:P ratio in their tissues is below the ratio of most sestonic assemblages, there is a tendency for crustacean zooplankton to retain P preferentially to N. As a result of this process, nutrient regeneration via feces of zooplankton can be skewed toward nitrogen and thereby enhance phosphorus limitations to phytoplankton during short periods of intense cladoceran grazing (e.g., "clear water phase").

In examining the chemical composition of particulate organic matter, large zooplankton can be effectively separated from smaller particles. However, detrital particles nearly always dominate (>50–80%) over algal and bacterial biomass in the remaining seston (Saunders, 1972a; Uehlinger and Bloesch, 1987; Gálvez *et al.* 1989). If the planktonic microbiota are reproducing rapidly, much of the detritus present can have chemical composition relatively similar to that of the living plankton. Appreciable loadings of particulate organic matter from the structural tissues of terrestrial and littoral plants, however, can result in seston relatively rich in carbon and lesser amounts of nitrogen and lead to high C:N, C:P, and N:P ratios. Although much of the particulate organic matter from external sources tends to be deposited in near-shore regions in natural lakes, importation from the drainage basin is much greater in reservoir ecosystems (Chaps. 15 and 21). In addition, because of the high ratio of drainage basin area to reservoir area, large quantities of inorganic particles (e.g., clay) can be imported to the pelagic zone. These particles of the seston can contain high and variable quantities of nutrients that are undifferentiated from particulate organic matter of biota and can lead to skewed results, requiring care in interpretation. However, in most lakes with water residence times of several months or longer, sestonic composition ratios reflect the general status of the availability of nitrogen and phosphorus for planktonic growth in these waters.

Furthermore, the predictive value of nutrients present in the seston as a reflection of nutrient availability has been extended by the obvious relationship of energy available as light for photosynthesis to nutrient available and incorporated into the seston (Sterner *et al.*, 1997). When phosphorus availability is low, C:P ratios of particulate organic matter will tend to be low and photosynthetic productivity low. Differences in nutrient use efficiency may occur at different light availability, and these ratios will be translated to higher trophic levels feeding upon them. Low light:phosphorus ratios of seston likely indicate simultaneous carbon and organic matter (energy) limitation in other dependent trophic levels, whereas high light:phosphorus ratios suggest phosphorus limitation among several dependent trophic levels.

VIII. PHOSPHORUS AND NITROGEN LOADING AND ALGAL PRODUCTIVITY

When phosphorus is added as a pulse to unproductive lakes or ponds, either experimentally, for purposes of intentional fertilization or in effluents resulting from

human activities, the usual response is a very rapid increase in algal productivity (e.g., Einsele, 1941; Maciolek, 1954; Mortimer and Hickling, 1954; Vinberg and Liakhnovich, 1965; Vollenweider, 1968; Correll, 1998). The increased productivity is not sustained as nutrient loadings are reduced, however, but decreases rather rapidly in a few weeks or months to levels near those prior to the addition. Losses in the colloidal fraction and from sedimentation of particulate phosphorus result in continuous reductions of phosphorus from the trophogenic zone. Inputs to the system must be maintained in a continuous or pulsed manner in order to sustain the increased productivity. In other words, steady phosphorus loading of the system is critical to sustaining increased productivity in most lakes of low or medium biological productivity.

Conversely, in order to reduce the productivity of a lake that is receiving a continuous loading of nutrients, algal growth is generally decreased most effectively by reduction of phosphorus inputs to below the level of losses within the lake. Reduction of total phosphorus of the water is the objective, since phosphorus is the major nutrient in greatest demand in relation to supply. Phosphorus is chemically reactive, technologically easier to remove from water than nitrogen, and does not have major reservoirs in the atmosphere.

A. Nutrient Loading

The nutrient loading concept implies that a relationship exists between the quantity of nutrient entering a water body and its response to that nutrient input. The effects of this relationship can be expressed by some quantifiable index of productivity or water-quality parameter (e.g., chlorophyll concentrations and water transparency).

The loading concept was recognized some time ago as applicable to lake changes in response to phosphorus and nitrogen enrichment (e.g., Rawson, 1939, 1955; Ohle, 1956; Edmondson, 1961). Sawyer (1947) suggested that if critical levels of dissolved inorganic nitrogen (300 μg N liter^{-1}) and phosphorus (10 μg P liter^{-1}) measured at the time of spring turnover in Wisconsin lakes were exceeded, nuisance populations of phytoplankton would likely develop during the growing season. Vollenweider (1966, 1968) first formulated definitive quantitative loading criteria for phosphorus and nitrogen and expected trophic conditions in water bodies. He defined boundaries between oligotrophic and eutrophic lakes by relating nutrient loadings to mean depth (as a measure of lake volume) and later refined these relationships (Vollenweider, 1969, 1975). Because phosphorus is commonly the initial limiting nutrient to algae, as discussed earlier, and because the many processes of nitrogen cycling (nitrification, denitrification, nitrogen fixation; Chap. 12) complicate accurate measurements of nitrogen loading of lakes, the loading criteria and models emphasized phosphorus relationships. Attempts to combine phosphorus and nitrogen loadings into lake enrichment models are empirically successful (e.g., Bachmann, 1984).

The loading relationships are all based on the mass balance equation of a substance M between its sources and losses (sinks) in an open system (Vollenweider *et al.*, 1980):

$$\Delta M/\Delta t = I - O - (S - R) \qquad (13\text{-}1)$$

where

$\Delta M/\Delta t$ = storage gain or loss of nutrient M over time Δt
I = external nutrient load
O = nutrient loss by outflow
S = nutrient loss to sediments
R = nutrient regeneration from sediments (internal loading)

While I and O can often be measured directly with accuracy, $(S - R)$ is more difficult to measure and is often obtained by difference. Under steady-state conditions, $\Delta M/\Delta t = 0$. Although in reality steady state does not exist in a lake, lakes that oscillate around relatively constant nutrient loads over periods of several years exhibit a set of trophic characteristics and may be viewed as a tendency toward a repetitive steady state. Often this steady state is defined as the nutrient storage content as measured at spring turnover or as the annual storage content. The models based on mass balance further assume that the nutrient load is instantaneously and completely mixed throughout the lake water (continuously stirred mixed reactor), an assumption that is only partially true for most lakes. The models, consequently, are particularly applicable to a large population of lakes, rather than to describing the specific behavior of an individual lake.

Assuming steady-state conditions, the simple mass balance equation accounts for volumnar loading of phosphorus as well as losses by flushing and sedimentation (Vollenweider and Kerekes, 1980):

$$\frac{\bar{d}[\bar{\mathrm{P}}]_\lambda}{dt} = \left(\frac{1}{\bar{\tau}_w}\right)[\bar{\mathrm{P}}]_i - \left(\frac{1}{\bar{\tau}_p}\right)[\bar{\mathrm{P}}]_\lambda \qquad (13\text{-}2)$$

where

$[\bar{\mathrm{P}}]_\lambda$ = average (total) lake concentration (both dissolved and particulate phosphorus components)
$[\bar{\mathrm{P}}]_i$ = average inflow concentration of total phosphorus
$\bar{\tau}_p$ = average residence time of phosphorus
$\bar{\tau}_w$ = average residence time of water

in which the right-hand terms represent the average rate of supply to and the average rate of loss of total phosphorus from the lake, respectively, and the left-hand term represents the corresponding temporal variations of the average lake concentration. Then, simplifying Equation (13-2):

$$[\bar{P}]_\lambda = (\bar{\tau}_p/\bar{\tau}_w)[\bar{P}]_i \qquad (13\text{-}3)$$

The premise of Equation (13-3) can also be expressed as:

$$[\bar{P}]_\lambda = (1 - R)[\bar{P}]_i \qquad (13\text{-}4)$$

where R = the phosphorus-retention coefficient:

$$R = \frac{[\bar{P}]_i - [\bar{P}]_\lambda}{[\bar{P}]_i} = 1 - \bar{\tau}_p/\bar{\tau}_w \qquad (13\text{-}5)$$

or statistically approximately

$$\bar{\tau}_p/\bar{\tau}_w = \frac{1}{1 + \sqrt{\bar{\tau}_w}}$$

(Larsen and Mercer, 1975; Vollenweider, 1976). An approximate retention coefficient as a function of hydraulic load (q_s) was found to be (Dillon, 1974; Kirchner and Dillon, 1975):

$$R = 0.426e^{-0.271q_s} + 0.574e^{-0.00949q_s}$$

where q_s = areal water load (hydraulic load) to the lake (m yr^{-1}), calculated as the lake outflow volume divided by the lake surface area. These two retention values, while not identical, yield similar results for lakes of mean depths between 10 and 30 m and hydraulic loads between 3 and 90 m yr^{-1} (Vollenweider and Kerekes, 1980). When either of these models was used and data plotted to show the extent of prediction of spring-turnover phosphorus concentration from loading, they described the average statistical behavior of lakes in terms of the relationship between phosphorus load and phosphorus accumulation within the lake (Vollenweider, 1976, 1979; Rast and Lee, 1978). Deviant lakes could be shown to have mechanisms operating to overestimate or underestimate the loading (e.g., high sedimentation rates, high regeneration of phosphorus from the sediments, particularly in lakes that developed anoxic deep waters, Nürnberg, 1984).

B. Biological Responses to Nutrient Loading

Based on these nutrient loading relationships, the loadings to a lake should be related to biological responses such as phytoplankton biomass (e.g., chlorophyll concentrations) and productivity. Early predictions of chlorophyll levels from phosphorus concentrations in lakes at spring turnover or during the growing season (Sakamoto, 1966; Dillon and Rigler, 1974; Jones and Bachmann, 1976; Schindler, 1978) were later extended further with larger worldwide data sets (Vollenweider, 1976; Schindler *et al.*, 1977; Oglesby and Schaffner, 1978; Rast and Lee, 1978; Canfield and Bachmann, 1981). Within certain boundaries, the regression between phosphorus loading and average annual chlorophyll concentrations is approximated by:

$$\overline{[\text{chl. } a]} = 0.55\{[P]_i/(1 + \sqrt{\tau_w})\}^{0.76}$$

Examples of this relationship are given in Figure 13-13; similar relationships have been found for many other lakes with only minor deviations.

The annual rate of primary productivity of the algae has also been related to the predicted phosphorus concentration (Fig. 13-14). The nonlinearity of the log–log plot results from the light-reducing, self-shading effects of dense algal populations (high biomass) at high levels of productivity (see Chap. 15). This well-known relationship was further reiterated by correlation analyses of Watson *et al.* (1992). The relationship can be represented by

$$\Sigma C(\text{g m}^{-2}\text{ yr}^{-1}) = 7\left[\frac{\{[P]_i/(1 + \sqrt{\tau_w})\}^{0.76}}{0.3 + 0.011\{[P]_i/(1 + \sqrt{\tau_w})\}^{0.76}}\right]$$

which operates similarly to the integral of daily photosynthesis and is based on average chlorophyll concentrations and light extinction resulting from turbidity and dissolved organic substances (Vollenweider and Kerekes, 1980).

C. Application of Predictive Models and Data

The evaluation of the trophic status of a lake has great practical importance. Eutrophicational status must be known before remedial corrective measures can be implemented in relation to the desired uses for any lake. Based upon many data obtained during an international program on eutrophication of the Organization for Economic Cooperation and Development (OECD), nutrient load–eutrophication response relationships for lakes and reservoirs were quantified and evaluated (Vollenweider, 1968; Rast and Lee, 1978; Canfield and Bachmann, 1981; Ortiz and Martínez, 1984; and others). The analyses provide a potential basis by which predictions can be made of the changes in water quality that will occur from changes in the phosphorus loadings to phosphorus-limited water bodies. Analyses of over 200 water bodies permitted a general classification of lakes based on water transparency and concentrations of phosphorus, nitrogen, and phytoplankton pigment (Table 13-18). Although any attempt at rigid classification of water bodies is subjective and fraught with exceptions, the general classification is useful.

[a] Based on data of an international eutrophication program. Trophic status based on the opinions of the experienced investigators of each lake. (Modified from Vollenweider, 1979.)

The models permit predictions of the probability of oligotrophic, intermediate, or eutrophic conditions developing in phosphorus-limited lakes in response to various loading regimes (Fig. 13-15). The literature on this subject is very large, for the models have been continuously tested, refined, and improved (e.g., Reckhow, 1979; Chapra and Reckhow, 1981, 1983). As with all modeling efforts of natural and disturbed ecosystems, one must not permit the mathematical manipulations to become an end in themselves (e.g., Pielou, 1981).

Models based on many data permit estimates of permissible loading rates of phosphorus and nitrogen while still allowing tolerable conditions of productivity. Considering a combination of influencing conditions, Vollenweider (1968) estimated very approximate provisional loading rates of nitrogen and phosphorus required to

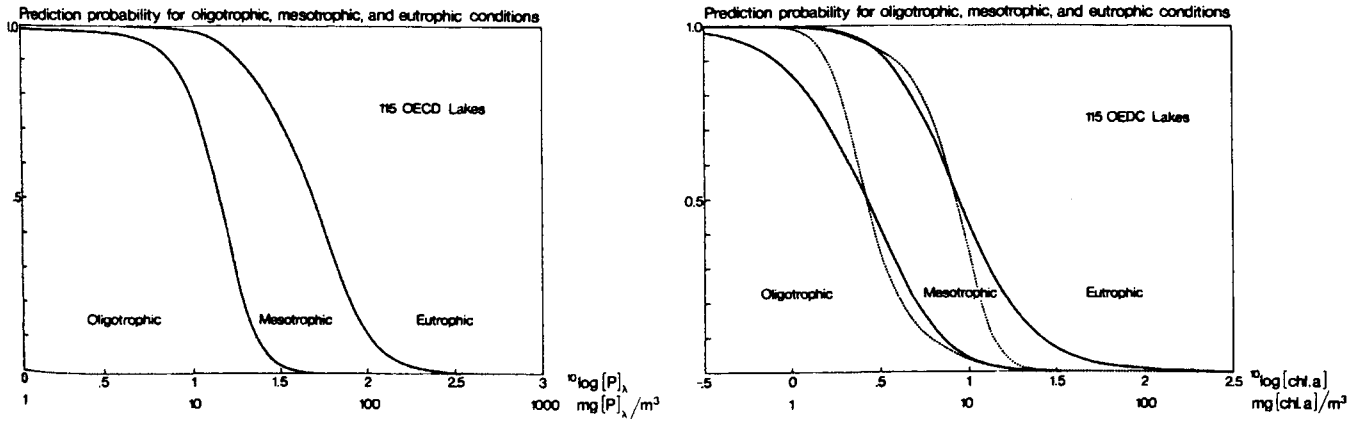

FIGURE 13-15 Probable boundaries of the degrees of trophy of water bodies with differing annual mean values of total phosphorus concentrations (*left*) and chlorophyll *a* concentrations (*right*). (Modified from Vollenweider, 1979.)

[a] After Vollenweider, R. A.: *Scientific Fundamentals of the Eutrophication of Lakes and Flowing Waters, with Particular Reference to Nitrogen and Phosphorus as Factors in Eutrophication,* OECD Report No. DAS/CSI/68.27, Paris, OECD, 1968.

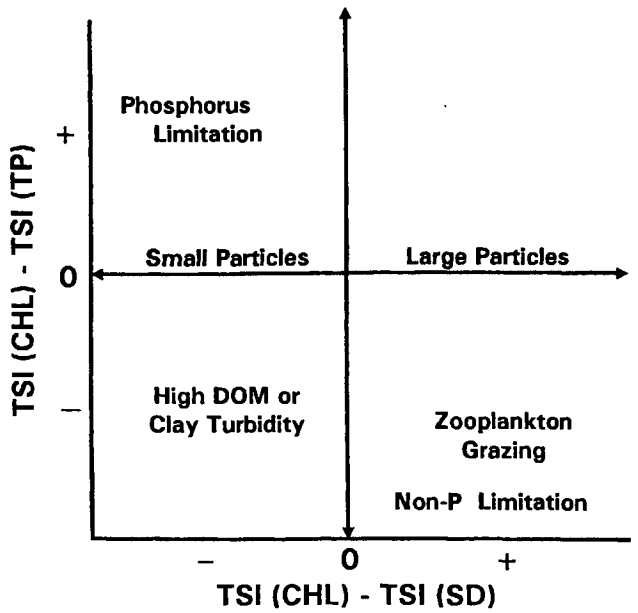

FIGURE 13-16 Potential nutrient-limited and nonnutrient-limited causes for deviation of biomass-based trophic state index (TSI). See text; based upon developments by Carlson (1992).

maintain lakes in a steady state (Table 13-19). Rapid eutrophication is likely to result as loading is increased. Although the predictive models have improved considerably since this analysis appeared, the tolerable loading level of 10 mg P m^{-3} remains unaltered, while the excessive loading level has been increased slightly to 25 mg P m^{-3} (Vollenweider and Kerekes, 1980).

A simple production-based ***trophic state index*** (TSI) uses phytoplankton biomass[4] as a basis for a continuum of trophic states of lakes and reservoirs under both nutrient-limiting and nonnutrient-limited conditions (Carlson 1977, 1980, 1992; Carlson and Simpson, 1996). Algal biomass can be estimated independently by chlorophyll pigment concentrations, Secchi depth, and total phosphorus concentrations. The trophic continuum is divided into units based on a base-2 logarithmic transformation of Secchi depth, with each 10-unit division of the index representing a halving or doubling of Secchi depth. Because total phosphorus is often inversely correlated with transparency, a doubling of the total *P* often corresponds to a halving of Secchi depth transparency. Chlorophyll pigments double every seven units (Carlson, 1980). Derivations of the ensuing linear regression models indicated that total P may be better than chlorophyll at predicting summer trophic state from winter samples, and transparency should be used only if no better data are available:

$$\text{TSI(SD)} = 60 - 14.41 \ln(\text{SD})$$

$$\text{TSI(CHL)} = 9.81 \ln(\text{CHL}) + 30.6$$

$$\text{TSI(TP)} = 14.42 \ln(\text{TP}) + 4.15$$

[4] Although the index was based on phytoplankton biomass, it could likely include macrophytic and periphytic chlorophyll as well.

where SD = Secchi disk transparency (m), CHL = chlorophyll pigment concentrations (mg m^{-3}), and TP = total phosphorus concentrations (mg m^{-3}). Values obtained by the three TSI models should not be averaged. TSI values of <30 are common among lakes and reservoirs of classical oligotrophy, and from 50 to 70 correspond to classical eutrophy. Hypereutrophic conditions are common at TSI values of >70. The TSI changes in some lakes over an annual period, for example, during periods of intensive zooplankton grazing, reduction of nutrient availability seasonally, and with differences in nonalgal turbidity. Deviations of the TSI relationships can be clarified by graphical expression (Fig. 13-16). Values below the zero *X*-axis indicate the likelihood of something other than *P* limitation; points above this axis suggest increasing possibility of *P* limitation. Points to the right of the *Y*-axis indicate transparency is greater than predicted from the chlorophyll index, such as dominance by large cyanobacteria or zooplanktonic grazing and the subsequent relative reduction of smaller particles. Points along the lower left diagonal to the left of the *Y*-axis indicate reduced transparency from nonalgal factors, such as high concentrations of dissolved organic matter or small particles of nonalgal turbidity.

The general trophic classification system for lakes has been extended to streams. Rather than use the chlorophyll of seston, the chlorophyll content of benthic algae has been correlated to total nitrogen and phosphorus content in temperate streams (Dodds *et al.*,

TABLE 13-20 Suggested Boundaries for Trophic Classification of Streams Based on Distributions of Benthic Chlorophyll Content and Nutrient Concentrations[a]

Variable	*Oligotrophic–mesotrophic boundary*	*Mesotrophic–eutrophic boundary*
Mean benthic chlorophyll (mg m^{-2})	20	70
Maximum benthic chlorophyll (mg m^{-2})	60	200
Sestonic chlorophyll (mg $liter^{-1}$)	10	30
Total phosphorus (μg $liter^{-1}$)	25	75
Total nitrogen (μg $liter^{-1}$)	700	1500

[a] After Dodds *et al.* (1998).

1998). The correlations between total phosphorus and chlorophyll for streams are distinctly weaker than is the case for lakes, but a set of proximate trophic categories has been proposed (Table 13-20).

D. Effects of Decreasing Nutrient Loading

The reduction of the productivity of lakes by decreasing phosphorus loading can be very effective. Many examples are given in Vollenweider's (1968) review. Among the most frequently discussed examples is Lake Washington, Seattle, Washington (Edmondson, 1972, 1991). Lake Washington was enriched with increasing volumes of effluent from secondary sewage treatment facilities during the period from 1941 to 1953. Production increased markedly, and the algae became more abundant. Phosphate concentrations also increased proportionally much more than those of nitrate or carbon dioxide. Effluent was diverted away from the lake in 1963, and by 1969, phosphate had decreased to 28% of its 1963 value. Summer chlorophyll concentrations had decreased about as much, but nitrate and total CO_2 fluctuated from year to year at relatively high values. Reduction in phytoplankton and phosphorus continued to a relatively stable level in the 1990s (Edmondson, 1969, 1991; Edmondson and Lehman, 1981).

The rate at which the productivity of a lake will revert toward conditions existing prior to increased loading is variable and depends upon basin morphometry, water chemistry, and the nature of the phosphorus sources (diffuse or concentrated at point sources). The loading of lakes with nitrogen and phosphorus is further influenced by the ratio of the surface area of the drainage basin to that of the lake (Ohle, 1965). Depending on the percentage losses from the land, some of which may be under cultivation, inputs increase roughly in proportion to the "surroundings" ratio.

Upon reduction of loading rates to or below those of the lake prior to accelerated inputs, recovery will require 2–10 yr for lakes of average size and average hydrological replenishment time. The relative residence time, or, inversely, the flow-through rate, of phosphorus is directly coupled to the efficiency of sediment removal and retention capacities in the regulation of phytoplanktonic productivity (e.g., Janus and Vollenweider, 1984; Vollenweider, 1985, 1990). In general, oligotrophic lakes will respond slowly to increasing loading but rapidly to decreasing loads as long as the loading perturbation is of short duration. In contrast, lakes with a long eutrophicational history and large accumulations of nutrients in the sediments have lost resilience and respond more slowly to reductions in nutrient loadings. The rate of recovery, therefore, is much slower in shallower lakes where the "internal loading" of phosphorus from sediment sources is high. In eutrophic Shagawa Lake, Minnesota, for example, where external phosphorus loading was reduced by >70%, predicted reduced equilibrium levels were not achieved (observed levels of phosphorus concentrations after diversion were >100% in excess of those predicted; Larsen *et al.*, 1975). Shagawa Lake is shallow, has an anaerobic hypolimnion, and has an extensively developed littoral zone of submersed macrophytes, all of which contribute to enhanced release of sediment phosphorus. Internal loading from sediment phosphorus sources has been observed in many other shallow lakes, reservoirs, or lakes with anoxic hypolimnia (e.g., Cooke *et al.*, 1977; 1994; Grobler and Davies, 1981; Hillbricht-Ilkowska and Lawacz, 1983; Nürnberg, 1984). The magnitude of internal phosphorus loading can be predicted from the product of an average rate of phosphorus release from anoxic sediments, the surface area of the anoxic sediment, and the period of anoxia. Such internal loading slows the rate of lake recovery implemented by reduction of phosphorus loading from external allochthonous sources. In most lakes, however, the "internal loading" contribution is a relatively small proportion of the external sources (e.g., Bannerman *et al.*, 1974; Edmondson and Lehman, 1981; Smith and Shapiro, 1981; Rast *et al.*, 1983), so that regulation of loading rates can often be effective in controlling phytoplankton productivity.

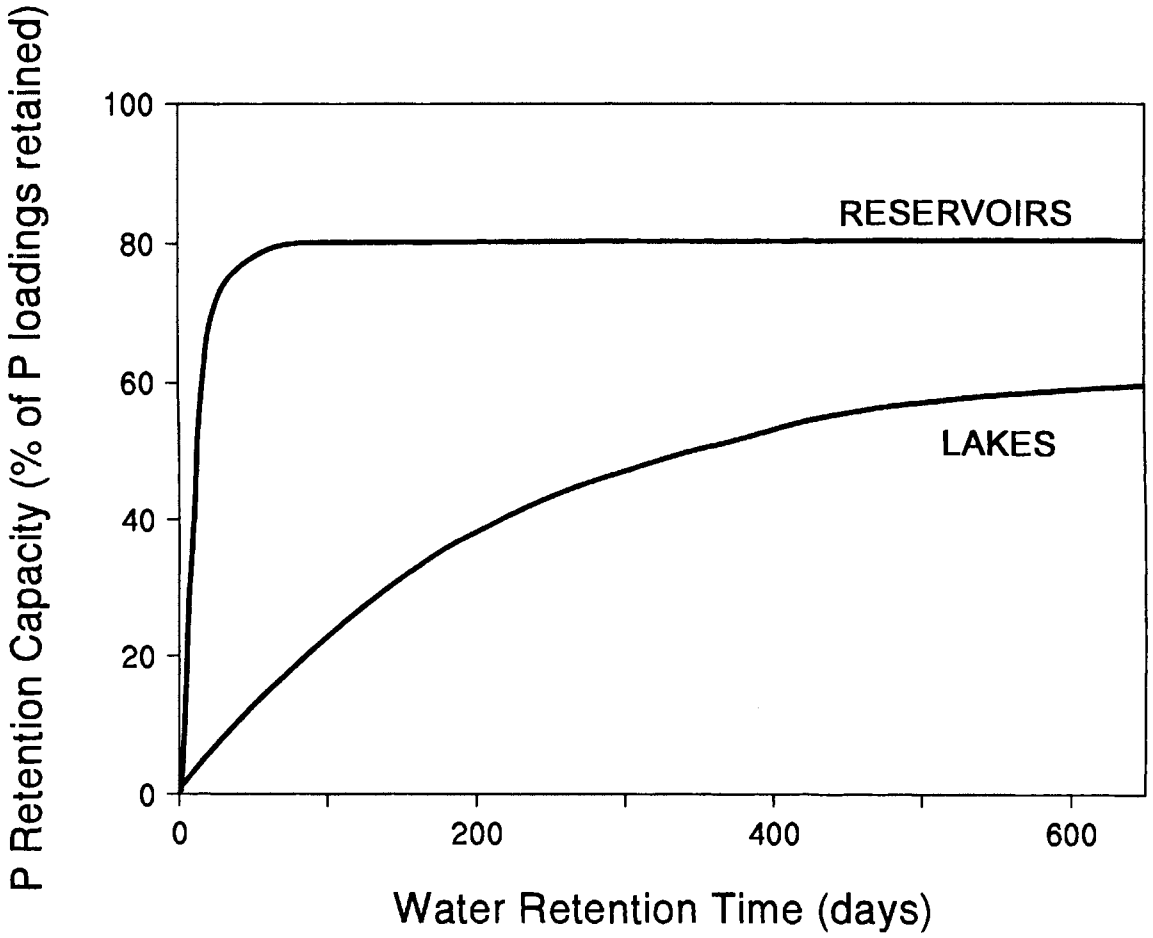

FIGURE 13-17 Phosphorus retention capacity of lakes and reservoirs as a percentage of total phosphorus loadings retained in relation to water retention times. (Modified from Straškraba, 1996.)

Finally, the retention capacities for phosphorus can differ considerably between stratified natural lakes and reservoirs. Much of the difference in phosphorus retention focuses on marked differences in water retention times. Water retention time can be estimated by the number of days needed in a given year to fill the lake or reservoir if it were empty. That water retention can be correlated to the phosphorus retention capacity estimated as the percentage of the total phosphorus loadings remaining and not lost from the water body via its outflow (Straškraba, 1996). Although the phosphorus retention times are similar when comparing water retention times of a year or longer (Fig. 13-17), the water retention times of lakes are much longer (1–7 yr on the average) than those of reservoirs (often <100 days and highly variable). The differences are most pronounced at water retention times <100 days (Fig. 13-16). These differences are related, in part, to more rapid sedimentation of particulate phosphorus and removal of outflow water deep in the stratified waters in reservoirs versus the slower sedimentation of biotic particles and water removal by surface outflows that predominate in lakes.

IX. SUMMARY

1. Phosphorus plays a major role in biological metabolism. In comparison to other macronutrients required by biota, phosphorus is the least abundant and commonly is the first element to limit biological productivity.
2. Many quantitative data exist on the seasonal and spatial distribution of phosphorus in streams and lakes and the loading rates to recipient waters from drainage basins.
   a. Orthophosphate (PO_4^{-3}) is the only directly utilizable form of soluble inorganic phosphorus. Phosphate is extremely reactive and interacts with many cations (e.g., Fe and Ca) to form,

especially under oxidizing conditions, relatively insoluble compounds that precipitate out of the water. Availability of phosphate is also reduced by adsorption to inorganic colloids and particulate compounds (e.g., clays, carbonates, and hydroxides).

b. A large proportion of phosphorus in fresh waters is bound in organic phosphates and cellular constituents of organisms, both living and dead, and within or adsorbed to organic colloids.

c. The range of total phosphorus in fresh waters is large, from <5 μg liter^{-1} in very unproductive waters to >100 μg liter^{-1} in highly eutrophic waters. Most uncontaminated fresh waters contain between 10 and 50 μg total P liter^{-1}.

d. Although concentrations of total and soluble phosphorus of oligotrophic lakes exhibit little variation with increasing depth, eutrophic lakes with strongly clinograde oxygen profiles commonly show a marked increase in phosphorus content in the lower hypolimnion (Fig. 13-1). Much of the hypolimnetic increase is from soluble phosphorus near the sediment–water interface.

3. Dissolved phosphorus in rivers is generally higher than in lakes and often increases markedly following rainfall and snowmelt events on land of the drainage basin.

a. At low concentrations in streams, phosphorus can be limiting and microbial productivity often increases with increased loading of phosphorus.

b. In addition to biological uptake, phosphorus abundance is regulated by abiotic adsorption and desorption reactions with organic and inorganic particles. Dissolved organic phosphorus compounds are utilized more slowly than inorganic forms and tend to be exported downstream for considerable distances.

c. Most of the recycling of phosphorus is associated with microbiota attached to particles. Less than 5% is associated with macroinvertebrates and higher organisms.

4. Exchanges of phosphorus across the sediment–water interface are regulated by oxidation–reduction (redox) interactions dependent on oxygen supply, mineral solubility and sorptive mechanisms, the metabolic activities of bacteria and fungi, and turbulence from physical and biotic activities.

a. In all but the upper few millimeters of sediment, exchange is slow and controlled by low diffusion rates.

b. If water above the sediments is oxygenated (approximately >1 mg O_2 liter^{-1}), an oxidized microzone is formed below the sediment–water interface (0 to -5 mm), below which the sediments usually become extremely reducing (Fig. 13-4). The oxidized microzone effectively prevents phosphorus (which is solublized under reducing conditions in the sediments) from migrating by diffusion upward into the water column (Fig. 13-5, *left*).

c. As the hypolimnion becomes anoxic in productive lakes, the oxidized microzone is lost. The release of phosphate and ferrous iron into the water occurs readily when reducing conditions reach a redox potential (E_7) of about $+200$ mV (Fig. 13-5, *right*).

d. Soluble phosphorus can accumulate in large quantities in anaerobic hypolimnia. With the advent of autumnal circulation, ferrous iron is rapidly oxidized and precipitates much of the phosphate as ferric phosphate.

e. Bacterial metabolism of organic matter is the primary mechanism by which organic phosphorus is converted to phosphate in the sediments and for creating the reducing conditions required for release of phosphate to the water.

f. Movement of phosphorus from sediment interstitial water can be accelerated by physical turbulence and by biota. If light reaches sediments, photosynthetic activity of epipelic algae can create a highly oxidized microzone in the surficial sediments and regulate phosphorus release to overlying water on a diurnal basis.

i. Rooted aquatic macrophytes often obtain phosphorus from the sediments and can release certain amounts into the water both during active growth but particularly upon senescence and death. Most of the released phosphorus is retained and recycled by attached algae, bacteria, and other microbiota.

ii. High population densities of sediment-dwelling invertebrates, such as midge larvae, can increase the exchange of phosphorus across the sediment–water interface.

5. Recent studies of phosphorus cycling in the trophogenic zone have demonstrated that the exchange of phosphorus between its various forms is often rapid and involves numerous complex pathways.

a. A large portion, often >95%, of the phosphorus is bound in the particulate phase of living biota, especially bacteria, algae, and other microbes.

b. Organic phosphorus of the seston of the open water consists of at least two major fractions:

i. A rapidly cycled fraction that is exchanged with soluble forms. In this fraction,

phosphate is transferred rapidly through the particulate phase to low-molecular-weight compounds.

ii. A fraction of dissolved organic and colloidal phosphorus material that is released and cycled more slowly.

c. Phosphorus uptake and turnover kinetics in numerous lakes show that turnover rates are extremely rapid (5–100 min) during summer periods of high demand and low loading inputs. During winter periods, turnover rates become as much as 2 orders of magnitude slower. Phosphorus turnover rates are generally faster under more oligotrophic conditions of lower phosphorus availability.

d. Flagellates, other protista, and zooplankton that feed on bacteria and other seston excrete soluble phosphorus and ammonia. These nutrients are rapidly utilized by algae and bacteria. When supplies of phosphorus are low, this source of recycled phosphorus can be critical to the growth and succession of phytoplankton.

e. Algal requirements for phosphorus are variable among species and can lead to selective advantages of certain algae as phosphorus supplies change seasonally or as phosphorus loadings to a fresh water change over a longer period of time. Algae must compete with bacteria for phosphorus sources; if organic substrates for bacterial growth are high, algal growth may be seriously impeded.

6. Sedimentation of particles results in constant losses of phosphorus from the trophogenic zone. As a result, new phosphorus supplies must enter the ecosystem in order to maintain or increase productivity.

a. Phosphorus enters fresh waters from atmospheric precipitation and from groundwater and surface runoff. The loading rates of phosphorus vary greatly with patterns of land use, geology and morphology of the drainage basin, soil productivity, human activities, pollution, and other factors.

b. When phosphorus is added to unproductive fresh waters, either experimentally or as a result of human activities, the usual response is a rapid increase in algal productivity. Inputs must be more or less continuous, however, to maintain a higher level of productivity.

c. Numerous mass balance models have been developed to predict, on the basis of phosphorus loading and retention times, the anticipated responses of algal biomass and productivity. The models predict a reasonably accurate estimation of permissible phosphorus loading needed to achieve a certain level of productivity if loading is lowered.

d. In certain shallow lakes with greater than average turbulence, large littoral areas, and small, anaerobic hypolimnia, reduced productivity does not always occur as rapidly in response to decreased loading as predicted from the models. In these lakes, phosphorus release from sediment sources ("internal loading") is much greater than values (10–30% of total loading) for deeper, more stratified lakes.

I. BIOGEOCHEMICAL CYCLING OF ESSENTIAL MICRONUTRIENTS

The biogeochemical cycling of essential micronutrients is complex and is regulated to a large extent by variations in oxidation-reduction states, which in turn are mediated by photosynthetic and bacterial metabolism. Many of the reactions among different elemental nutrients are coupled, and the state of one can influence the availability of another. Although the coupled reactions must be viewed simultaneously, the following discussion separates the components as much as possible.

II. OXIDATION-REDUCTION POTENTIALS IN FRESHWATER SYSTEMS

In pure inorganic chemical systems, oxidation-reduction (redox) reactions proceed with a flow of electrons between the oxidized and reduced states until equilibrium is attained. There is a tendency for the reduced phase to lose electrons and be transformed to an oxidized state (e.g., $Fe^{3+} + e^- \rightleftharpoons Fe^{2+}$). Free electrons, however, usually inhibit this process, so large quantities of free ions in reduced and oxidized states can exist together. If electrons are removed, as for example by an immersed platinum electrode, then a transformation of

the reduced state to the oxidized state (Fe^{2+} to Fe^{3+}) occurs, and a current of electrons passes through the electrodes. By applying a current (electrons) in the opposite direction, reduction can be induced; the reactions are reversible. Such potentiometric changes in electron flow can be accomplished with any solution containing ionic species, including the composite system of lake water, by drawing off electrons with a calomel[1]–platinum electrode. The resulting measurement, taken against standard conditions, is an expression of the oxidizing or reducing intensity or condition of the solution. The current, referenced against the hydrogen electrode, is termed the *redox potential* or the *electrode potential.*

A. The Redox Potential

Redox potential is proportional to the equivalent free energy change per mole of electrons associated with a given reduction (Stumm, 1966; Morris and Stumm, 1967). Although aqueous solutions do not contain free protons and electrons, it is possible to define proton activity [$pH = -\log(H^+)$] and electron activity [$pE = -\log(e^-)$]. pE is large and positive in strongly oxidizing solutions (low electron activity), just as pH is high in strongly alkaline solutions (low proton activity). Thus, both pH and pE are intensity factors of free energy levels and are not related to capacity or condition (e.g., alkalinity and acidity).

When oxygen is dissolved in water, a redox potential is generated according to the reaction (cf. discussion in Stumm, 1966, and Stumm and Morgan, 1996):

$$H_2O \rightleftharpoons \tfrac{1}{2}O_2 + 2H^+ + 2e^-$$

The pE of water at equilibrium is relatively insensitive to a change in oxygen concentration and extent of saturation, for it is influenced by the fourth root of the partial pressure of oxygen. If the oxygen content is decreased by 99%, the redox potential would be reduced by only about 30 mV. The activity of the hydroxyl ions, however, influences the activity of the hydrogen ions. Therefore, the redox potential is significantly changed by alterations of H^+ and is reflected in the pH. It is customary to express the pE of redox reactions in natural waters at their activities in neutral water at pH 7 rather than at unity. Thus, the redox potential is expressed as E_h or as E_7, in which a correction is made for the change in redox at the pH of the sample to a pH of 7.[2] A change in pH of one unit is accompanied by a change in redox potential of 58 mV. Hence, a common practice is to correct potentials to pH 7 by subtracting 58 mV for every pH unit on the acid side of neutrality and by adding 58 mV for every pH unit on the alkaline side of neutrality. E_h is influenced to only a small extent by temperature, for example, E_h of water = 860 mV at 0°C and 800 at 30°C at pH 7.

The preceding discussion applies to an ideal situation under conditions of equilibrium in which oxidation–reduction systems are reversible (Stumm, 1966). True redox equilibrium is not found in any natural aquatic system because of the extreme slowness of most redox reactions in the absence of appropriate biochemical catalysis. There is, in addition, a continuous cyclic input of photosynthetic energy that disturbs the trend toward equilibrium conditions. In addition to nonequilibrium redox conditions, which are related to the highly dynamic state of biotic activities, electrochemical measurements of redox depend on the nature and composite rates of reactions at the electrode surface. In practice, the redox measurements reflect irreversible electrochemical redox potentials. Thus, in neutral, fully oxygenated water equilibrated with air, redox potentials slightly greater than 500 mV are obtained, which are considerably less than the theoretical E_h of 800 mV.

Few elements (C, O, N, S, Fe, Mn) are predominant reactants in redox processes in natural waters. By the conversion of energy into chemical bonds, photosynthesis produces reduced states (negative E_h) of high free energy and results in nonequilibrium concentrations of C, N, and S compounds (Stumm, 1966). Respiratory, fermentative, and other nonphotosynthetic reactions of organisms tend to restore equilibrium by catalytically decomposing, through energy-yielding redox reactions, the thermodynamically unstable products of photosynthesis. It is through such reactions that nonphotosynthetic organisms obtain a source of free energy for their metabolic demands. The mean E_h is increased by these combined processes. It should be noted that organisms act as redox catalysts by mediating the reactions and transfer of electrons; the organisms themselves do not oxidize substrates or reduce compounds.

Reduced and oxidized iron (Fe^{2+} and Fe^{3+}) is among the most electroactive redox reactants in natural water systems. Other than iron and to a certain extent manganese, the redox components of organic carbon, nitrogen, and sulfur are not electronegative and yield reversible potentials only following enzyme-mediated changes. As a result, redox measurements in natural waters do not lend themselves to quantitative interpretation and comparison. Qualitative, relative comparisons of E_h, representing mixed composite potentials, however, can be extremely instructive, as was demonstrated by the monographic comparison of pH

[1] A calomel electrode consists of a chloride solution (usually KCl), solid Hg_2Cl_2 (calomel), and metallic mercury.

[2] E_h is compared to the hydrogen half-cell at any designated pH; usually it is pH O($[H^+] = 1$). Thus, E_h is usually, but not necessarily always, corrected to neutral pH.

and E_h limits in different environments and among organisms (Baas and Becking *et al.*, 1960).

Redox potentials, as measured with electrodes, cannot be used to predict the dominant redox reactions in anaerobic sediments because of the significant overlap in redox potentials for different reactions. As we will see in the discussion of bacterial metabolism in sediments (cf. Chap. 21), only microorganisms catalyze the oxidation of hydrogen (H_2) coupled to the reduction of nitrate, Mn(IV), Fe(III), sulfate, or carbon dioxide. At steady-state conditions, H_2 concentrations are primarily dependent upon the physiological characteristics of the microorganisms consuming the H_2. Organisms catalyzing H_2 oxidation, with the reduction of a more electrochemically positive electron acceptor, can maintain lower H_2 concentrations than organisms using electron acceptors that yield less energy from H_2 oxidation (Lovley and Goodwin, 1988; Chapelle *et al.* 1996). Each predominant terminal electron-accepting reaction in sediments has a unique range of steady-state H_2 concentrations associated with it: nitrate or Mn(IV) reduction, less than 0.05 nM H_2; Fe(III) reduction, 0.2 nM (range 0.2–0.8 nM); sulfate reduction, 1–4 nM; and methanogenesis, 7–10 nM (range 5–25 nM). Sediments with the same terminal electron acceptor for organic matter oxidation had comparable H_2 concentrations, in spite of variations in the rate of organic matter decomposition, pH, or salinity.

From this discussion, one would anticipate little change in redox potential with increasing depth as long as the water contained dissolved oxygen. Even though a distinctly clinograde oxygen curve may be found, as long as the water is not near anoxia the E_h will remain positive and fairly high (300–500 mV). Such conditions have been found repeatedly in detailed studies of E_h in lake waters of widely diverse types (Kuznetsov, 1935; Hutchinson *et al.*, 1939; Allgeier *et al.*, 1941; Mortimer, 1942; Kjensmo, 1970; Eckert and Trüper, 1993). As oxygen concentrations approach zero and anoxic conditions appear, as in the lower hypolimnion and near the sediments, the E_h decreases precipitously. Similar relationships at the sediment–water interface were discussed in some detail in the previous chapter on phosphorus release from the sediments (cf. Figs. 13-4, 13-5, and 13-6). Within the sediments, reducing conditions prevail, and the E_h declines to 0 mV or below within a few millimeters of the interface (Figs. 13-4, and 13-5). Of the many reducing compounds that contribute to the reductions in E_h, ferrous iron of the sediments is the most important (Fig. 13-5).

Lower redox potentials are generally observed in lake systems containing relatively high concentrations of dissolved humic compounds (Allgeier *et al.*, 1941, Kjensmo, 1970). Humic acids, especially those derived

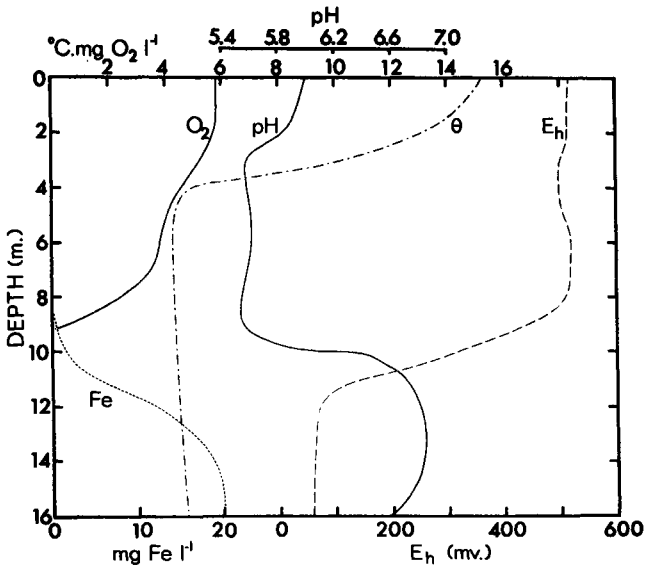

FIGURE 14-1 Vertical distribution of temperature, oxygen, pH, total iron, and redox potential E_h in permanently meromictic Lake Skiennungen, Norway, June 1967. (After Kjensmo, 1970.)

from the moss *Sphagnum* of bogs and bog lakes, have an E_h of about 350 mV (Visser, 1964b), and their reducing properties lead to a metal enrichment by complexing and adsorption to the acid molecules (Szilágyi, 1973; Zimmerman, 1981). The redox potentials of the deep monimolimnia of meromictic lakes are generally extremely low, among the lowest found in natural waters (Fig. 14-1). Extremely high concentrations of soluble total iron are frequently found in the monimolimnia of these permanently stratified lakes of high dissolved organic matter content (Hongve, 1980). In shallow meromictic lakes where the water of the monimolimnion is slowly (over several years) exchanged with the overlying water strata, high monimolimnetic iron concentrations are maintained through the oxidation of ferrous iron in the chemolimnion (Campbell and Torgersen, 1980). Up to 90% of the iron entering the chemolimnion is oxidized and is returned to the monimolimnion by sedimentation and subsequent resolubilization.

III. IRON AND MANGANESE CYCLING IN LAKES

The similarities in chemical reactivity between iron and manganese permit us to discuss them together. Although clear differences exist between the two metals, and although much more is known about the dynamics and cycling of iron, the two metals behave in similar fashion in freshwater systems. A strong interaction exists between the cycling of these metals, especially iron and sulfur. The biogeochemical fluxes of iron and

manganese reflect the combined spatial and temporal variations in physical chemistry, which are almost totally controlled by the dynamic conditions regulating bacterial metabolism.

A. Chemical Equilibria and Forms of Iron and Manganese

Iron exists in solution in either the ferrous (Fe^{2+}) or ferric (Fe^{3+}) state. (Detailed reviews are given in Hem and Cropper, 1959; Hem, 1960; Stumm and Lee, 1960; Doyle, 1968a; Millero *et al.*, 1995; and Stumm and Morgan, 1996). Amounts of iron in solution in natural water and the rate of oxidation of Fe^{2+} to Fe^{3+} in oxygenated water are dependent primarily on pH, E_h, and temperature. Ferrous constituents tend to be more soluble than ferric constituents.

Soluble ferrous iron occurs mainly as hydrated Fe^{2+} and hydrated hydroxo ions, the solubility of which is determined largely by the solubility of ferrous hydroxide [$Fe(OH)_2$], ferrous carbonate ($FeCO_3$), and ferrous sulfide (FeS). $Fe(OH)_2$ is exceedingly insoluble within the normal pH range of oxygenated natural waters. The solubility of ferrous iron is generally controlled by the solubility of $FeCO_3$. Even at low pH, carbonate concentrations are usually sufficient to limit solubilization. If water is saturated with $CaCO_3$, $FeCO_3$ is about 200 times less soluble than $CaCO_3$, unless very high pH values (>10) occur. Soft waters with very low concentrations of bicarbonate usually contain somewhat higher concentrations of Fe^{2+}, although most is oxidized to Fe^{3+}. For example, a water free of bicarbonate at pH 7 would contain more than 1000 times as much Fe^{2+} as a water containing 2 meq liter^{-1} alkalinity, an average value for many waters. FeS is also exceedingly insoluble and forms both amorphous and stable, crystalline phases that darken the color of anaerobic sediments (Doyle, 1968b; Davison, 1991). At low redox potentials in the anaerobic hypolimnia of productive or meromictic lakes, bacterial reduction of sulfate to sulfides is common. The resulting excess of sulfide can decrease concentrations of Fe^{2+} through the formation of insoluble FeS.

B. Iron Complexes

The most common species of ferric iron in natural waters is hydrated ferric hydroxide, $Fe(OH)_3$. At equilibrium in the pH range of 5–8, $Fe(OH)_3$ is in the solid state, because its solubility is very low (equilibrium constant approximately 10^{-36} at 25°C). Other insoluble ferric salts are of less significance. For example, phosphate does not influence the solubility of Fe^{3+} when inorganic phosphorus concentration is $<10^{-4}$ mol liter^{-1}, as is usually the case. It is apparent, therefore, that in the absence of organic matter and based only on solubility criteria as mediated by pH and E_h, a number of forms of inorganic iron can exist in natural waters. The simultaneous influence of hydrogen ions and electrons on the equilibria of aqueous iron is illustrated in Figure 14-2. All of the oxygenation reactions of Fe^{2+} to Fe^{3+} are exergonic and capable of supplying energy;

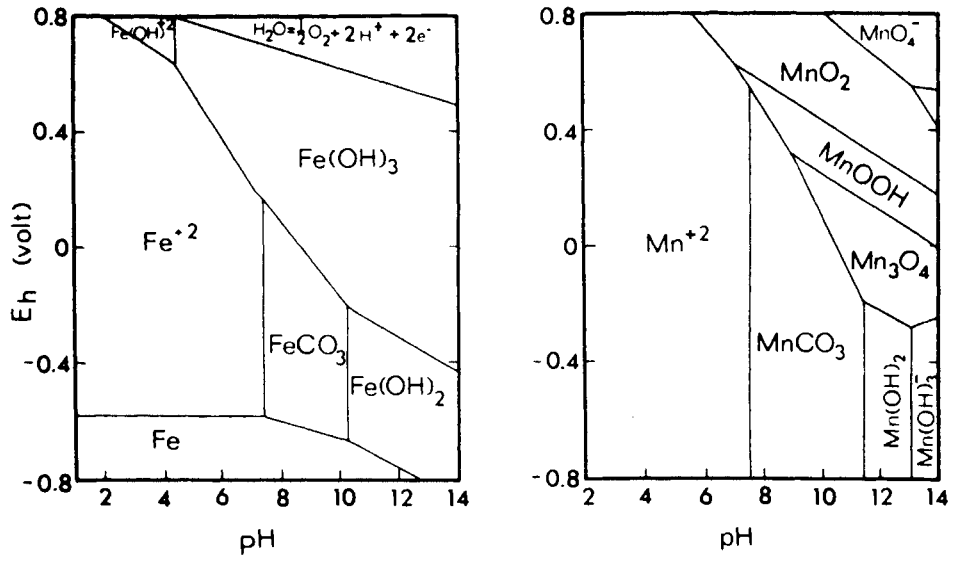

FIGURE 14-2 Approximate distribution of species of iron and manganese in relation to pH and redox potential E_h. Alkalinity is assumed to be equal to 2 meq liter^{-1}. Lines denote points at which the activities of soluble Fe and Mn are 10^{-5} mol liter^{-1}. (Modified from Stumm and Lee, 1960, and Stumm and Morgan, 1996.)

some of these reactions serve as an energy source for microorganisms.

Some of the iron of normal lake water is present as suspensions of flocculent ferricoxyhydroxide, removable by filtration with membranes of a pore size of 0.5 μm (Hutchinson, 1957; Hem and Cropper, 1959; Hem and Skougstad, 1960; Davison and DeVitre, 1992). Under some conditions, a very finely divided precipitate of ferric hydroxide, which has colloidal properties (0.001–0.5 μm, charged), may form (e.g., Tipping *et al.,* 1981; De Haan and De Boer, 1986; Leppard *et al.,* 1988). Colloidal particles of $Fe(OH)_3$ are commonly positively charged, although a negatively charged sol can occur at high pH. Ions in solution, and negatively charged clay particles, organic colloids, and other suspended solids can neutralize the charges on the hydroxide colloidal particles. The uncharged aggregates join to form a rapidly settling precipitate. Other metals, such as copper ions, can be adsorbed by and coprecipitated with the ferric hydroxide precipitate.

Although ferrous iron in solution occurs in extremely low concentrations in oxygenated water, some apparently occurs in particulate and colloidal form. Such suspended ferrous iron is presumably associated with soil and sediment particles. A portion of total iron is contained in the living plankton, but this quantity is a very small part of the whole. The iron content of higher aquatic plants averages 5 mg g^{-1} dry weight, about an order of magnitude greater than the content of terrestrial plants (Oborn, 1960). Plant roots contain a higher proportion of iron than do stems or leaves.

Iron complexes with numerous organic compounds, and this process greatly alters iron solubility and availability to organisms. Many organic bases form strong soluble iron complexes with ferrous and ferric ions (Gjessing, 1964; Millero *et al.,* 1995). Iron enrichment is common in surface waters with a high content of dissolved organic matter, particularly humic and fulvic acids, tannic acids, and other lignin derivatives (Shapiro, 1957; Hem, 1960b; Nürnberg and Dillon, 1993; Shaw, 1994). The intense yellow–brown color of bog waters is, in part, a result of these iron–organic complexes. Natural and synthetic organic compounds, for example, citrate and ethylenediamine tetraacetic acid (EDTA), of high complexing capacity for metals, are commonly used in studies of plant and especially algal nutrition because they can maintain iron available for assimilation. Shapiro (1964, 1966, 1969) showed that complexing of iron with humic derivatives, particularly organic acids of low molecular weight, was by peptization, in which iron is dispersed in a solubilized form of the $Fe(OH)_3$ precipitate by adsorption of the organic acids onto the surfaces of the particles. Some iron is chelated with organic acids by weak chemical bonding, although chelation is not the primary complexing mechanism (cf. Steinberg, 1980). In acidic (pH 4–5) bog lakes, ferric iron may exist not as an inorganic complex but as reactive ferric iron by complexation with colloidal organic acids (Koenings, 1976).

Precipitation particles of iron oxide contain some 30–40% iron by weight (Tipping *et al.,* 1981; Davison and DeVitre, 1992). Carbon content is variable but adsorbed humic carbon can contribute some 4–7% of the total weight. Some particles are negatively charged because of adsorbed humic substances or complexing with COOH and phenolic OH groups of fulvic and humic acids (Tipping, 1981; Schnitzer and Ghosh, 1982; Tipping and Woof, 1983; McKnight *et al.,* 1992; Jones *et al.,* 1993). This complexing, as well as adsorption of phosphate and silicate, would slow flocculation rates. The iron oxide–humic substance complexes can gradually sediment out, of course, and potentially enrich the hypolimnion with humic substances. There is also evidence (Deng and Stumm, 1993) that the reducing power of fulvic acids of the Fe(III)-organic complex can accelerate the shift of the complex to Fe(II).

Photochemical redox reactions of Fe(III) compounds are an important source of Fe(II) and dissolved iron in surface waters. In the absence of organic complexes, iron oxides are solubilized to varying degrees through photodissociation of ferric hydroxy groups at the colloid surfaces (Walte and Morel, 1984). Photochemical redox reactions of Fe(III)-dissolved complexes, dimers, polymers, and precipitates transfer electrons and reduce Fe(III) to Fe(II). Many species of Fe(III) absorb light at wavelengths >300 nm and include species with ligands such as OH^-, H_2O, HO_2^-, HSO_3^-, Cl^-, carboxylates, and O_2^- (Faust, 1994; Sulzberger *et al.,* 1994). Sunlight irradiation of natural waters produced hydrogen peroxide and other radicals in quantities sufficient to affect the speciation of iron.

Natural organic compounds significantly increase the initial rates of dissolution. However, the efficacy of photochemical reductive dissolution of particulate iron varies greatly with stabilization with organic ligands. Organic species may enhance the production of Fe(II) by scavenging hydroxyl and other radicals and thereby decrease the rate of reoxidation of Fe(II). That enhancement is greater in both shallow waters of lakes and streams, particularly in waters of lower pH of 4–6, and is accompanied with an irreversible photooxidation of organic matter (e.g., Collienne, 1983; McKnight *et al.,* 1988).

Another important aspect of photochemical reduction of complexes of humic materials and iron is that phosphorus is commonly adsorbed as well. Irradiance with ultraviolet light resulted in release of phosphate as

well as release of reduced Fe(II) in acidic bog water (Cotner and Heath, 1990). The significance of such photochemical release of phosphorus adsorbed to humic–Fe complexes over seasonal scales is unclear.

Total iron found in oxygenated surface waters of pH 5–8 typically ranges from about 50 to 200 μg liter^{-1}, almost none of which occurs in ionic form (Wetzel, 1972). Much higher levels occur in lakes heavily stained with dissolved humic compounds, in acidic volcanic lakes, acidic bog waters, and certain alkaline, closed lakes rich in organic matter.

C. Manganese Complexes

The theoretical thermodynamic redox equilibria of manganese have been studied in some detail (Hem, 1963, 1964; Stumm and Morgan, 1996) and permit an evaluation of manganese species and equilibria under various conditions of oxidation reduction found in natural surface waters. In general, the behavior of manganese in lakes follows these predictions.

Although Mn occurs in several valence states, Mn^{3+} is thermodynamically unstable in aqueous solutions under normal conditions, and Mn^{4+} compounds are insoluble at most environmental pH values. As with ferrous iron, ionic divalent Mn^{+2} occurs at low redox potentials and pH (Fig. 14-2). Some form of oxidized Mn will be in equilibrium with Mn^{2+} under oxidizing conditions of high pH and E_h, and some form of Mn^{2+} may be in equilibrium with manganese carbonate under reducing conditions of low pH and E_h. Supersaturation of both ferrous and manganese carbonate has been observed in anoxic hypolimnia of eutrophic lakes (Verdouw and Dekkers, 1980). The redox equilibrium E_h values are higher and the rates of oxidation slower than for iron; as a result, detectable quantities of Mn are commonly observed longer than comparable quantities of iron under lake conditions. Above a pH of 8.5, an intermediate complex forms in which Mn^{+2} is adsorbed onto manganese oxides. The Mn^{2+} of these oxide complexes can react relatively rapidly with other anions and precipitate as manganous carbonate ($MnCO_3$), manganous sulfide (MnS), and manganous hydroxide ($Mn(OH)_2$). Manganese is also adsorbed to iron oxides and coprecipitates with ferric hydroxide when the pH exceeds 7.

Manganese has a solubility of about 1 mg liter^{-1} in distilled water of E_h of 550 mV and pH 7; solubility decreases markedly with increases in E_h and pH. Manganese forms soluble complexes with bicarbonate and sulfate. Increased bicarbonate activity decreases Mn solubility. At high concentrations, bicarbonate has been found to reduce the oxidation rate of manganese. In a manner analogous to iron, organic molecules can form stable complexes with Mn^{2+}, although their operation in aquatic systems is poorly understood. Manganese occurs in relative abundance in alkaline soils as hydrated oxides, and no doubt organic complexing plays a role in retention of Mn in a complexed dissolved form for transport once redox conditions are altered by microbial and plant metabolism. Igneous rock contains about 0.01% manganese, which is involved in biogeochemical cycling following weathering and subsequent mobilization. Drainage from forest litter, especially from more acidic coniferous forests, is often high in manganese. This observation again points to the probability of the major role of organic complexes in the effective transport of easily oxidized metal ions.

D. Distribution of Iron and Manganese in Lakes and Streams

Under oxidized conditions, as in the epilimnia of lakes and most streams, large amounts of iron are found only in acidic water (pH <3–4), such as in lakes of volcanic origin and influence (Yoshimura, 1936) or runoff streams from strip mining operations. In both cases, organic content is relatively low and acidity usually results from sulfuric acid. When streams that receive acidic mine drainage are exposed to sunlight, photoreduction of ferric iron, likely in colloidal forms, can result in a daytime production of ferrous iron that is nearly four times as great as nighttime oxidation of ferrous iron (McKnight *et al.*, 1988).

The quantity of total iron found in most typical neutral or alkaline surface waters, however, is in the range of 50–200 μg liter^{-1} and is dominated by $Fe(OH)_3$, usually in colloidal and particulate forms, organically complexed iron, and adsorbed sestonic iron in particulate forms. The world average is variable among continents (Table 10-1), and higher than would be generally expected among most oxygenated surface waters of lakes. The range of manganese concentrations (approximately 10–850 μg liter^{-1}) is also highly variable in relation to lithology and drainage of the lake basins (Hutchinson, 1957; Livingstone, 1963; Hongve, 1980). The average quantity of manganese is about 35 μg liter^{-1}, somewhat less than that of iron. The ratio of Fe to Mn in water is generally considerably lower than that of the lithosphere (50:1) and indicates the relative enrichment of Mn with respect to Fe; this is in agreement with the reaction equilibria already discussed.

The vertical distribution of iron and manganese is reflected in the distribution of redox potentials. Concentrations of ionic iron of oxygenated waters of oligotrophic lakes, epilimnia of more productive lakes and of circulating waters are exceedingly low. Manganese is

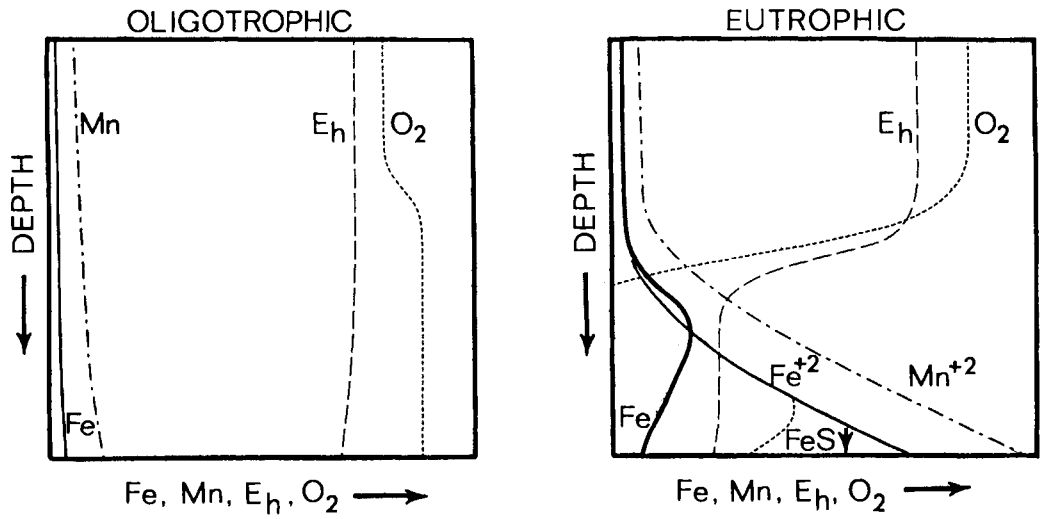

FIGURE 14-3 Generalized vertical distribution of iron, manganese, and redox potential (E_h) in stratified lakes of very low and high productivity.

somewhat more soluble (Fig. 14-3). Ferrous ions diffuse readily from the sediments when redox potentials decline to about 200 mV; migration of Mn^{2+} from the sediments occurs at somewhat greater redox potentials (Robbins and Callender, 1975; Ostendorp and Frevert, 1979). These relationships were demonstrated very well in Mortimer's studies of the sediment interface, both experimentally (see Fig. 13-5) and in a eutrophic lake (see Fig. 13-6). Here it can be seen that the release of Mn precedes that of iron. Released manganese will remain soluble if the oxygen saturation is less than about 50% (Burns and Nriagu, 1976). Iron oxide can form in the absence of particulate matter, but its particle morphology depends upon the presence of particulates. In contrast, the formation of manganese oxide requires living microorganisms to catalyze the oxidation of manganous ions (see later discussion; Ghiorse, 1984; Tipping, 1984; Balikungeri *et al.*, 1985; Tipping *et al.*, 1985).

Thus, a commonly observed seasonal sequence is observed in productive lakes in which the oxic/anoxic boundary migrates from the sediment–water interface well into the hypolimnion (Fig. 14-4). As the hypolimnion becomes more reducing, a progressive shift occurs from the amorphous particulate iron oxyhydroxides to soluble ferrous iron. Where appreciable sulfide is formed by biological reduction of sulfate, ferrous and total iron can be reduced by the formation of and precipitation of insoluble FeS (e.g., Hutchinson, 1957; Cook, 1984). Although the dissolved iron concentrations may be controlled in the lower strata during stratification by FeS precipitation, MnS phases are generally undersaturated and appreciably less than the solubility constants needed for precipitation (Balistrieri *et al.*, 1992). Most of the iron (>90%) reaching the sediments by sedimentation is reduced and redissolved at the sediment–water interface and recycled back into the water column.

Although the seasonal distribution of iron has been studied in some detail (reviewed in Hutchinson, 1957; McMahon, 1969; Davison and De Vitre, 1992), that of manganese has been investigated less extensively (Delfino and Lee, 1968, 1971; Brezonik *et al.*, 1969; Howard and Chisholm, 1975). The general pattern of seasonal distribution is apparent from the examples given of a mesotrophic lake that undergoes hypolimnetic oxygen reduction in the later phases of summer stratification (Fig. 14-5) and of an interconnected eutrophic lake (Fig. 14-6). The eutrophic lake, Little Crooked Lake, is a small, protected eutrophic lake that frequently undergoes partial, temporary meromixis, as was the case in the year shown here when autumnal circulation was incomplete. Of the total manganese, nearly all was in soluble and colloidal form (passing through a 0.45-μm pore size membrane filter) in anaerobic water of the hypolimnion of a small eutrophic lake in New York (Howard and Chisholm, 1975). Less than 13% of the total manganese was in soluble form in the aerobic water strata of this lake.

As decomposition proceeds in the hypolimnion of very productive, thermally stratified lakes, the redox potential of hypolimnetic waters can decline to well below 100 mV. At an E_h below 100 mV, sulfate is reduced to hydrogen sulfide. Hydrogen sulfide is also produced by bacterial decomposition of sulfur-containing organic compounds. Since ferrous iron is released in significant quantities from the sediments at a higher E_h of about

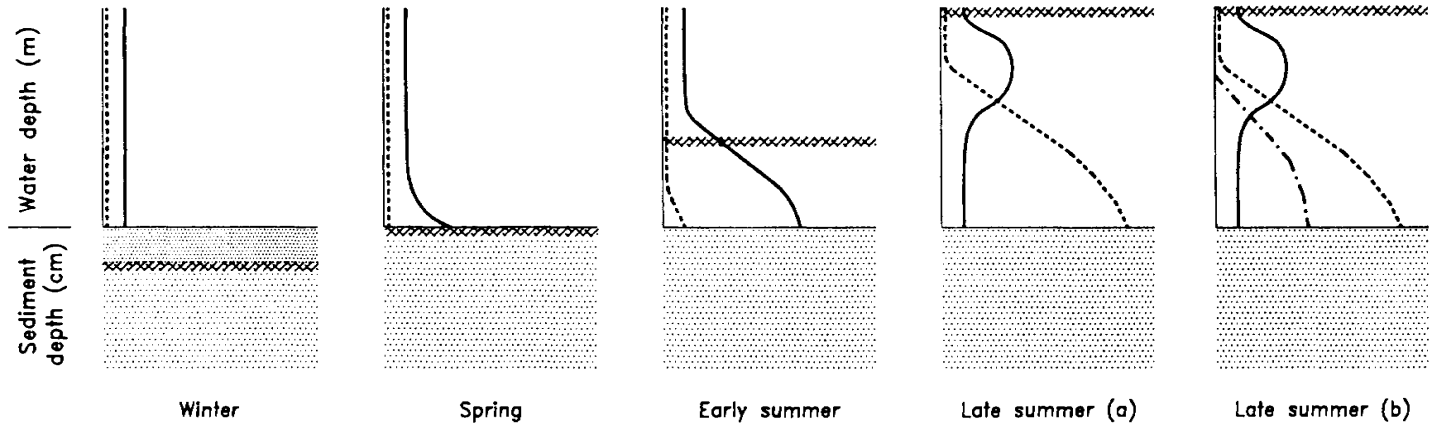

FIGURE 14-4 Changes in the concentration of particulate iron (——) and Fe(II) (- - - -) in the water column of a lake as the oxic/anoxic boundary (xxxx) undergoes seasonal migration. The sediment is represented by light hatching, elevated concentrations of particulate iron in the sediment are represented by darker hatching. The alternative late summer conditions (b) represent marked reducing conditions where sulfide (-·-·-·) and FeS precipitation can contribute to the alterations of vertical distributions. (Modified from Davison and DeVitre, 1992.)

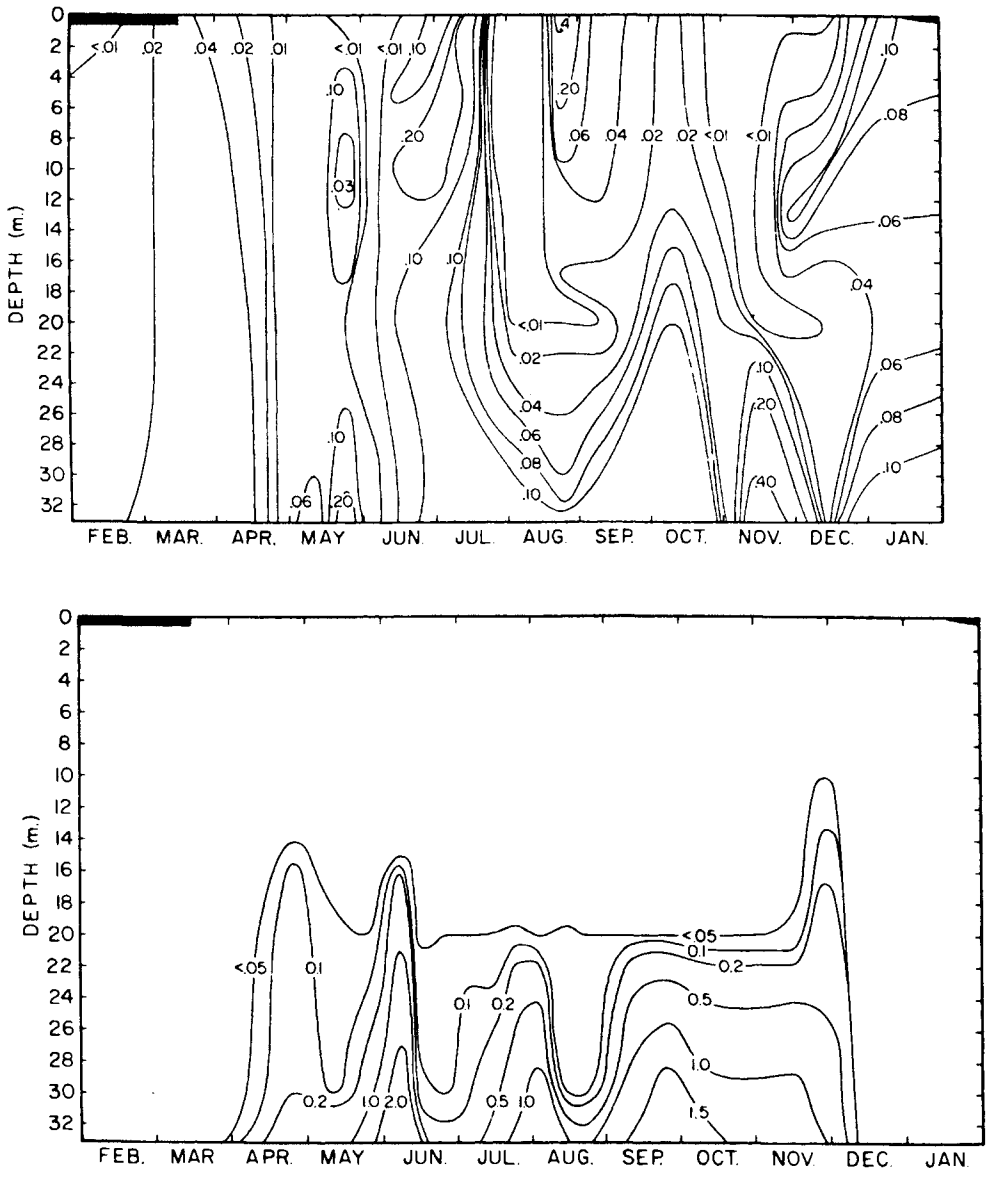

FIGURE 14-5 Depth–time diagrams of isopleths of total iron (*upper*) and manganese (*lower*) in mg liter^{-1} of mesotrophic hardwater Crooked Lake, northeastern Indiana, 1963. (From Wetzel, unpublished data.)

250 mV, much Fe^{2+} is present in the hypolimnion at the time of sulfide formation. The formation of FeS and other metal sulfides (cuprous sulfide, CuS, cadmium sulfide, CdS, et cetera), all of which are very insoluble under normal lake conditions, can result in a significant reduction of iron and other metals toward the end of summer stratification (Davison and Heaney, 1978). Manganous sulfide, on the other hand, is much more soluble and has little effect on the Mn^{2+} concentrations under normal lake conditions.

Iron concentrations in the hypolimnia of softwater lakes can reach very high levels under conditions that prevail in small, deep basins, especially in bog waters receiving high concentrations of humic organic matter. Levels of sulfate are low in such waters, and sulfide concentrations seldom become sufficient to precipitate iron as FeS. Kjensmo (1962, 1967, 1968) demonstrated that the hypolimnetic iron accumulations in protected lakes can reach such levels (>250 mg liter^{-1}) that the salinity gradient becomes adequate to render the lakes permanently meromictic. The precipitation of iron sulfides is inadequate to reduce such high iron concentrations appreciably and contributes to meromictic conditions by allowing iron to accumulate.

Stages along the continuum of declining redox potentials can be divided into four phases of hypolimnetic

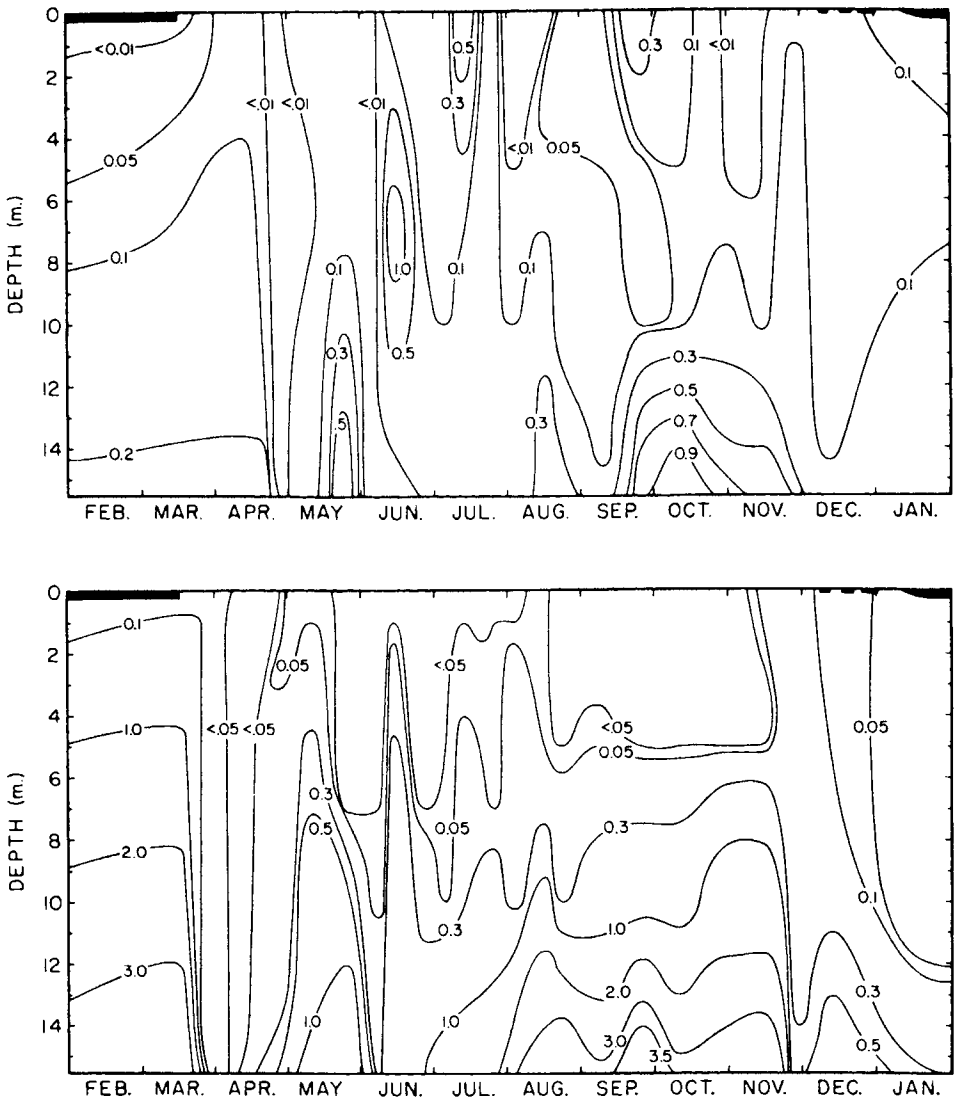

FIGURE 14-6 Depth–time diagrams of isopleths of total iron (*upper*) and manganese (*lower*) in mg liter $^{-1}$ of eutrophic hardwater Little Crooked Lake, northeastern Indiana, 1963. (From Wetzel, unpublished data.)

conditions in stratified lakes of increasing productivity or within a very productive lake during the period of summer stratification (Table 14-1).

E. Cycling of Iron and Manganese

The spatial and temporal distribution of iron and manganese therefore depends upon the balance of many physical, chemical, and biological parameters. Solar radiation and wind affect the hydrodynamic stability of stratification. Biologically mediated chemical processes regulate the redox conditions and the availability of electron acceptors and extent of reduction to allow accumulation of sulfide and subsequent precipitation of metal sulfides.

The mass of particulate iron, for example in eutrophic Esthwaite Water of England, changes little throughout the year (Davison *et al.*, 1980). The large summer increase in the mass of total iron was almost entirely in the soluble and colloidal (<0.7 μm) fraction (Fig. 14-7). Sediment-derived ferrous iron accounted for only 3–18% of the annual iron loading to the lake; most of this sediment-derived fraction was likely oxidized and washed out of the lake rather than returned to the sediment (Fig. 14-7). Most (70–90%) of the iron annually entering the lake accumulated in the sediment (Table 14-2). Redissolution of sinking ferric particles is significant to iron fluxes within the hypolimnion. For example, in Esthwaite Water minimal sinking fluxes were 3–22 μg Fe cm^{-2} day^{-1}. In contrast, much

Lake status	$[O_2]$	E_h	Fe^{+2}	H_2S	PO_4^{-3}
Oligotrophic	High (orthograde)	400–500 mV	Absent	Absent	Very low
↓	↓ Much reduced (clinograde)	↓ 400–500 mV	↓ Absent	↓ Absent	↓ Very low
Europhic	↓ Much reduced (clinograde)	↓ Approx. 250 mV	↓ High	↓ Absent	↓ High
↓	↓	↓	↓	↓	↓
Hypereutrophic	Much reduced (or absent)	<100 mV	Decreasing	High	Very high

[a] After discussion of Hutchinson (1957).

of the total manganese is in organic forms. For example, about 40% of total dissolved manganese was present in organic compounds, mainly with a molecular weight of 1000–50,000 kD in the hypolimnion of a eutrophic Japanese lake (Yagi, 1988).

Within the metalimnion, upward and laterally diffusing Fe(II) oxidizes and coprecipitates a large fraction of soluble phosphorus (Stauffer, 1986; Stauffer and Armstrong, 1986). As the epilimnion deepens in late summer and depresses the oxic/anoxic boundary, reduced iron and manganese of the hypolimnion is progressively oxidized and mixed into the epilimnetic water. The most prevalent form of iron in this fraction is amorphous Fe(III) oxide of small size (<0.5 μm) (Tipping *et al.*, 1982). The concentrations of epilimnetic iron reach maximum near overturn and then slowly decline. Sedimentation of iron oxides likely occurs by flocculation by self-association or by association with other particulate matter. Much iron remains in the water column by resuspension of sedimented materials (Davison *et al.*, 1980).

The cycling and fluxes of manganese are influenced by microbial utilization, particularly in strongly stratified, eutrophic lakes. Although these specialized bacteria are discussed collectively later in this chapter with sulfur, it is instructive to note here forms and fluxes

of manganese in a representative eutrophic lake (Fig. 14-8). In Lake Fukami-ike, the boundary stratum between oxic and anoxic waters contained ca. 0.5 mg O_2 liter^{-1} and 0.5 mg S^{-2} liter^{-1} as H_2S (Yagi, 1993). Some 0.08 g Mn m^{-2} day^{-1} was gained in this stratum from epilimnetic sedimentary fluxes and from the anoxic hypolimnion. The largely manganous ions and organically bound Mn of the hypolimnion accumulated from chemical reactions as the redox declined and from manganese-reducing bacteria. DOC concentrations were reduced only in the metalimnion, where some 40, 33, and 27% of the total decrease in DOC was attrib-

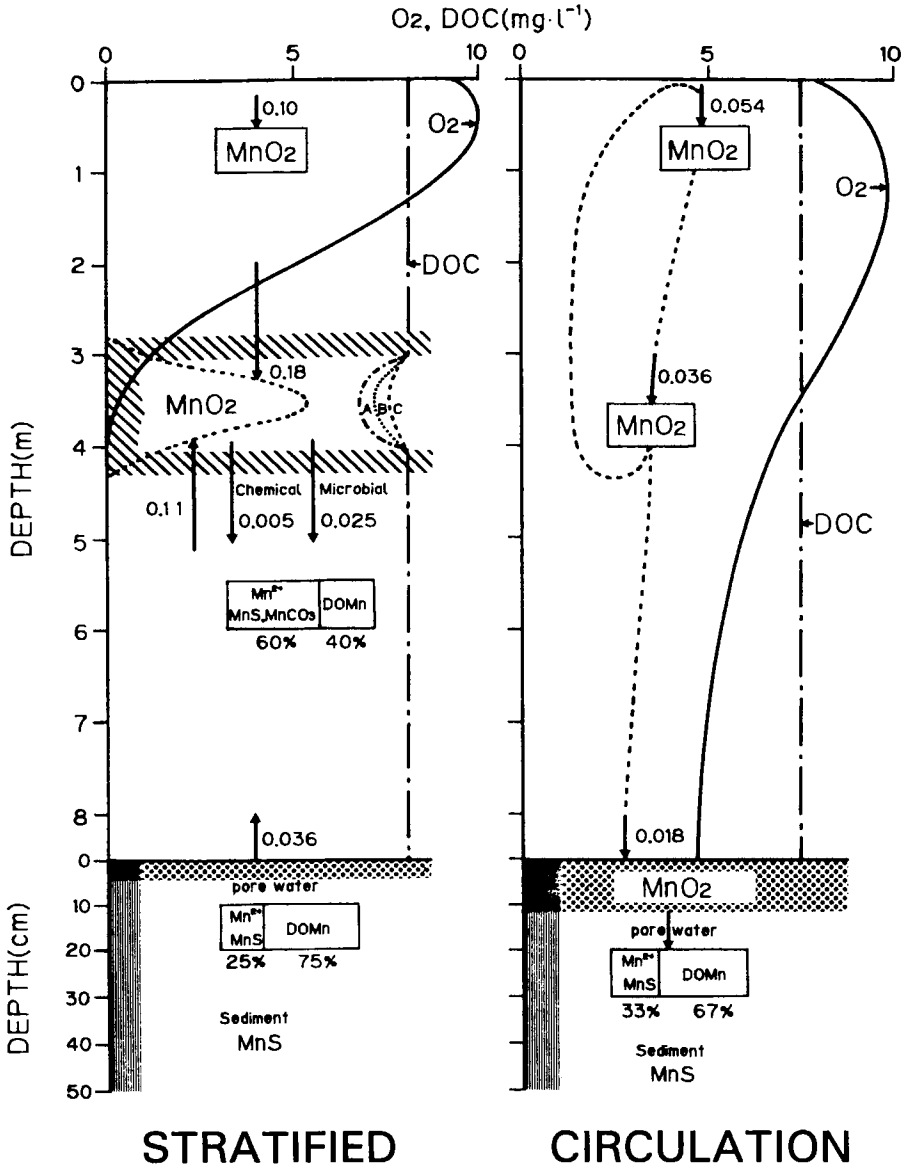

FIGURE 14-8 Manganese cycling and fluxes in relation to dissolved oxygen and dissolved organic carbon in eutrophic Lake Fukami-ike, Japan, during summer stratification and during autumnal circulation. Units of Mn = g Mn m^{-2} day^{-1}. *A*, *B*, and *C* = minimum DOC decrease by Mn-reducing bacteria (40%), the purple nonsulfur bacteria *Rhodopseudomonas paulustris* (33%), and heterotrophic bacteria (27%), respectively. (Modified from Yagi, 1993.)

utable to the Mn-reducing bacteria, a purple nonsulfur bacterium, and heterotrophs, respectively (Fig. 14-8). During lake circulation, most of the Mn was in the form of MnO_2, with appreciable mixing and resuspension in the upper strata. When lakes are acidic or become acidic from anthropogenic causes, Mn tends to be highly conservative, with low rates of retention (e.g., White and Driscoll, 1987).

Fluxes to and mobilization of Fe and Mn from the sediments has already been treated in some detail here and in Chapter 13 in relation to the release of phosphorus from sediments. The cycling and importation of Fe and Mn to the sediments must be evaluated within redox conditions in the lake strata or river system, the settling and focusing (see Chap. 21) of particles, particularly Fe and Mn oxyhydroxides, and the resuspension of surficial sediments. Because sediments of deeper areas tend to be more reducing than those of shallower areas, particulate sedimentation of Fe and Mn oxides tend to be greater in shallow-water sediments (Hamilton-Taylor and Morris, 1985). Hypolimnetic sediments normally exhibit high Mn remobilization rates throughout the year despite a well-mixed, oxygen-saturated water column during autumn and much of winter. Not only are the manganese compounds more soluble than iron, much (40–75%) of the total dissolved Mn in the interstitial waters can be in organic forms of relatively high molecular weight (e.g., two fractions of 1–50 and 50–200 kD; Yagi, 1990).

Iron remobilization from the sediments is regulated by oxygen-mediated redox and rates of sedimenting organic matter (Figs. 13-5 and 13-6). Under the prevailing anoxic conditions of nearly all sediments of lakes, Fe(III) oxides are subject to dissimilatory microbial Fe(III) reduction in which Fe(III) or Mn(IV) are used as an electron acceptor in metabolism. Microbial utilization by Fe(III)-reducing bacteria continues until Fe(III) oxides are depleted. Fe(III)-reducing bacteria are able to outcompete both sulfate-reducing and methanogenic bacteria for organic substrates (Lovley, 1991). High Fe(III) oxide concentrations can be regenerated by rapid oxidation of Fe(II) compounds coupled to oxygen inputs from overlying water, if oxygenated, or in littoral and wetland areas from oxygen released from plant roots (Roden and Wetzel, 1996). Where this oxidation is not available to the sediments, Fe(II) accumulates and migrates into the overlying anoxic water. Radial oxygen loss from roots of aquatic plants (cf. Chap. 18) induces the oxidation of Fe(II) and the formation of appreciable deposits of iron plaque on the roots (e.g., St-Cyr and Crowder, 1989; Kirk and Bajita, 1995; Snowden and Wheeler, 1995; Roden and Wetzel, 1996). Although these deposits have both positive and negative effects on the physiology of the plants, the deposition can result in appreciable oxidation and retention of iron in vegetated sediments.

F. Utilization and Transformations of Iron and Manganese

The metabolic demands for iron and manganese are usually sufficiently low so that the biota do not materially reduce the concentrations of these metals in the environment. Both iron and manganese, however, are essential micronutrients of microflora, plants, and animals (Oborn, 1960b; Wangersky, 1963; Coughlan, 1971). Iron is required in the enzymatic pathways of chlorophyll and protein synthesis, the protein integrity of cell membranes, and in the respiratory enzymes of all living organisms. The function of iron in cytochromes and as the basic component of hemoglobin in higher animals is well known. Manganese and iron are functional components of nitrate assimilation (e.g., Verstreate *et al.,* 1980; Rueter and Ades, 1987), nitrogen fixation (e.g., Wurtsbaugh and Horne, 1983; Rueter, 1988), and photosynthesis and are essential catalysts of numerous enzyme systems in bacteria, cyanobacteria, algae, and animals (Ferreira and Straus, 1994).

Even though the biological requirements for iron and manganese are low, their reactivity, very low concentrations, and restricted availability (particularly of iron) in the trophogenic zone of lakes and in streams suggests that under certain conditions, availability of Fe and Mn can limit photosynthetic productivity. The mechanisms for assimilation of iron from the forms available in oxygenated natural waters are emerging from research. The peptizing and chelating properties of organic acids for iron, which have been found in a large number of lakes (e.g., Shapiro, 1966, 1969), have been shown in a large number of studies to maintain assimilable iron and to enhance the metabolism and growth of many microbiota. Several examples are presented next.

Bacteria, cyanobacteria, and certain algae produce ***siderophores,*** low-molecular-weight glycoproteins that are specific for Fe(III). Under iron-limiting conditions, siderophores are mostly produced extracellularly and excreted into the environment (e.g., Kerry *et al.,* 1988; Benderliev and Ivanova, 1994; Wilhelm, 1995). The iron of these complexes must be transported across the membrane by transport proteins for internal reduction to Fe(II) and assimilation (Guerinot, 1994). Among those microbiota that do not synthesize and release siderophores, iron complexed with natural organic compounds, such as humic acids, can be utilized.

The available iron content of hardwater calcareous lakes is extremely low. For example, the reactive iron of Lawrence Lake, Michigan, seldom exceeded 5 μg liter^{-1}

over an annual period (Wetzel, 1972). In this and similar lakes, it is evident that iron availability is so low that high sustained primary productivity is limited by an effective iron unavailability (Schelske, 1962; Schelske *et al.*, 1962; Wetzel, 1965a, 1966b, 1972). The addition of iron in complex form, either by synthetic chelating or natural complexing organic compounds, resulted in immediate increases in photosynthetic rates. Additions of competing organic compounds were less effective but presumably increased the availability of iron already present in the water. The effectiveness of natural organic compounds from the hypolimnion and amino compounds in maintaining solubility of iron in hardwater lakes has also been demonstrated (Wetzel, 1972). Since these early, detailed studies, iron availability has been implicated, sometimes with marginally convincing experimental evidence, as essential for sustained phytoplanktonic rates of primary production (e.g., Wurtsbaugh and Horne, 1983; de Haan *et al.*, 1985; Chang *et al.*, 1992; Pollingher *et al.*, 1995) and planktonic bacterial productivity (Berman *et al.*, 1993) as well as altering species successions of planktonic algae. It may also be noted that iron can be toxic at very high concentrations, particularly as ferric hydroxide and Fe–humus precipitates on biological and inert surfaces, especially in rivers (Vuori, 1995). Ingestion of sorbed or coprecipitated heavy metals with Fe-oxides can increase the dietary supply of metals to toxic concentrations in the food web.

High concentrations of manganese (>1 mg liter^{-1}) are very inhibitory to cyanobacteria and green algae and can induce marked changes in development and morphology (Gerloff and Skoog, 1957; Patrick *et al.*, 1969; Lorch, 1978). An antagonistic response was demonstrated in which increasing calcium concentrations progressively reduced the inhibitory effects of high manganese. This relationship indicates that high levels of manganese, for example at the time of fall circulation, could be inhibitory to natural populations of cyanobacteria and green algae. Manganese concentrations of <50 μg liter^{-1} were found to inhibit the development of green algae and cyanobacteria in streams and to strongly favor diatom growth. This response by diatoms may be ubiquitous; if so, the moderate levels of Mn and high levels of Ca in hardwater lakes may contribute both to the general dominance of diatoms and to the stimulatory effects of primary productivity in response to small additions of chelated manganese observed by Wetzel (1966b) in these lakes.

In Lake Superior, an apparent synergistic effect between low concentrations of manganese and phosphorus can occur (Shapiro and Glass, 1978). Phytoplanktonic photosynthesis was enhanced much more by low-level enrichments of combined manganese and phosphate than by the addition of either substance alone.

IV. BACTERIAL TRANSFORMATIONS OF IRON AND MANGANESE

The cycling of iron and manganese is largely dictated by the oxidation-reduction conditions of lakes. Although bacterial and photosynthetic metabolism greatly influences these controlling conditions, which indirectly regulate the states of these metals and their fluxes, certain bacteria utilize iron and manganese directly in energetic transformations (Lundgren and Dean, 1979; Ghiorse, 1984; Jones, 1986). These transformations are usually minor, however, in comparison to heterotrophic metabolism of organic substrates in most natural systems.

A. Iron and Manganese Deposition (Oxidation)

Most oxidation of Fe(II) at neutral pH is essentially a chemical process. Clearly, however, bacteria are associated with oxidized iron, and their cellular structures become encrusted with Fe(III). Filamentous forms of iron-oxidizing bacteria are gram-negative rods that form chains bound by sheaths, such as *Sphaerotilus/Leptothrix* (Ghiorse, 1984; Jones, 1986). Prosthecate and appendaged forms (e.g., *Gallionella*) and encapsulated and coccoid forms (e.g., *Metallogenium*, and *Siderocapsa*) add to a diverse group of morphological types. Fe(III) is generally deposited on outer cell surfaces that are usually anionic in charge. Iron- and manganese-depositing bacteria develop at the sites of a redox gradient, usually dominated by the Fe(II)/Fe(III) couple. These redox gradients can be as large as several meters of water strata in the metalimnion and upper hypolimnion of eutrophic lakes or only a few centimeters at oxic/anoxic interfaces, such as iron groundwater seeps into rivers. Chemosynthetic utilization of energy from inorganic oxidations is relatively inefficient, especially in the case of the oxidation of iron and manganese. For example, the oxidation of Fe^{2+} to Fe^{3+} by iron bacteria releases only about 11 kcal per mole Fe.

The cycling of iron and manganese is influenced by two processes (Kuznetsov, 1970; Ghiorse, 1984). First, as pointed out earlier, reduction of the oxidized combined metal occurs under appropriate redox conditions as ferrous bicarbonate or is precipitated and sedimented as a sulfide. Example reactions are

$$Fe_2O_3 + 3H_2S \rightleftharpoons 2FeS + 3H_2O + S$$

$$FeS + 2H_2CO_3 \rightleftharpoons Fe(HCO_3)_2 + H_2S$$

Second, sheathed and stalked bacteria, algae, protozoan flagellates, and some true bacteria precipitate ferric and manganic oxides on their cells. The true iron bacteria occur in iron-rich waters of neutral or alkaline pH. Characteristic reactions of the few chemoautotrophic bacteria that deposit hydroxides and oxides are

$$4Fe(HCO_3)_2 + O_2 + 6H_2O \longrightarrow 4Fe(OH)_3 + 4H_2CO_3 + 4CO_2 + 58 \text{ kcal}$$

$$4MnCO_3 + O_2 \longrightarrow 2Mn_2O_3 + 4CO_2 + 76 \text{ kcal}$$

Some species of *Leptothrix* are facultative iron bacteria that can oxidize both ferrous and manganous salts, whereas *Gallionelia (Spirophyllum)* is restricted obligately to iron. Since at neutral pH and in the presence of oxygen, Fe^{2+} is spontaneously oxidized, iron-oxidizing bacteria are restricted to zones of steep redox gradients, in which they can compete effectively with oxygen for reduced iron. Therefore, the iron bacteria are restricted to the interface regions of iron-bearing rock seeps, swamps, and bogs and to upper hypolimnetic areas, where the redox potential is sufficiently low for reduced iron to occur. Over 220 g of ferrous iron are required to produce 0.5 g of cellular carbon. As a result, much oxidized iron will be precipitated on the sheaths of the bacteria and extruded materials (e.g., Emerson and Revsbech, 1994). Although this iron may not be important from the standpoint of synthesis of organic carbon, it is often important economically, for it causes corrosion and clogging of pipes. These examples refer to strict autotrophic bacteria that satisfy their CO_2 requirements without organic matter; they obtain all required energy from the oxidation of some specific, incompletely oxidized inorganic substance. Iron or manganese thereby enters the cells. Certain facultative autotrophic bacteria (mixotrophic) can develop in water containing only inorganic substances; other facultative autotrophic species are able to utilize organic substances as well. When these organisms occur together and some iron reduction can occur, iron cycling is possible within the attached microbial communities (Emerson and Revsbech, 1994).

Other groups of bacteria involved in the cycling of iron and manganese are heterotrophic. Certain filamentous forms (*Cladothrix*, some *Leptothrix*), in particular, deposit iron and manganese on the cell in sheaths during the process of metabolizing organic compounds. The colonial, coccoid cells or short rods of *Siderocapsa* of the Eubacteriales are a common form occurring at the oxic–anoxic interface zone of hypolimnion–metalimnion, especially in iron meromictic lakes (Dubinina *et al.*, 1973). *Siderocapsa* also is widely distributed in oxygenated zones of streams and lakes (Hardman and Henrici, 1939) and during periods of circulation (Sokalova, 1961). Species of this genus can mineralize humates and increase in numbers coincident with increases in iron humates during periods of high rainfall. *Spirothrix* is another dominant iron bacterium found in both aerobic and anoxic zones of Lake Glubok, Russia, whereas large populations of *Gallionella* developed only at the interface zone of the metalimnion. Over the period of an annual cycle in this lake, the number of iron bacteria reached a very high percentage (19%) of the total bacteria during the later portion of summer stratification. At other times of the year, the percentage was about 5% of the total bacteria. It is apparent that the iron bacteria significantly influence the iron cycle of more productive lakes.

Closely related to *Thiobacillus* (see the next section) is *Ferrobacillus ferrooxidans*, which is abundant in very acidic (pH <3) mine waters, in which ferrous iron is soluble and stable. *Ferrobacillus* oxidizes ferrous carbonate to ferric hydroxide and CO_2:

$$4FeCO_2 + O_2 + 6H_2O \longrightarrow 4Fe(OH)_3 + 4CO_2$$

A few heterotrophic species of iron-oxidizing bacteria of the genera *Sphaerotilis, Leptothrix, Clonothrix,* and *Siderobacter* deposit oxidized manganese along with iron on capsules in their sheaths. Some species of *Metallogenium* obtain part of their energy requirements from the oxidation of manganous oxide (MnO), manganous sulfate ($MnSO_4$), or manganous carbonate ($MnCO_3$) to manganese sesquioxide (Mn_2O_3) and manganese dioxide (MnO_2); others are heterotrophic and, along with several other manganese- and iron-oxidizing bacteria, contribute to the formation of manganese and iron oxides in lake sediments (Oborn, 1964; Perfil'ev and Gabe, 1969; Kuznetsov, 1970; Jaquet *et al.*, 1982). *Metallogenium* is undoubtedly one of the dominant microorganisms involved in the deposition of manganese nodules in lakes (Sokalova, 1961; Sorokin, 1970; Miyajima, 1992).

B. Iron and Manganese Reduction

Microorganisms can catalyze enzymatically the reduction of many metals. Microorganisms have specific metabolic systems for oxidized Fe(III) and Mn(IV) in which the oxidation of organic matter is coupled to metal reduction. Nonenzymatic processes, for example, reduction of Fe(III) by organic compounds and sulfide, are generally of minor significance (Lovley, 1987, 1991, 1995; Nealson and Saffarini, 1994). Mn(IV) reduction by nonenzymatic processes is somewhat more common than that of Fe(III).

During the metabolism, complex organic matter is first hydrolyzed by enzymes that release monomeric compounds such as sugars, amino acids, and

long-chain fatty acids (Lovley, 1991). Fermentative bacteria metabolize the sugars and amino acids to short-chain fatty acids (e.g., acetate) and H_2. These fermentative products are then oxidized with the reduction of Fe(III) to CO_2 and water.

Under acidic conditions, several autotrophic bacteria (e.g., *Thiobacillus thiooxidans, T. ferrooxidans,* and *Sulfolobus acidocaldarius*) can oxidize iron disulfides and sulfur (S^0) to sulfate, with Fe(III) serving as the electron acceptor (ZoBell, 1973; Lovley, 1995). For example:

$$FeS_2 + 3\tfrac{1}{2}O_2 + H_2O \longrightarrow FeSO_4 + H_2SO_4$$

$$2FeSO_4 + \tfrac{1}{2}O_2 + H_2SO_4 \longrightarrow Fe_2(SO_4)_3 + H_2O$$

Evidence also indicated that Mn(IV) can also be reduced with S^0 as the electron donor in aquatic sediments.

As will be discussed subsequently in detail (see Chap. 23), a major portion (>60%) of the dissolved organic matter of inland waters consists of humic substances, largely originating from structural tissues of higher plants. Recently, it has been demonstrated that a wide variety of microorganisms capable of Fe(III) reduction were also able to transfer electrons to humic compounds, primarily quinone groups, during the process of oxidation of substrates such as acetate to CO_2, both in water (Lovley *et al.* 1996, 1998; Scott *et al.*, 1998) and in sediments (Roden and Wetzel, 2000). Humic substances can stimulate the reduction of poorly crystalline Fe(III) oxide forms (goethite and hematite) in clay by an electron shuttling between Fe(III)-reducing microorganisms and Fe(III). The transfer of electrons from humic compounds to Fe(III) is an abiotic process, which can occur in the absence of microorganisms. Once oxidized by Fe(III), humic compounds may again accept electrons from humic-reducing microorganisms.

Although Fe(III) reduction is a significant redox process in eutrophic lakes, it contributes to only a small portion of their reducing potential. For example, it has been calculated that Fe(III) and Mn(IV) reduction accounted for <1% of the potential reducing equivalents that enter anoxic hypolimnia as sedimentary organic carbon from primary production (Verdouw and Dekkers, 1980; Davison *et al.*, 1981).

C. Overview

A general summary of these inorganic and bacterial relationships is given diagrammatically in Figure 14-9. The primary distinction between the fluxes of

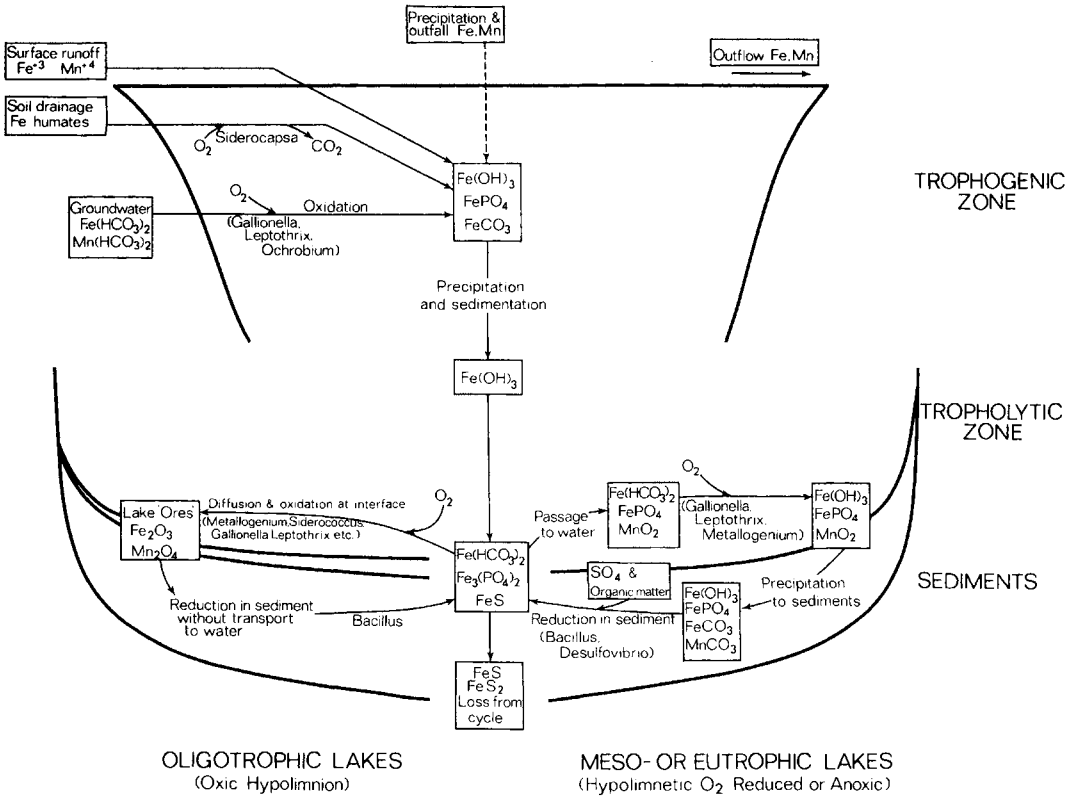

FIGURE 14-9 General iron and manganese cycles in lakes of low and high productivity emphasizing microbial interactions. (Modified from Kuznetsov, 1970.)

iron and manganese in the hypolimnia of lakes of increasing productivity centers on the reduction of redox potential and pH. Our knowledge of the iron and manganese cycles at the bacterial level is largely qualitative owing to the paucity of quantitative information concerning both between-component flux rates and whole-lake metabolism of these two materials. Very little is known about the role of the littoral flora in this cycling. Iron, for example, is translocated from the sediments to the leaves of submersed vegetation (Oborn and Hem, 1962; DeMarte and Hartman, 1974; Wetzel, 1990c). The magnitude of this transport from the sediments to the water in organic-bound phases of plant material as the plants decay is unknown.

V. MINOR ELEMENTS

Minor metallic elements, collectively referred to as ***micronutrients,*** include Fe, Mn, zinc (Zn), copper (Cu), boron (B), cobalt (Co), molybdenum (Mo), nickel (Ni), and vanadium (V), nearly all of which are required for the nutrition of plants and many animals. The universality of an absolute requirement for all of these elements is not clear. In some cases, as with iron and manganese, the essentiality of the element is established. In others, such as vanadium, it is known that one element can substitute for another, for example, vanadium can replace molybdenum in enzymes, and that growth is enhanced by vanadium among certain algae and cyanobacteria (e.g., Meisch *et al.,* 1977; Patrick, 1978; Vaishampayan, 1983; Attridge and Rowell, 1997; Rowell *et al.,* 1998) but not among others (Gerloff, 1963; Holm-Hansen, 1968; Nalewajko *et al.,* 1995). Common physiological functions of these micronutrients are summarized in Table 14-3.

Selenium is another trace element of unknown biochemical significance among aquatic organisms. The dinoflagellate alga *Peridinium cinctum* requires a small amount of selenium (approximately 50 ng Se^{4+} $liter^{-1}$) for optimal growth and reproduction (Lindström and Rodhe, 1978). In a Swedish lake, the concentrations of total and biologically available selenium showed considerable seasonal and vertical variation, which likely resulted from variations in loading from the atmosphere and the drainage basin, as well as algal uptake (Lindström, 1980; cf. Suzuki *et al.,* 1981). Although the potential for regulation exists, the significance of a trace element such as selenium in the regulation of algal growth in natural systems is unclear at the present time.

Most of the information on micronutrient requirements is obtained from studies of physiological deficiencies in cultures, which present an array of experimental difficulties, particularly involving contamination (Weissner, 1962). Requirements are further complicated by observed differences that depend on the composition and concentration of other minerals and an antagonism among these elements. These effects,

TABLE 14-3 Primary Physiological Functions of Micronutrients Generally Accepted as Essential or Potentially Essential for Aquatic Organisms[a]

Element	*Primary functions*
Iron	Electron transport in redox systems of respiration and photosynthesis; enzyme activation, oxygen carrier in N_2 fixation
Manganese	Enzyme activation; electron transport reactions particularly in photosynthesis, detoxification of superoxide radicals; synthesis of secondary metabolites; ribosome structure
Zinc	Membrane integrity; enzyme activation, particularly carbonic anhydrase; gene structure, expression, and regulation; carbohydrate metabolism, anaerobic respiration, protein synthesis; ribosome structure; detoxification of superoxide radicals; phytohormone activity
Copper	Redox reactions of respiration and photosynthetic electron transport; detoxification of superoxide radicals; lignification; haemocyanin in aquatic invertebrates.
Nickel	Iron absorption; nitrogen fixation; several constitutive enzymes, particularly urease; reproductive growth in plants
Boron	Cell wall formation and stabilization; membrane integrity; carbohydrate utilization; pentose phosphate metabolism; lignification; xylem differentiation; stomatal regulation; heterocyst structure and nitrogen fixation in cyanobacteria
Molybdenum	Electron transfer reactions; nitrate reduction and nitrogen fixation (see Chap. 12); sulfate oxidation; protein synthesis
Chloride	Osmoregulation; cation uptake; photosynthesis; reactivity of enzymes
Selenium	Essential growth regulator among certain algae; enhancement of phosphorus metabolism; amino acid and protein synthesis; mitosis; cuticle integrity
Cobalt	Essential for growth among many microbiota, particularly algae; essential component of vitamin B_{12}; potential substitution for zinc
Vanadium	Unclear functions and absolute requirements; enhancement of nitrogenase and nitrate reductase activities; substitution for molybdenum in some algae; phosphorylation
Cadmium	Unclear if a required nutrient in algae; implicated in functions in carbonic anhydrase activity; possible substitution for zinc

[a] Summarized from Lee (1983), Vaishampayan (1983), Keating and Dagbusan (1984), Soeder and Engelmann (1984), Oliveira and Antia (1986), Willsky (1990), Läuchli (1993), Hamilton (1994), Hausinger (1994), Lee *et al.* (1995), Welch (1995), Attridge and Rowell (1997), Kisker *et al.* (1997), Blevins and Lukaszewski (1998), Taylor and Anstiss (1999), and other sources cited in the text.

often found under the conditions of a controlled culture, become much more significant in the inorganic and organic solution of natural waters, which are rendered heterogeneous because of constant seasonal and spatial variations. Hence, one finds a large number of analyses of concentrations of ionic and, less frequently, particulate micronutrients in water that may bear little relationship to actual metabolic requirements. The question of requirements concerns the ***availability*** of the micronutrient within the constraints of other ionic components of salinity, the extent of organic complexing of the micronutrient, and the metabolic demands of varying species. In general, concentrations and availability of micronutrients in most natural waters are adequate to sustain active populations of algae within constraints of light, temperature, and macronutrient availability. There are, however, clear cases in which micronutrients can limit photosynthesis to a degree. A true deficiency of micronutrients is found in some oligotrophic aquatic systems of granitic arctic, alpine, and volcanic areas, in which a paucity of these elements is well known (reviewed by Goldman, 1972). In other situations, such as in hardwater calcareous lakes, the micronutrients are not deficient in the system but are present in forms unavailable for assimilation (Wetzel, 1972). In both situations, the control of productivity can be quite transitory and effective on only certain microbial species, thereby indirectly influencing, for example, algal succession and productivity as well as higher trophic levels.

The importance of dissolved organic matter in regulating micronutrient availability and growth, although long known to be effective in cultures, has been emphasized only recently as a major controlling factor of productivity in lakes (Wetzel, 1968, 1979, 1995; Wetzel and Allen, 1970; Wetzel *et al.*, 1972). Although involved in lake metabolism in many ways (cf. Chap. 23), complexation of micronutrients by organic compounds increases the physiological availability of many micronutrients when the ratio of organic matter to micronutrient concentration is reasonably high. For example, the soluble ionic fraction of total copper along the course of an Asian river was directly proportional to concentrations of dissolved organic carbon (Jun and Bae, 1998). The effects of chelated iron and manganese on algal productivity, discussed earlier, provide only one important example of this process.

It is important to note that the relative concentrations of trace elements in fresh waters can have a significant effect on the competitive abilities of species in algal communities. For example, low concentrations of vanadium and hexavalent chromium favor the development of diatoms; at higher concentrations, green algae and cyanobacteria can dominate the communities (Patrick, 1978). Low concentrations of manganese were correlated with the development of cyanobacteria, whereas diatom communities dominated at concentrations of >40 μg Mn liter^{-1} (Patrick *et al.*, 1969).

Most metallic micronutrients are very toxic when present in excess ionically or when complexed organically to the point where their availability exceeds physiological tolerance limits of biota. The heavy metal toxicity changes markedly with environmental conditions. For example, the inhibitory effect of Cu and of Cd on phosphorus uptake by certain green algae is highly pH-dependent and increases strongly (nearly 200-fold) with increasing pH over the range of 5.5–8.5 probably as a result of competition between H^+ and free metal cations for cellular binding sites (Peterson *et al.*, 1984). Such changes in pH occur commonly on a diurnal basis in shallow productive lakes. An increase in water hardness and concentration of dissolved calcium and magnesium, however, will compete for available binding sites on dissolved organic molecules and reduce the binding of heavy metals. An increase in toxicity of certain metals, such as cadmium, can occur as a result in hard waters even with the same concentrations of dissolved organic matter (Penttinen *et al.*, 1998). In another example, high concentrations of copper (usually as $CuSO_4$) have been used repeatedly as an herbicide to control algal blooms and growth of larger aquatic plants (Hodson *et al.*, 1979; McKnight, 1981). Fogg and Westlake (1955) have demonstrated that polypeptides secreted by cyanobacteria can effectively complex copper ions and reduce toxic effects. These examples indicate many ways in which organic complexing can influence the availability of micronutrients. The effects of micronutrients and their availability to animals are less well understood. It is generally assumed that requirements are met by means of ingestion of and uptake from food. Positive and negative correlations between fluctuations of micronutrient concentrations of the water and animal populations (see Parker and Hazelwood, 1962) yield little insight into this question but suggest that variations in micronutrient content of food can influence, in part, the succession and development of the fauna.

The general average concentrations of the soluble form of minor metallic micronutrients for a range of lakes and streams are given in Table 14-4. However, the ranges of concentration are extreme not only seasonally but particularly in relation to contamination from industrial and other sources of pollution. Some of the concentrations cited in this summary are likely overestimates, particularly from very oligotrophic waters. Contamination from sampling equipment, storage, and analytical instrumentation can be significant, and "metal-clean" sampling can result in appreciably lower

TABLE 14-4 Average Concentrations ($\mu g\ liter^{-1}$) of Soluble Minor Metallic Elements of Natural Waters (Surface)

Water	*Fe*	*Mn*	*Cu*	*Zn*	*Co*	*Mo*	*V*

true concentrations of soluble metals (Nriagu *et al.*, 1993, 1996). Higher concentrations are generally found in nearshore areas and particularly near urban centers and polluted river mouths. Examples are discussed at length in the references given in Table 14-4 and in Chawla and Chau (1969), Mills and Oglesby (1971), Robbins *et al.* (1972), Cowgill (1976, 1977a, 1977b), Hegi (1976), Baccini (1976), Boyle (1979), Leckie and Davis (1979), Martin *et al.* (1980), Nriagu *et al.* (1996), and many others.

A. Distribution of the Minor Elements in Lakes

The distribution of the minor elements among ionic (soluble), organically complexed, and adsorbed fractions, as well as the amounts in living biota, is poorly understood. Quantitative rates of flux between the living and abiotic organic and inorganic phases are even less well delineated; generally, much is inferred from better understood analogous chemical species, such as iron and manganese. Fragmentary evidence on the cycling of the minor elements indicates that these similarities are real and that much of their cycling is comparable.

The concentrations of Cu, Zn, Co, and Mo in ionic solution are usually very small in aerated surface waters. Transport of these trace metals in flowing waters can be partitioned analytically into (1) ionic forms, (2) those complexed in organic materials, (3) those adsorbed to and precipitated onto solids, and (4) those incorporated into crystalline structures (Gibbs, 1973). Although the solubilities of the metals vary somewhat (cf. Groth, 1971; Stumm and Morgan, 1996), in most cases, particularly in lakes, most (>70%) of each adsorbed to biologically produced particulate matter and otherwise associated crystalline solids (Hart, 1982; Wangersky, 1986; Twiss and Campbell, 1998). Much of the remainder is in organic complexes, with very little in solution. Some proportion of the metals removed from the surface waters with settling seston can be solubilized in the deeper water strata by bacterial decomposition of the particles. Thus, many trace metals have distributions in stratified waters that resemble those of the inorganic macronutrients. It should be again emphasized that these distributions are mediated by interacting physical and biological processes, and chemical speciation reactions based on pure chemical analyses in homogeneous systems cannot be applied effectively to natural systems.

A summary of older literature on the cycling of Cu, Zn, Mo, and Co is given in Hutchinson (1957). The detailed analyses of Groth (1971) on Schöhsee in northern Germany highlight the basic phases of the dissolved and particulate fractions over an annual cycle. The total amounts of Co, Mo, and Zn, as well as of Fe and Mn, accumulated in hypolimnetic waters during summer stratification as shown in Table 14-5. The concentrations of Fe and Mn were found to be strongly

TABLE 14-5 Average Concentrations ($\mu g\ liter^{-1}$) of Minor Elements in the Epilimnion and Hypolimnion of Schöhsee, Northern Germany[a]

Stratum	*Mn*	*Fe*	*Cu*	*Zn*	*Co*	*Mo*
Epilimnion (E)	4.5	15	1.0	1.8	0.03	0.21
Hypolimnion (H)	590	425	0.9	1.9	0.07	0.30
Enrichment ratio of H/E	130	28	0.9	1.1	2.3	1.4

[a] Data after Groth (1971).

related to redox conditions, while the primary source of the hypolimnetic accumulation of Co, Mo, and Zn was from release and mineralization of sedimenting organic detritus (cf. also Baccini, 1976). No significant differences in vertical distribution of Cu were found in Schöhsee or the Great Lakes during summer stratification, although moderate increases in hypolimnetic sestonic Cu have been observed elsewhere in eutrophic lakes (Riley, 1939; Baccini and Joller, 1981; Nriagu *et al.*, 1996).

Co, Cu, and Zn, like Fe and Mn, form stable complexes with organic compounds, so that losses of free ions by formation of insoluble hydroxides, sulfides, phosphates, and carbonates can be reduced appreciably (Groth, 1971). Copper is strongly complexed by organic ligands and many of these compounds are likely produced by algae (Becher *et al.*, 1983; Verweij *et al.*, 1989; Xue and Sigg, 1993; Sigg *et al.*, 1995; Jun and Bae, 1998). Greater than 80%, and often nearly all, of total dissolved Co occurs as organic complexes (Qian *et al.*, 1998). Although most of the trace metal micronutrients are in organic complexes, a large fraction of Zn is present in ionic form or weak complexes. Molybdenum, however, exhibits greater mobility than the other ions (Mo > Cu > Zn > Co).

Phytoplankton tend to accumulate minor metallic elements in the order: Fe > Zn > Cu > Co > Mn > Mo (Table 14-6). During decomposition and mineralization of plankton, release to a soluble phase occurs in the order of Mo > Co > Cu > Zn > Fe > Mn, approximately opposite the order of amounts of the elements found to be transported to the sediments by sedimenting organic detritus: Fe > Mn > Co > Zn > Cu > Mo. Coprecipitation of these trace elements with $Fe(OH)_3$ was greatest with Cu, in the order of Cu > Mo > Co > Zn. Therefore, during summer stratification, algal uptake and sedimenting detritus play a major role in the cycling of Co and Zn, but less so for Cu (cf. Reynolds and Hamilton-Taylor, 1992), whereas concentrations of Fe and Mn are regulated largely by redox conditions. Although variations among lakes are great, amounts of minor elements (especially copper)

TABLE 14-6 Average Accumulation of Minor Metallic Elements in the Plankton and Sediment in Comparison to the Average Concentrations in the Epilimnion of Schöhsee, Northern Germany, 1968–1969[a]

Element	*Dissolved in epilimnetic water* ($\mu g\ liter^{-1}$)	*In plankton* ($\mu g\ g^{-1}$)	*In sediment* ($\mu g\ g^{-1}$)

[a] Data after Groth (1971).

often increase during fall circulation and during winter. Hypolimnetic oxygenation can enhance the release of Cu during aerobic degradation of organic matter in relatively mobile, likely organically complexed forms (Xue *et al.*, 1997). Reduction of Fe and Mn in the sediment and their rapid reoxidation at the sediment/oxic water interface results in an enrichment and deposition of Cu and Zn by freshly formed Mn- and Fe-oxides. Mo is enriched in the sediment and correlates with Mn (Schaller *et al.*, 1997). Similarly, vanadium distributions are highly correlated with iron. Ionic concentrations increase somewhat in winter, but most of this maximum is in the organic fractions (Riley, 1939; Kimball, 1973; Wangersky, 1986). In general, the activity of zinc (Bachmann, 1963) and cobalt (Benoit, 1957; Parker and Hasler, 1969) follows the conclusions summarized above. Molybdenum exhibits much greater mobility than the other minor elements discussed and does not show analogous patterns of distribution (cf. Dumont, 1972; Cowgill, 1977b). In the seasonally anoxic hypolimnion of a eutrophic lake, Mo concentrations declined with depth particularly in the presence of H_2S (Magyar and Moor, 1993). Much of the vertical flux was in the form of particle-bound Mo at 1.1–4.6 $\mu g\ m^{-2}\ day^{-1}$.

It should be noted that the inputs of many trace elements to fresh waters are increasing. These increases

often result from industrial and combustion emissions, which are subsequently deposited onto the drainage basins of rivers and lakes (e.g., Nriagu, 1979; Nriagu and Davidson, 1980). In other cases, the widespread acidification of rain and snow falling on poorly buffered soils and fresh waters can result in high rates of leaching of trace metals. Detailed discussion of metal enrichments above natural concentrations in surface waters is beyond the compass of this synthesis. However, several primary metal pollutants have become so widespread and influential to freshwater biota that some comments are necessary.

B. Cadmium

Cadmium (Cd) occurs in natural fresh waters in the range of ca. 0.01–0.1 μg Cd liter^{-1}, and usually in the high portion of that range in rivers (Martin *et al.*, 1980; Raspor, 1980; Laxen, 1984). Much of the Cd is associated with particles (>0.2 μm) or complexed with dissolved organic macromolecules. As a result Cd availability is often much higher in fresh waters than would be anticipated simply on the basis of inorganic solution chemistry and solubilities. Cadmium releases to the atmosphere are very large (Nriagu, 1980). Natural emissions (e.g., volcanism and soils) are completely dwarfed by anthropogenic emissions from industry and fuel combustion. Concentrations of a few μg Cd liter^{-1} are highly toxic to many organisms, particularly plankton and fishes, primarily by enzyme inhibition (Wong *et al.*, 1980). At very low levels, Cd can function as a metal replacement for Zn in carbonic anhydrase when concentrations of Zn are low (Price and Morel, 1990).

C. Lead

Lead (Pb) is another heavy metal that is widely known for its toxicity to aquatic organisms at relatively low levels. Much of the Pb loadings to drainage basins emanated from the combustion of fossil fuels, particularly from gasoline that contained alkyl–lead additives to improve engine performance. Analyses of lake sediments showed that atmospheric lead deposition increased above background levels from preindustrial uses of Pb in Europe, starting with the Greek and Roman cultures, more than 2600 years B.P. (Renberg *et al.*, 1994). The Pb deposition accelerated throughout the northern hemisphere in the nineteenth and particularly the twentieth centuries, with a deposition maximum in about 1970. In the 1970s, legislation restricted use of lead additives in gasoline and Pb in precipitation has declined in many areas by 97% between 1976 and 1989 (Johnson *et al.*, 1995; Nriagu, 1996). Accumulated Pb in forest soils has declined at much slower rates because of low loss rates to drainage waters. Once in flowing systems, most Pb is associated with dissolved organic substances and adsorbed to particle surfaces (Botelho *et al.*, 1994). Pb content in lake sediments indicates a gradual decline.

D. Mercury

Mercury (Hg) in fresh waters and biota has become of intense interest because of the acute neurological toxicity of this element and widespread findings of elevated concentrations of Hg in fish in lakes remote from direct pollution of surface waters. Recent studies have evaluated the mercury cycle in aquatic ecosystems in some detail (Verta, 1984; Miskimmin *et al.*, 1992; Driscoll *et al.*, 1994, 1995; Henry *et al.*, 1995; Mason *et al.*, 1995; Vandal *et al.*, 1995; Watras *et al.*, 1995; Cai *et al.*, 1996; Baldi, 1997; Lin and Pehkonen, 1999). Atmospheric deposition of Hg to drainage basins and lakes occurs largely as inorganic Hg(0). In oxygenated waters, reactive Hg(0) is converted to Hg(II), which will complex with inorganic ions (e.g., Cl^- and OH^-) and dissolved organic compounds or absorb to particulate matter. Hg(II) can be reduced by bacteria to form Hg(0). Most waters are supersaturated with respect to the solubility of atmospheric Hg(0), and Hg(0) is volatilized to the atmosphere. Within anoxic strata, Hg can form aqueous complexes with sulfide and precipitate as HgS. Sulfate-reducing bacteria of anoxic zones convert Hg(II) to toxic methylmercury (CH_3Hg) and possibly to ethylmercury, which may bind to dissolved organic compounds (particularly humic substances) or be demethylated by microbes. Under anoxic conditions, Hg toxicity is reduced by this complexation and the reaction with sulfides. The reaction of Hg(II) and CH_3Hg can produce stable HgS and the volatile and less toxic dimethylmercury. CH_3Hg accumulates in particulate layers in anoxic strata and is a predominant form of mercury that is assimilated and concentrated in fish. Monomethylmercury tends to be higher in acidified lakes where sulfate concentrations are low and acidic conditions favor CH_3Hg stability. Concentrations of total mercury and CH_3Hg increase directly with increasing concentrations of dissolved organic carbon and with the percentage of nearshore wetlands in the drainage basin. In general, trace and toxic metals tend to be retained more strongly in wetland hydrosoils and detritus than in upland soils (Gambrell, 1994). Mobility of CH_3Hg tends to increase among acidified waters and during warmer periods of low flows in streams and wetlands (Driscoll *et al.*, 1998; Monson and Brezonik, 1998).

E. Aluminum

Acidic precipitation is causing high concentrations of aluminum to be leached from poorly buffered soils in many continental regions (Almer *et al.*, 1978; Cronan and Schofield, 1979). Many inorganic and biotic processes in upland soils can maintain aluminum in nonreactive forms and prevent appreciable loadings with runoff. Sudden acidic precipitation events, however, such as rapid spring snowmelt releases of accumulated acidity from air pollution, can result in marked declines in pH of runoff water to pH 4–5. The result is large increases of reactive Al to receiving streams and lakes. The effectiveness of mobilization of Al from soils depends greatly on the buffering capacities and solubilities of the soils (e.g., Hooper and Shoemaker, 1985; Cronan *et al.*, 1986; Lawrence *et al.*, 1986; Gensemer and Playle, 1999).

Aluminum (Al) chemistry is complex because of the large number of forms occurring in aquatic ecosystems. Within the range of pH and common limnological conditions, Al is a minor dissolved constituent. However, as widespread acidification occurs in poorly buffered surface waters in many areas of the world from atmospheric precipitation of acidic anthropogenic pollution, Al can leach from soils in relatively large amounts, particularly when it is accompanied by an increase of dissolved organic matter leached from the soils (Lorieri and Elsonbeer, 1997). Aqueous ionic Al is highly reactive and is toxic at very low concentrations, can serve as a pH buffer, and is an absorbent of phosphate and organic carbon (Schafran and Driscoll, 1987; Helmer *et al.*, 1990; Gensemer and Playle, 1999). Much of the total dissolved Al is complexed with dissolved organic matter in acidic waters, with a binding capacity that increases from pH 3 to 5, but decreases above pH 5 by formation of Al-hydroxy species (e.g., $Al(OH)_3$). Therefore, in acidic waters (pH <5), concentrations of reactive Al can be 200–500 or more μg liter^{-1} (e.g., Hongve, 1993). Concentrations of reactive Al are usually <10 μg liter^{-1} in waters of neutral pH, although some persists in organically complexed and colloidal forms.

VI. THE SULFUR CYCLE

Sulfur is utilized by all living organisms in both inorganic and organic forms. Sulfate is reduced to sulfhydryl (—SH) groups in protein synthesis, with a concomitant production of oxygen that is utilized in oxidative metabolic reactions. Interest in the sulfur cycle of fresh waters, however, extends beyond nutritional demands of the biota, which are almost always met by the abundance and widespread distribution of sulfate, sulfide, and organic sulfur-containing compounds. Decomposition of organic matter containing proteinaceous sulfur and the anaerobic reduction of sulfate in stratified waters both contribute to altered conditions that markedly affect the cycling of other nutrients, ecosystem productivity, and distribution of the biota.

A. Forms and Sources of Sulfur

Sources of sulfur compounds to natural waters include solubilization from rocks, fertilizers, and atmospheric precipitation and dry deposition. At the present time, atmospheric sources, augmented greatly by the combustion products of industry, dominate all other sources.

1. Weathering

Sulfate is released during geochemical weathering of rocks and soils containing either sulfides or free sulfur, which are oxidized in the presence of water to form sulfuric acid (ZoBell, 1973):

$$\underset{\text{(pyrite)}}{FeS_2} + 3\tfrac{1}{2}O_2 + H_2O \longrightarrow FeSO_4 + H_2SO_4$$

$$2S + 3O_2 + 2H_2O \longrightarrow 2H_2SO_4$$

These two reactions tend to lower both the pH and E_h, which affects the oxidative weathering reactions of numerous other minerals. Calcium sulfate, which is moderately soluble in water, is a common constituent of sedimentary rocks. As a result, drainage from calcareous regions generally contains higher-than-average concentrations of sulfate (Nriagu and Hem, 1978; Kilham, 1984). As will be discussed further on, bacteria contribute to the oxidation of sulfides and elementary sulfur, both in soil and in water.

2. Atmospheric Loadings

Large quantities of reduced sulfur, as hydrogen sulfide, are added to the atmosphere from volcanic gases and biogenic and industrial sources (Kuznetsov, 1964; Kellogg *et al.*, 1972). H_2S undergoes a number of oxidative reactions to become sulfur dioxide (SO_2), sulfur trioxide (SO_3), and sulfuric acid (H_2SO_4). Sulfur dioxide constitutes about 95% of the sulfur compounds resulting from the burning of sulfur-containing fossil fuels. Although the oxidation of SO_2 to H_2SO_4 in air is slow (hours to days), SO_2 is rapidly oxidized to sulfuric acid as it dissolves in atmospheric water. The global cycling of sulfur compounds (Table 14-7) indicates clearly that in industrialized regions, sulfur inputs from human activities are rapidly exceeding inputs from natural sources. In eastern North America, for

TABLE 14-7 Sources, Sinks, and Residence Times of Atmospheric Sulfur Compounds (Units Are 10^6 Tons as Sulfate per Year)[a]

Sources	*10^6 ton yr^{-1}*	*Approximate residence time*
Windblown sea salt SO_4^2 in precipitation, 10% of global total deposited on all land	130	
Bacterial and plant production of H_2S (SO_2)	268	0.5–6 days
Man-made production of SO_2 and SO_4^{2-} from fossil fuels (80% deposited on land; 93% of global production in the Northern Hemisphere)	150	0.5–6 days
Volcanic sources (H_2S, SO_2, SO_4^{2-})	2	<1 day
Deposition

Dry fallout deposition (SO_4^{2-})	30	

[a] From data of Kellogg *et al.* (1972).

example, industrial emissions exceed natural ones by a factor of 10 (Table 14-8). The removal processes over land are sufficiently slow (several days) to result in markedly increased concentrations in areas hundreds to thousands of kilometers downwind. In nonindustrial areas, the primary source of sulfate (SO_4^{2-}) in rain and snow is atmospherically oxidized H_2S that is produced along coastal regions by anaerobic bacteria (Jensen and Nakai, 1961). The SO_4^{2-} derived from sea spray is largely returned to the ocean; over land, this source is minor and is generally restricted to coastal lakes (Table 14-8).

The retention of sulfur compounds in soils of the drainage basin and their release to natural waters

[a] Modified from Galloway and Whelpdale (1980).

varies with regional lithology, agricultural application of sulfate-containing fertilizers, and atmospheric sources in relation to other sources. In calcareous areas of sedimentary rock, atmospheric contributions can be a small portion of the total. In contrast, in crystalline rock areas of many areas of northeastern North America and of Europe and Asia, wet- and dryfall precipitation supplies nearly all of the sulfate of natural waters (Fisher *et al.*, 1968; Johnson *et al.*, 1972; Kramer, 1978; Dillon *et al.*, 1983; among many others). Much of that atmospherically derived sulfate can be bound in organic compounds of soils of the drainage basin for long periods of time before being released to ground and surface waters.

Such acidic, sulfatic precipitation can increase weathering geochemical processes at rates equal to or greater than the carbonic acid system in these geological regions. The atmospherically derived sulfatic acidity adds to acidity resulting from the organic acids of soils and surface waters. The organic acids can produce ca. 5–10 meq H^+ mg^{-1} organic carbon and lower both the pH of natural waters and the acid-neutralizing capacities of natural waters (Hemond, 1994). Organic acids also increase somewhat the acid–base buffer capacity of water, which can render the pH less sensitive to changes from sulfatic and nitric mineral acid enrichments. Despite these sources, the strong acids associated with sulfate are major contributors to the reduction of acidity in lakes and rivers, even those that contain very high concentrations of natural organic acids (e.g., Gorham *et al.*, 1986; Kerekes *et al.*, 1986; Brakke *et al.*, 1987).

Where soils are sensitive to acidic precipitation, aluminum silicate minerals weather (Dillon *et al.*, 1983):

$$\text{cation–Al-silicate} + \text{acid} + H_2O \longrightarrow H_2SiO_4 + \text{cation} + \text{Al-silicate} + \text{acid anion}$$

Even in noncalcareous terrain, the ionic content of lakes and streams is dominated by HCO_3^- and Ca^{2+}, although in low quantities. The HCO_3^- supplied by the drainage basin is a major component of the acid neutralizing capacity (ANC) of the waters. In surface waters of very low alkalinity, biologically mediated processes add to the ANC by algal uptake of nitrate during photosynthesis, denitrification, and reduction of sulfate and FeOOH. Deposition of strong acids, especially sulfatic, results in the export of cations (Ca^{2+}, Mg^{2+}) and metals (Al, Fe, Mn) and a shift in anion content in the runoff water from bicarbonate to the anions of the anthropogenic acids (SO_4^{2-} and NO_3^-). Because nitrate is readily utilized biologically in the drainage basin, primarily sulfate will increase.

Much of the acidity can accumulate adsorbed to soil particles and in snowfall. Most (ca. 90%) of the total sulfur content is found, however, in the organic matter of the mineral soils (e.g., Houle and Carignan, 1995). Because these organic S pools are often 100–200 times greater than the annual S deposition, the loss of <1% of the organic S pool would be sufficient to explain the long-term releases from soils. Release of the sulfate and associated H^+ ions is often very high during the flushing process associated with commonly occurring rapid snowmelt periods. For example, in a small Canadian Shield basin, flushing of soluble SO_4^{2-} from organic and upper mineral soil horizons during the melt was some four times the amount supplied in meltwater and precipitation (Steele and Buttle, 1994).

Much of the loading of sulfur compounds to streams and lakes, therefore, is in the form of sulfate and soluble organic S constituents (C-bonded S and ester sulfate) (e.g., David and Mitchell, 1985; Lelieveld *et al.*, 1997). Because much of the total S is bound in seston and most of the seston is not mineralized during sedimentation, organic S accumulates and constitutes a major portion (ca. 75%) of the total S of the sediment.

B. Distribution of Sulfur in Natural Waters

The sulfur content of biota ranges from 0.05 to nearly 5% of dry weight in a few bacteria; the average content is 0.2%. The amounts in the biota and detritus, although significant, are generally small in comparison to the inorganic sulfur components of aquatic systems. The distribution and cycling of sulfur therefore involve (a) the chemical species under various conditions, (b) biotic influences on the transformations of sulfur species, and (c) sulfur transport in the system.

The lowest concentrations of sulfate in oxic waters (often slightly <1 mg $liter^{-1}$) appear to be a common feature of numerous African lakes situated in crystalline rock drainage basins (Talling and Talling, 1965). The other extreme is found in sulfate saline lakes (>50 g $liter^{-1}$). The usual range is about 5–30 mg $liter^{-1}$, with an average of about 11 mg SO_4^{2-} $liter^{-1}$. Low levels of SO_4^{2-} were implicated in the limitation of algal productivity in Lake Victoria, Africa (Fish, 1956), but more recently this role of SO_4^{2-} has been shown to be unlikely (Evans, 1961, 1962; Lehman and Branstrator, 1994).

The predominant form of dissolved sulfur in water is sulfate (Fig. 14-10). Nearly all assimilation of sulfur is as sulfate, but during decomposition of organic matter, sulfur is released largely as hydrogen sulfide. Under oxic conditions, H_2S is oxidized rapidly. Therefore, little H_2S would be anticipated in aerated regions of aquatic systems. However, strict application of redox and pH to the evaluation of reactions involving sulfur is difficult because some are chemically slow and medi-

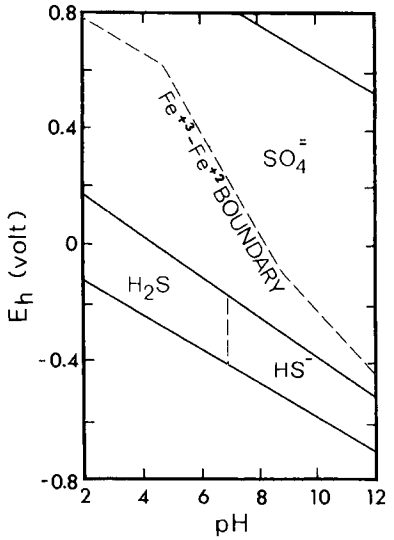

FIGURE 14-10 Approximate redox–pH fields of stability of dissolved sulfur species likely to occur in natural water. (Modified from Hem, 1960, with Chen and Morris, 1972.)

ated by bacterial metabolism. Although SO_4^{2-} and H_2S dominate, HS^- and very low concentrations of S^{-2} occur in strongly alkaline solutions because H_2S, which is very soluble in water, dissociates weakly (k_1 10^{-7}; k_2 10^{-15}) (Hutchinson, 1957; Hem, 1960c). Under certain conditions of low redox and pH, partial oxidation of sulfides occurs and free S^0 may be formed.

Metal sulfides are exceedingly insoluble at the neutral or alkaline pH values commonly encountered in a majority of natural waters. The equilibrium ion activity product of FeS of anaerobic lake sediments is $10^{-17.7}$ (Doyle, 1968b). Therefore, Fe^{+2} released from sediments reacts vigorously with H_2S to form FeS. In an anaerobic hypolimnion, the water must be somewhat acidic in order for appreciable H_2S to accumulate. If the water is alkaline, H_2S will accumulate only after most of the Fe^{+2} has been precipitated as FeS. The removal of sulfide by the release of ferrous ions permits an increase in the migration of other metals from the sediments, such as Cu, Zn, and lead (Pb), which form even more insoluble sulfides than does iron.

Organic volatile sulfur compounds (OVS) of biogenic origins are found in quantities throughout aquatic environments sufficient to contribute to the global atmospheric sulfur cycle (cf. reviews of Caron and Kramer, 1994; Kiene, 1996). Although dimethyl sulfide (CH_3SH) is the most abundant OVS in salt marshes and saline ecosystems, it also occurs by bacterial degradation of dimethylsulfaniopropionate in freshwater ecosystems (Ginzburg *et al.*, 1998). Other sulfide species in addition to H_2S in fresh waters include methanethiol (CH_3SH), dimethyl disulfide (CH_3SSCH_3), carbonyl sulfide (COS), and carbon disulfide (CS_2). OVS are ubiquitous in surface waters and OVS production is independent of sulfate concentrations. Methylated sulfide production often requires methionine, and some of their precursors are readily interconverted during microbial metabolism but are ultimately mineralized. Only a small fraction remains for exchange with the atmosphere.

Because of the high concentrations of organic S in the sediments, these sites of organic enrichment are likely sites of much of OVS production. Concentrations of OVS have been found to be much higher in shallow lakes and wetland/littoral habitats (Richards *et al.*, 1991; Kiene and Hines, 1995; Hines, 1996). As sulfate concentrations, but not dissolved salt concentrations, increase in a gradient of saline lakes, OVS concentrations were several orders of magnitude greater than in fresh waters and saline lakes of low salinity (<7 g liter^{-1}) in saline lakes with >20 g SO_4^{2-} liter^{-1} (Richards *et al.*, 1994). As in marine environments, dimethyl sulfide was the dominant species in these saline lakes. OVS compounds are readily degraded in the oxic epilimnion and metalimnion of stratified lakes (Sim *et al.*, 1993) and increase in the hypolimnia of acidified lakes. As a result, volatilization and emissions of OVS from stratified lakes are usually very small and not considered a major sulfur loss mechanism compared to processes such as sulfate reduction in the sediments.

A generalized vertical distribution of sulfate and hydrogen sulfide for stratified lakes is depicted in Figure 14-11. Under oxic conditions, as is the case in many oligotrophic and mesotrophic lakes, and during periods of circulation, H_2S is absent and SO_4^{2-} concentrations change little with depth. Some release of SO_4^{2-} occurs from the sediments, and this increase in sulfate in the hypolimnion can become more pronounced in hypolimnia of mesotrophic or eutrophic lakes in the earlier phases of summer stratification (Fig. 14-12). Reduction of sulfate to H_2S occurs as the redox potential declines to less than about 100 mV as a result of bacterial decomposition. Particularly near the sediments, much of the H_2S reacts with Fe^{2+} ions to form insoluble FeS. In this way, considerable quantities of sulfur can be lost to the sediments (Ingvorsen *et al.*, 1981; Jones *et al.*, 1982). Lakes receiving rich sources of sulfate from inflowing water, such as meromictic lakes of crenogenic formation, often contain immense concentrations of H_2S in their anoxic monimolimnia. Analogous situations occur in certain anoxic stretches of rivers that are polluted with sulfate-rich organic wastes. Effluents from paper-producing industries are a common source of such pollution. Horizontal variations in concentrations of sulfate and sulfides can be large, especially in reservoirs, and are complicated by flow patterns (e.g., Hanušová, 1962).

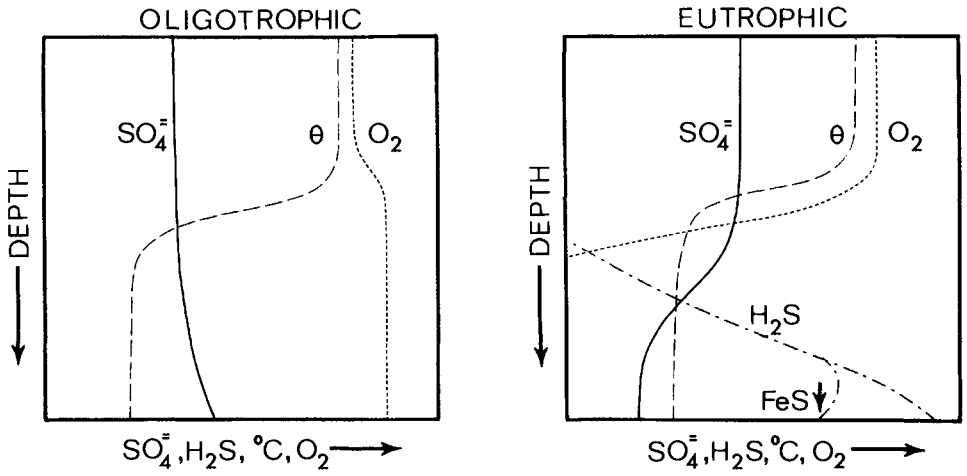

FIGURE 14-11 Generalized distribution of sulfate and hydrogen sulfide in lakes of very low and very high productivity.

The reduction of SO_4^{2-} to sulfide, some of which is lost to the sediments as insoluble metallic sulfides, and oxidation of H_2S to sulfate play a significant role in the modification of conditions for mobilization of phosphate and numerous other nutrients. In an excellent discussion of these reactions and their mediation by various bacterial groups, Ohle (1954) characterizes sulfate as a "catalyzer" of limnetic nutrient cycling.

The sulfur cycle in Linsley Pond, Connecticut, was studied during summer stratification in appreciable detail using ^{35}S-labeled sulfuric acid (Stuiver, 1967). In this eutrophic lake, large quantities of sulfate were lost from the metalimnion and hypolimnion, especially at the sediment–water interface. The rates of reduction of sulfate in the metalimnion and hypolimnion differed little between regions that were anoxic or partly devoid of oxygen but were about 10 times faster than in the fully aerobic epilimnion. Vertical diffusion of sulfate in the metalimnion and upper layers of the hypolimnion was very small during stratification. Horizontal diffusion at a given depth within the lower strata of water was sufficient to transport sulfates to the surrounding sediments, where reduction occurs. Transport of sulfur by sedimenting biological material was negligible and influenced the sulfur cycle of this lake only by providing organic substrates for bacterial metabolism in the hypolimnion and sediments.

This analysis permitted calculation of a total sulfur budget, estimated from the ^{35}S activities of the water and organic compounds (Fig. 14-13). Most of the sulfur was stored as sulfate and sulfide in the water, and as sulfide in the sediments. That fraction utilized by organisms was small and did not materially influence the total cycle. The H_2S in the hypolimnion was oxidized in the epilimnion; escape of H_2S to the atmosphere by diffusion or gas bubbles was low.

Organic sulfur compounds were not studied extensively in this budgetary analysis. Most of the sulfur of the seston occurs as ester sulfates and protein sulfur. The bulk (up to 80%) of sulfur in the sediments of productive lakes consists of organic sulfur compounds (ester sulfates and protein sulfur), and the remainder as pyritic sulfur, acid-volatile sulfides, sulfides dissolved in interstitial water, elemental sulfur, and dissolved sulfates (Table 14-9) (Doyle, 1968a,b; Nriagu, 1968; King and Klug, 1980, 1982a; Mitchell *et al.*, 1981; Smith and Klug, 1981). At least 40% of the acid-soluble sulfide of Linsley Pond was identical to tetragonal FeS (mackinawite).

Sulfur-containing organic compounds are degraded more slowly than other organic compounds. In Lake Mendota, Wisconsin, about 45% of the sulfur precipitated as sulfide was estimated to be derived from mineralization of organic matter, and the remainder (55%) originated from bacterial reduction of sulfates (Nriagu, 1968). Rates of sulfate reduction in the water column were 10^3 times lower than those of the surface sediment and, on an areal basis, accounted for less than 18% of the total sulfate reduction in the hypolimnion during summer stratification (Ingvorsen *et al.*, 1981). Estimates of net mineralization of sestonic sulfur inputs to the sediments in hypereutrophic Wintergreen Lake, Michigan, indicated that only about 45–50% of the total and ester sulfate sulfur inputs, and 75% of the protein sulfur inputs, were mineralized (King and Klug, 1982a). About 3% of the total water column sulfur was permanently lost to the sediments each year.

Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

C. Bacterial Metabolism and the Sulfur Cycle

Sulfate is reduced to the sulfhydryl (—SH) form during the synthesis of proteins by plants and animals. Further reduction of HS^- to H_2S occurs upon decomposition of this organic material by heterotrophic bacterial metabolism (Fig. 14-14). The most important of a large number of protein-decomposing bacteria belong to the genus *Proteus*, which are gram-negative, nonspore-forming rods that usually possess large numbers of flagella (Butlin, 1953). *Proteus* species are particularly active in soil systems. The dominant bacteria involved in proteinaceous decomposition to form H_2S in lakes of varying productivity (Table 14-10) are discussed in Kuznetsov (1970), Zinder and Brock (1978), and Jørgensen (1983). Bacterial densities in the water are 1–3 orders of magnitude lower than in the surface sediments.

A number of bacteria reduce sulfate, sulfite, thiosulfate, hyposulfite, and elemental sulfur to hydrogen sulfide. These ***sulfate-reducing bacteria*** are heterotrophic and anaerobic and use the sulfur compound as a hydrogen acceptor during oxidative metabolism.

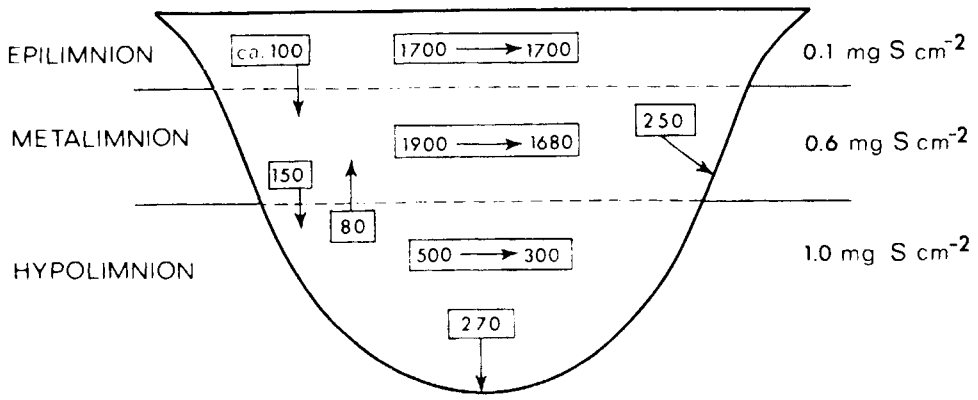

FIGURE 14-13 The total sulfate budget of Linsley, Pond, Connecticut, estimated for an early stage of thermal stratification (*left-hand numbers in central squares*) and final stages (*right hand numbers in central squares*). The other numbers give the transfer rates of sulfate, in kg S, between the different strata. At the right is the total amount of sulfate reduced and stored per cm^2 of sediment during the four-month period. The total amount of dissolved H_2S at the end of stratification was about 15 kg S in the hypolimnion. (After Stuiver, 1967.)

Finally, several groups of bacteria oxidize sulfide to sulfur and sulfur to sulfate.

The ***sulfur-reducing bacteria,*** such as those of the genera *Desulfovibrio* and *Desulfotomaculum,* are obligate anaerobes and derive oxygen from sulfate for the oxidation of either organic matter or molecular hydrogen (Hamilton, 1985; Singleton, 1993):

$$H_2SO_4 + 2(CH_2O) \longrightarrow 2CO_2 + 2H_2O + H_2S$$

$$H_2SO_4 + 4H_2 \longrightarrow 4H_2O + H_2S$$
$$(\Delta G_0' = -60 \text{ kcal mole}^{-1})$$

Although these reactions do not consume oxygen directly (Peck, 1993), the H_2S generated by sulfate-reducing bacteria is readily oxidized and consumes oxygen upon intrusion into, or transport to, aerobic regions. The sulfate-reducing bacteria can reduce sulfite more rapidly, and thiosulfate less rapidly, than sulfate. Colloidal sulfur, but not pure noncolloidal sulfur, is reduced very slowly. Over a concentration range of 20–130 mg SO_4 $liter^{-1}$, the rate of production of H_2S by bacteria is roughly proportional to SO_4 concentration (Ohle, 1954). The biological oxygen demand of oxidizable organic matter can theoretically be satisfied with about 1.6 g SO_4 g^{-1} by this reduction.

The ***sulfur-oxidizing bacteria*** are commonly differentiated into two groups (Kuenen *et al.,* 1985). The ***chemosynthetic (colorless) sulfur-oxidizing bacteria***

TABLE 14-9 Distribution of Forms of Sulfur in Surface Sediments (0–10 cm)

Sulfur form	*Concentration (moles)*	*Percentage of total*	*Site*	*Percentage ester sulfate of total*
Wintergreen Lake Michigan[a]			Wintergreen Lake, Michigan[b]

[a] Smith and Klug (1981); King and Klug (1982).
[b] King and Klug (1980).
[c] Mitchell *et al.* (1981).

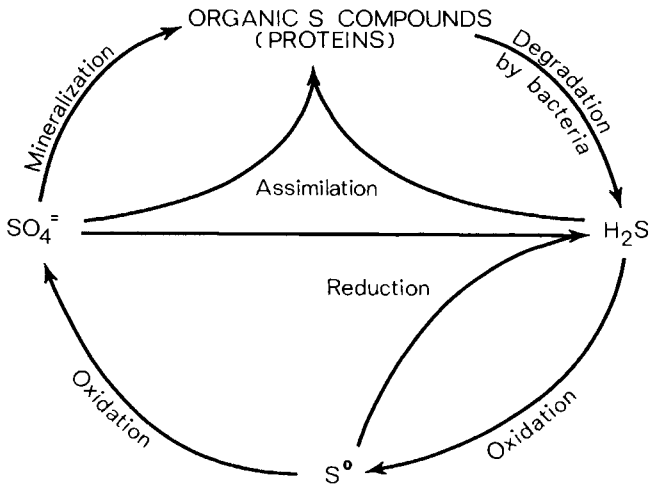

FIGURE 14-14 General sulfur cycle in nature. (Modified from Butlin, 1953.)

are mostly aerobic forms that oxidize H_2S, and are of two types. The first deposits sulfur *inside* the cell:

$$H_2S + \tfrac{1}{2}O_2 \longrightarrow S^0 + H_2O$$
$$(\Delta G_0' = -41 \text{ kcal mole}^{-1})$$

which accumulates as long as H_2S is available. As sulfide sources are depleted, the internally stored sulfur is oxidized and sulfate is released:

$$S^0 + 1\tfrac{1}{2}O_2 + H_2O \longrightarrow H_2SO_4$$
$$(\Delta G_0' = -118 \text{ kcal mole}^{-1})$$

Beggiatoa, a long, filamentous bacterium, and *Thiothrix* are common bacteria that oxidize H_2S with deposition of sulfur intracellularly. These two genera occur in areas where H_2S is being formed (e.g., canals, swamps, and sulfur springs).

By similar reactions, a second type of chemosynthetic sulfur-oxidizing bacteria deposits sulfur *outside* of the cell. This assemblage is represented best by the genus *Thiobacillus,* which oxidizes sulfide, S^0, and other reduced sulfur compounds such as thiosulfate:

$$2Na_2S_2O_3 + O_2 \longrightarrow 2S^0 + 2Na_2SO_4$$

Of the many species of *Thiobacillus,* some (e.g., *T. thiooxidans)* are restricted to acidic waters (pH 1–5), while others such as *T. thioparus* grow optimally at neutral or alkaline pH values. The anaerobe *T. denitrificans* oxidizes thiosulfate in alkaline waters by reduction of nitrate to N_2:

$$5S_2O_3^{2-} + 8NO_3^- + 2HCO_3^- \longrightarrow$$
$$10SO_4^{2-} + 2CO_2 + H_2O + 4N_2$$

or

$$5S^0 + 6NO_3^- + 2CO_3^{2-} \longrightarrow 5SO_4^{2-} + 2CO_2 + 3N_2$$
$$(\Delta G_0' = -179 \text{ kcal mole}^{-1}).$$

The elemental sulfur-oxidizing bacteria commonly adhere to sulfur granules, continuously utilizing a little at a time in the formation of sulfate.

The other major group of sulfur-oxidizing bacteria is the ***photosynthetic (colored) sulfur bacteria,*** anaerobes that can be divided conveniently into the ***green sulfur bacteria*** (Chlorobacteriaceae) and the ***purple sulfur bacteria*** (Thiorhodaceae). Excellent detailed reviews of the photosynthetic bacteria and their metabolism are given by Gest *et al.* (1963), Vernon (1964), Kondrat'eva (1965), Pfennig (1967), Fierdingstad (1979), Madigan (1988), Kelly (1990), Collins and Remsen (1991), Stolz (1991), and Friedrich (1998). The green sulfur bacteria require light as an energy source and use the sulfur of H_2S as an electron donor in the photosynthetic reduction of CO_2:

$$CO_2 + 2H_2S \xrightarrow{\text{light}} (CH_2O) + H_2O + 2S$$
$$2CO_2 + 2H_2O + H_2S \xrightarrow{\text{light}} 2(CH_2O) + H_2SO_4$$

TABLE 14-10 Predominant Bacteria that Form Hydrogen Sulfide from the Decomposition of Proteinaceous Organic Matter in Different Types of Lakes[a]

Type of lake	*Dominant bacteria*
Oligotrophic	*Mycobacterium phlei, Mycobacterium filiforme*
Mesotrophic	*Bacterium nitriftcans, Pseudomonas liquefaciens, Chromobacter aurantiacum*
Eutrophic	*Pseudomonas liquefaciens, Bacterium delicatum*
Bog lakes of high organic matter	*Pseudomonas fluorescens, Bacillus pituitans*
Saline lakes and estuaries	*Mycobacterium luteum, Micrococcus nitriftcans, Achromobacter halophilum, Flavobacterium halophilum, Bacterium albo-luteum, Vibrio hydrosulfureus*

[a] After data of Kuznetsov (1970).

A few species can utilize molecular hydrogen alone. The green sulfur bacteria, notably the genera *Chlorobium* and *Pelodictyon,* are generally unicellular and nonmotile and produce sulfur granules outside of their cell membranes. At least four bacteriochlorophylls occur in the photosynthetic bacteria that differ from chlorophyll *a* in a primary absorption maximum at higher wavelengths (770–780 nm versus 665 nm for chlorophyll *a*). The green sulfur bacteria can tolerate fairly high concentrations of H_2S, whereas the purple sulfur bacteria are less tolerant of H_2S and grow optimally at high pH values (9.5).

The *purple sulfur bacteria* require light energy for the oxidation of H_2S and other reduced sulfur compounds, especially thiosulfate, to sulfate in the photosynthetic reduction of CO_2. Members of this group are generally large (5–10 μm) and actively motile and deposit free S^0 intracellularly. Sulfide is oxidized to S and SO_4^{2-} by the same reactions described for the green sulfur bacteria. In addition, some of the purple sulfur bacteria are able to grow photoautotrophically, with thiosulfate as the electron donor *(Thiopedia, Thiocapsa, Thiocystis* and *Rhodothece*). Other important genera (*Chromatium, Chlorobium* and *Thiospirillum)* are unable to utilize significant amounts of thiosulfate. Like the green sulfur bacteria, many purple bacteria can utilize hydrogen as the only electron acceptor, simultaneously with an assimilatory sulfate reduction system. In anaerobic environments where iron is abundant, phototrophic sulfur bacteria can use FeS as an electron donor as well as H_2S (Davison and Finlay, 1986; Garcia-Gil *et al.,* 1990; Ehrenreich and Widdel, 1994). Thus, under conditions where light supports phototrophic sulfur bacteria in proximity to combined sources of reduced iron and sulfide, the sulfide is oxidized either directly or indirectly through FeS to sulfate at rates adequate to prevent iron sulfide from forming in the water column.

The Calvin cycle has been shown to be operational in all photosynthetic bacteria studied. Many strains can utilize low-molecular-weight organic substrates, especially fatty acids, as their carbon source, singly or in combination with CO_2. Nearly all green and purple sulfur bacteria require vitamin B_{12} from exogenous sources. This vitamin, as will be discussed further on, is an organic micronutrient that influences photosynthetic productivity under some limnological conditions.

A third group, the ***purple nonsulfur bacteria*** (Athiorhodaceae), is included here among the other pigmented photosynthetic bacteria because of its many metabolic and distributional similarities. The nonsulfur purple bacteria, including *Rhodopseudomonas, Rhodospirillum,* and *Rhodomicrobium,* are facultative photoautotrophs that grow photosynthetically or heterotrophically either aerobically or anaerobically in the dark on organic substrates. Some *Rhodopseudomonas* can utilize thiosulfate anaerobically as a hydrogen donor:

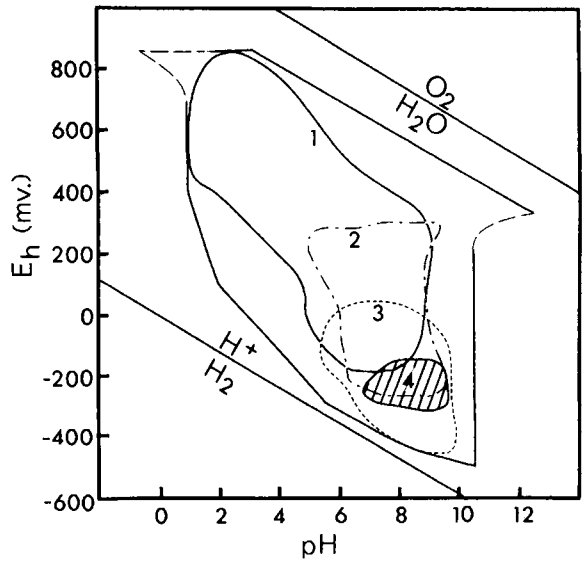

FIGURE 14-15 General E_h–pH environmental limits of (1) chemosynthetic (colorless) sulfur-oxidizing bacteria, (2) photosynthetic purple bacteria, (3) sulfate-reducing bacteria, and (4) green sulfur bacteria, all within the composite distributional field of E_h–pH measurements of habitats of organisms. (After data of Baas Becking *et al.,* 1960.)

$$2CO_2 + Na_2S_2O_3 + 3H_2O \xrightarrow{\text{light}} 2(CH_2O) + Na_2SO_4 + H_2SO_4$$

In this group, sulfur is not stored intracellularly, and hydrogen sulfide inhibits growth.

The occurrence and distribution of the various sulfur-oxidizing or -reducing bacteria are restricted by the redox and pH conditions in relation to oxygen and the state of sulfur compounds (Fig. 14-15). The reducing conditions required by strictly anaerobic photosynthetic sulfur bacteria, for example, must coincide with adequate light of high wavelength before large populations can develop. Often, conditions required for optimal growth of sulfur bacteria occur in stratified lakes as sharply defined layers with steep physical and chemical gradients and result in thin layers or strata of bacterial populations.

Microbial processes involved in the sulfur cycle of lakes are diagrammatically represented in Figure 14-16. The processes on the left-hand side of the figure would be more characteristic of a lake with relatively high concentrations of sulfur in various forms. The gradient between the oxic upper strata and the lower H_2S-rich strata would be steep, but with a diffusion interface zone where both oxygen and H_2S occurred. Those

processes on the right-hand side of Figure 14-16 are more representative of lakes with lower sulfate content.

The rather specific requirements of the sulfate-reducing bacteria, photosynthetic and colorless sulfur bacteria, and sulfur-oxidizing bacteria would lead one to expect development of massive populations only in localized strata. Such is indeed the case in many situations, particularly in meromictic lakes where gradients within the chemolimnion are steep. Green sulfur bacteria are commonly found in profusion in a thin layer immediately below a dense population of purple sulfur bacteria at the interface of the oxic–anoxic layer of very productive lakes. Light levels at this region are almost always low, usually <10% of intensities at the surface, and rapidly become the dominant limitation to photosynthesis in the bacterial plates. The seasonal development of optimal conditions for the specific groups of sulfur bacteria can be transitory, so that their contribution to the total annual productivity of the lake may be short-lived. Within meromictic lakes, bacterial plates can persist more or less continuously (cf. Abella *et al.*, 1980; Guerrero *et al.*, 1980, 1985; Baker *et al.*, 1985; Overmann *et al.*, 1991).

Although descriptions of the distribution of the sulfur bacteria in aquatic systems are fairly common, and much is known about the physiology of these interesting organisms, little is known of their contribution to the total productivity of lakes. It is clear that at certain periods in productive dimictic and in meromictic lakes, bacterial photosynthesis easily can exceed that of algae and macrophytes (Table 14-11). Most of the data given in Table 14-11, however, are taken from periods when the photosynthesis of bacteria was maximal. Occasionally, when the algal photosynthesis is low, as in the example of Smith Hole Lake, which receives high amounts of allochthonous organic matter, the brief but very productive photosynthetic bacterial development represents a major part of the lake's annual photosynthetic productivity (Wetzel, 1973). In most situations, however, the contribution of bacterial photosynthesis to the entire system over an annual period is small, even though spectacular localized populations may develop periodically.

In several systems, as for example in Lake Gek Gel, an oligotrophic meromictic lake of crenogenic origin, and in the deep, meromictic Black Sea, the most intensive rates of bacterial reduction of sulfates occurred near sediments and in water layers on the littoral slopes at the upper boundary of the anaerobic H_2S zone (Fig. 14-17) (Sorokin, 1964, 1966, 1970). The higher rates of sulfate reduction in these cases were apparently related to higher inputs of organic matter from the littoral zone brought in allochthonously from the drainage basin. Higher H_2S concentrations along these sediment interfaces were then dispersed by weak water currents to the open water (Sorokin, 1970). High rates of sulfate reduction occurred below the zone of most active bacterial chemosynthesis (Fig. 14-17), where again the concentrations of organic substrates were presumably higher.

A similar dichotomous distribution of sulfate-reducing bacteria below the zone of most active

chemosynthesis is seen even more clearly from data of Lake Belovod (Fig. 14-18). The major bacteria in the zone of chemosynthesis were several species of *Thiobacillus,* over which lay a dense population of purple sulfur bacteria. Sorokin has provided evidence on the movements of zooplankton populations in response to changes in bacterial stratification, and studies of feeding indicate that zooplankton, especially the cladoceran microcrustacea, actively feed on the dense populations of these large bacteria.

A detailed study was undertaken of the organic carbon budget and comparative productivity of phytoplankton and phototrophic sulfur bacteria in Mahoney Lake, a small (11 ha), saline meromictic lake in British Columbia (Overmann, 1997). The purple sulfur bacterium *Amoebobacter purpureus* (Chromatiaceae) completely dominated (98%) the microorganisms and concentrated in a 20-cm plate in the monimolimnion between 6- and 7-m depths. Fluxes of organic carbon were calculated from the rates of photosynthesis, sulfate reduction, and sedimentation (Fig. 14-19). Upwelling was a major loss process for *A. purpureus* (80% moved upward to the oxic strata), and sedimentation provided only a small fraction of the carbon substrates of sulfate-reducing bacteria (7.9 of ca. 47 g C m^{-2} yr^{-1}). Only a third of the sulfate reduction within the bacterial plate (13.9 g C m^{-2} yr^{-1}) could be attributed to recycling of *A. purpureus* carbon. Because production and sedimentation of phytoplankton was very

small, most of the organic carbon supporting sulfate reduction and generation of H_2S that fueled the phototrophic bacterial production emanated from allochthonous particulate and, especially, dissolved organic carbon (DOC to 90 mg C $liter^{-1}$). In this way, recalcitrant organic carbon from allochthonous sources is converted into readily degradable bacterial biomass using light as the energy source and sulfide as an electron acceptor in the formation of biomass that is then returned to the oxic part of the ecosystem.

D. Sulfur Cycling in the Sediments

Large variability in rates of sulfate reduction within sediments has been observed among different lakes (Table 14-12). Early studies suggested that sediment sulfate concentrations varied little over time, with a relatively constant turnover time for the sulfate (Smith and Klug, 1981). Organic sulfate esters, entering the sediments from settling seston, can serve as a major source of sulfur and be mineralized by an active

sulfhydrolase system in surficial sediments (King and Klug, 1980, 1982a). These organic sources would augment inorganic reduced sulfur generated from sulfate reduction.

Much of the sulfur in sediments is organic, particularly in eutrophic lakes. In lakes with highly organic sediments and low iron concentrations, a larger portion of the sedimentary iron is present as ferrous sulfides (Giblin *et al.*, 1990). Much of the reduced sulfate is rapidly converted to organic sulfur compounds, and this organic sulfur is more persistent in the sediments than iron sulfides (Rudd *et al.*, 1986). Several recent studies indicate that high rates of sulfide oxidation (pyrite, organically bound sulfur and sulfides) can accompany high rates of sulfate reduction (Marnette *et al.*, 1992; Urban and Brezonik, 1993; Urban *et al.*, 1994). Sulfide oxidation can occur nearly as rapidly as sulfate reduction. Importantly, the formation of organic sulfur in sediments consumes H^+ ions via sulfate reduction in acidified lakes (Anderson and Schiff, 1987). Rates of sulfate reduction in sediments can be significantly enhanced in moderately acidic, organic rich sediments that receive high sulfate inputs from atmospheric or influent sources (Herlihy and Mills, 1985; Schuurkes and Kok, 1988).

VII. THE SILICA CYCLE

Silica (SiO_2) is usually moderately abundant in fresh waters and, although it is relatively unreactive, it is of major significance to diatomaceous algae, chrysophytes, and some higher aquatic plants and sponges. Diatoms assimilate large quantities of silicon in the synthesis of their frustules. Silicon is a major factor influencing algal production in many lakes, and diatom utilization of silica greatly modifies the flux rates of silica in lakes and streams. Availability of silica can have a strong influence on the overall pattern of algal succession and productivity in lakes and streams.

A. Forms and Sources of Silicon

Silicon occurs in fresh waters in two major forms of silicon dioxide or silica (SiO_2). (1) *Dissolved silicic acids* form stable solutions of H_2SiO_4 at much higher concentrations than are encountered in fresh waters (60–80 mg SiO_2 liter^{-1} at O°C to 100–140 mg SiO_2 liter^{-1} at 25°C at commonly occurring pH values; Krauskopf, 1956). Unreactive silicon is not generally found; polymeric silicon is unstable and depolymerizes rather rapidly (within hours) (Burton *et al.*, 1970). The solution of silica from various rock sources is modified, however, by surface adsorption of silicic acid, which reduces solubility and leads to a general situation in which nearly all natural waters are greatly undersaturated with respect to silica (Tessenow, 1966; Stöber, 1967). (2) *Particulate silica* is found in two forms—that in biotic material, in particular in diatoms and a few other organisms that use large amounts of silica, and that adsorbed to inorganic particles or complexed organically. Silicate complexes with iron and aluminum hydroxides and this process decreases the solubility of silicates in sediments, especially in interstitial waters at pH values above 7 (Ohle, 1964). The solubility of silica is increased by humic compounds and through the formation of iron and aluminum–silicate–humic complexes.

The silica content of drainage to natural waters is less variable than many of the other major inorganic constituents. The world average is about 13 mg SiO_2 liter^{-1}, with relatively little variation among the continents; the average of ground water is somewhat higher than that of surface drainage (Davis, 1964). The major source of silica is from the degradation of

aluminosilicate minerals. The greatest concentrations of silica are found in ground water in contact with volcanic rocks; intermediate amounts occur in association with plutonic rocks and sediments containing feldspar and volcanic rock fragments; and small amounts originate from marine sandstones. The lowest amounts of silica are found in water draining from carbonate rocks. Silica forms aggregations and becomes relatively immobile at pH values below 3, but its mobility increases somewhat in the range of pH 4–9. Adsorption is the only significant mechanism of inorganic precipitation; flocculation of colloidal silica could not be demonstrated (Tessenow, 1966).

Carbonic acid originating from dissolved CO_2 reacts with silicates to form carbonates and silica. Concentrations of dissolved silica in soil water increase slightly with higher temperature and decrease with increasing soil pH values (McKeague and Cline, 1963a, b) as adsorption increases within pH 4–9. Above a pH of 10, adsorption decreases sharply. Mineralization of silicates is presumed to be largely or entirely a nonenzymatic hydrolysis (Golterman, 1960). However, silicate bacteria are known to play a role in the weathering of rocks and minerals both in the presence and the absence of organic substrates (Savostin, 1972; Joseph and Bravo, 1990), and benthic-living diatoms are known to attack silicious materials of sediments. Mechanisms of this mineralization are unclear, however.

The silica content of river waters tends to be remarkably uniform and shows little response to change in discharge rates (Edwards and Liss, 1973). This situation is in distinct contrast to other major constituents of river water, which commonly show an inverse relationship between concentration and discharge rates. Although rapid diurnal changes in the silica content of river waters are known and can be associated inversely with division rates and growth of diatoms (Müller-Haeckel, 1965), these and other biological factors are insufficient to explain the relative stability of silica concentrations. An abiological buffering mechanism is apparently also operational, with adsorption reactions between dissolved silica and silica in the solid phase (i.e., in association with hydrated oxides). Adsorption and desorption equilibria can buffer changes in concentration over a period of several days. The effects of dissolved silica and degraded silicates assume much more significance in the oceans, where reactions occur in which silica and alkali metal cations are fixed. Hydrogen ions are released and result in an effective buffering of both pH and silica concentrations (Garrels, 1965; Mackenzie *et al.*, 1965, 1967).

Silica loadings to lakes are usually largely from influent surface waters of rivers. In certain lakes, however, ground waters can be the primary source of silica. For example, even though the short-term, seasonal input of ground water to a small, precipitation-dominated oligotrophic lake in northern Wisconsin was <10% of the annual water budget of the lake, groundwater influents accounted for nearly all of the external silica loading (Hurley *et al.*, 1990).

B. Distribution of Silica in Lakes and Reservoirs

Concentrations of silica within lakes and reservoirs frequently exhibit marked seasonal and spatial variations. Even in oligotrophic waters a conspicuous decrease in silica is often found in the epilimnetic strata during early winter, as well as in the spring during circulation and during thermal stratification (Fig. 14-20). In eutrophic lakes, silica concentrations in the trophogenic zone are commonly reduced to near analytical undetectability. Reductions in silica concentrations within the epilimnetic and metalimnetic zones result in a negative heterograde silica curve against depth (Figs. 14-20 and 14-21). The heterograde silica distribution is clearly associated with intensive assimilation of

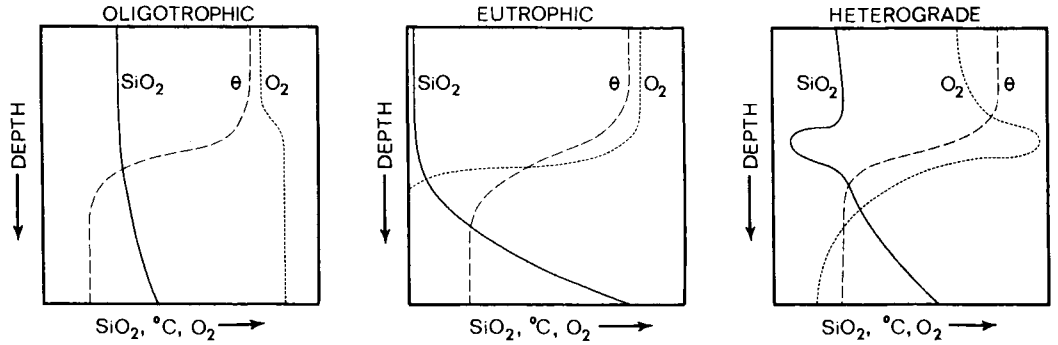

FIGURE 14-20 Generalized distribution of silica concentrations in unproductive and very productive lakes, and in a lake exhibiting a metalimnetic development of diatom algae and a negative heterograde silica curve.

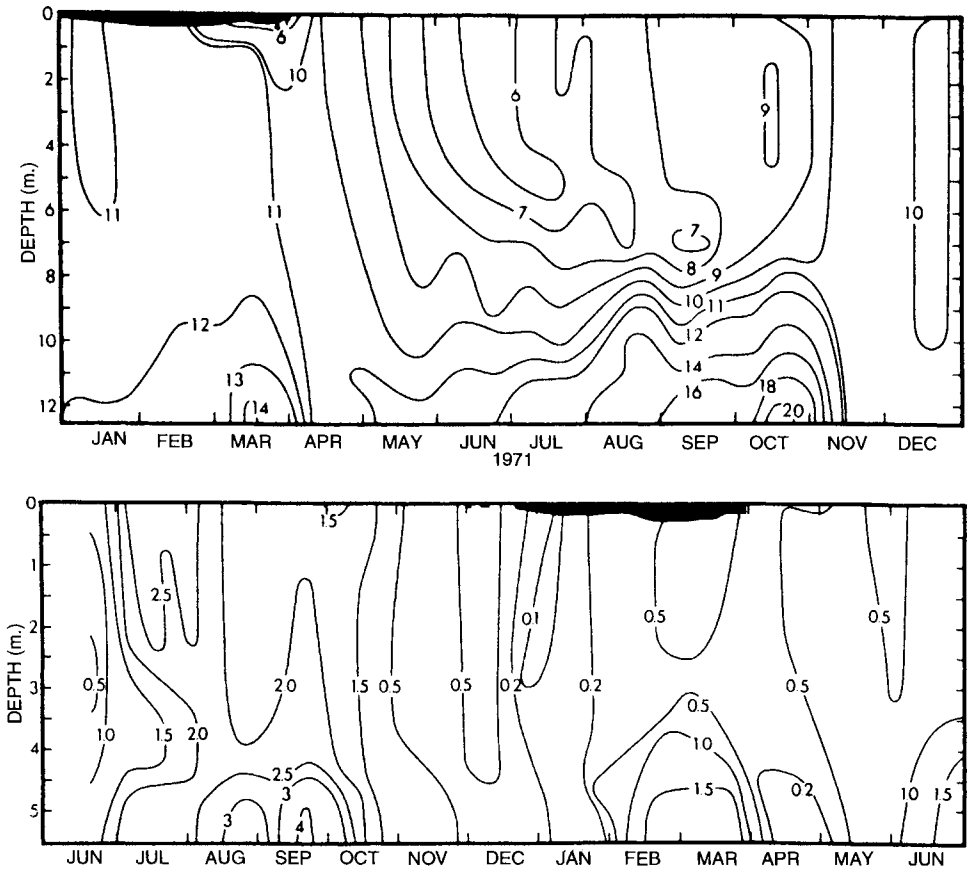

FIGURE 14-21 Depth–time diagram of isopleths of silica concentrations (mg SiO_2 liter^{-1}) in oligotrophic hardwater Lawrence Lake, 1971 (*upper*) and hypereutrophic Wintergreen Lake, 1971–1972 (*lower*), southwestern Michigan. Opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

silica by diatoms, which sediment with their incorporated silica from the trophogenic zone more rapidly than silica is replaced by inputs to the system from surface water and ground water. Other sinks of silica are minor relative to the quantities transported by diatoms. Abiogenic precipitation in the open water is relatively unimportant in the cycle of silica. Dilution by water low in silica can occur, as, for example, by rain percolating through decaying ice (March–April, Lawrence Lake, Fig. 14-21).

The seasonal cycle of silica, demonstrated in Figure 14-21, has been observed frequently. By far the most detailed experimental investigations of mechanisms controlling silica dynamics in lakes is that of Tessenow (1966), from which many of the following statements are drawn. Utilization of silica by diatoms occurs during photosynthesis and increases somewhat in darkness. Adsorption of SiO_2 to dead cells under some conditions can lead to reduction of silica content even below the trophogenic zone. Silica concentrations usually increase in the tropholytic zone of a lake during both summer and winter periods of stratification. The silica gradient becomes more steep in eutrophic lakes that exhibit an anaerobic clinograde oxygen curve. In most stratified lakes, silica concentrations increase in water immediately above the sediments (Fig. 14-21; cf. Conway *et al.*, 1977).

The amorphous silica of diatoms often settles to the sediments. This biochemical condensation of dissolved silica and sedimentation greatly exceeds inputs to the sediments from abiogenic sources and reaches the sediments with variable periodicity. Diatom production is typically greatest in the spring and early winter but often proceeds more or less continuously, particularly in oligotrophic lakes.

Interstitial water is enriched in dissolved silica at concentrations far in excess of those of water entering the lake (Tessenow, 1966; Harriss, 1967). Interstitial concentrations increase as the pH declines below 7, decrease between pH 7–9, and greatly increase above pH 9. Concentrations also increase at higher temperatures within the range found in fresh waters. The dissolved silica of interstitial water is not in equilibrium with amorphous silica, but rather with chemically bound or

adsorbed silica. Silica concentration of the interstitial water is controlled by dissolution of ferroaluminum silicate. This complex is formed in the sediments by the reaction of silica from diatoms with aluminum and ferric oxyhydroxides or through the hydrolysis of clay minerals (Nriagu, 1978). Liberation of silica to the overlying water in relatively isolated lake sediments is governed by these equilibria, which are stable only in the presence of the solid phase of adsorbed silica. Sediment material rich in hydrated Al and Fe oxides has a high phosphorus sorption capacity and a very low P concentration (<5 μg liter^{-1}) in the interstitial water under aerobic conditions. Some 25–30% of total P and almost 90% of total Si were found to be bound in mineral lattices in a stable form not participating in biological and chemical transformations (Hartikainen *et al.*, 1996). When the sediments are anaerobic, both P and Si dissolve into the interstitial water. The dissolution patterns suggest that both P and Si are bound to the same components and compete with each other for the sorption sites.

Exchange between sediment and water decreases concentrations of interstitial water and results in greater redissolution from the sediments. Sediment silica release rates increase with rising temperatures (Rippey, 1983), even though in stratified, moderately deep temperate lakes most sediments are continually cold (<10°C). Sediment silica release rates range from ca. 0.5 mmol m^{-2} day^{-1} in oligotrophic lakes to much higher values (1–14 mmol m^{-2} day^{-1}) in eutrophic lakes. Silica regeneration in nearshore regions of shallow sediments, subject to varying seasonal temperatures and high diatom production, can have much higher rates than colder deep sediments (e.g., Quigley and Robbins, 1984). The rate of silica release also varies with differences in silica concentrations between the sediments and the overlying water. Equilibrium is not attained because of the slowness of diffusion (weeks). The difference between silica of interstitial water and in the overlying water is influenced by currents, movements produced by benthic organisms (e.g., larvae of chironomid insects; Tessenow, 1966), and by gas bubbles escaping from the sediments. In unstratified lakes, the concentrations of dissolved silica can increase greatly in the spring from release of silica from the sediments as the temperatures increase among the disturbed sediments (Gibson, 1981).

In lakes dominated by diatom algae, large numbers of sedimenting diatom frustules can accumulate within the sediments and be lost permanently from the system. The extent of this permanent loss depends on rates of diatom productivity, on the morphometry of the lake basin, and upon the percentage of the sediments located in the quiescent waters of the deep hypolimnion. In deep lakes, many of the diatom frustules undergo partial dissolution before reaching the sediments. The dissolution of suspended silica can be accelerated by consumption and fragmentation of diatom frustules by zooplankton, a process that is apparently of significance in both productive shallow ponds and in deep lakes (e.g., Ferrante and Parker, 1978). Silica sedimented from biogenic sources to shallower sediments is returned more rapidly to the overlying and circulating waters. Therefore, the metalimnetic and upper hypolimnetic waters that experience greater movement than the deeper waters are commonly enriched with silica in relation to strata above and below. A resulting positive heterograde silica curve has often been observed (numerous examples are given in Tessenow, 1966). The increased exchange induced by circulation over littoral sediments in shallow lakes can lead to silica concentrations that are sometimes greater than those of drainage inlet sources and can, in addition, result in silica losses from the system by outflow. The silica cycle and economy of most lakes are regulated largely by autochthonous metabolism within the lake, but losses are balanced strongly by allochthonous inputs.

C. Utilization and Role of Silica

Silicified structures occur in many aquatic organisms, but none approaches the importance of the diatoms (Bacillariophyceae). All diatoms are enclosed in a silica wall or frustule in which silicic acid has been dehydrated and polymerized to form silica particles (J. C. Lewin, 1962). The vegetative cells of some species of yellow-brown algae (Chrysophyceae) bear discrete siliceous scales and form cysts with silicified walls. These algae, as well as certain silicoflagellates, however, probably have only an insignificant impact on silica cycling in comparison to the active utilization and more extensive distribution of the diatoms. Similarly, utilization of silicon by certain aquatic macrophytes (*Equisetum*) and siliceous sponges, while of major importance to the organisms *per se* and their development and productivity, is rarely sufficient to alter the quantitative cycling of silica in lakes (cf., however, Conley and Schelske (1993) on the potential additional role of sponge spicules in influencing the silicon biogeochemistry of shallow lakes in Florida).

The succession and productivity of algal populations will be discussed in detail further on, but it is appropriate here to stress the importance of diatoms on the silica cycle and their effects on their own population dynamics. Of all of the aspects of chemical determination of succession and productivity, the relation between diatoms and silica concentrations is among the

most apparent. The data, upheld by the detailed investigations of Lund (1949, 1950, 1954, 1955; Heron, 1961; Lund *et al.*, 1963), are irrefutable and have been corroborated by experimental work (cf. Chap. 15).

Phytoplankton in temperate waters usually undergo a spring maximum. This population development may begin beneath the ice as light conditions improve but is most conspicuous during and following spring circulation when the water is relatively rich in nutrients as the winter accumulations are mixed throughout the water column. One or several algal species usually dominates this exponential growth maximum for several weeks, and in a large number of lakes, diatoms constitute the predominant algae of the spring maximum. Increasing light, and to a lesser extent a rise in water temperatures, are major factors initiating the development of diatom populations from smaller residual winter planktonic populations. Circulation and turbulence are much higher in the spring than later in the season and assist in maintaining the relatively dense diatom cells in optimal intensities of light. Other factors influencing the development of succession and development of the algal populations will be treated later (Chap. 15).

The diatom *Asterionella* commonly precedes other diatoms such as *Cyclotella, Fragilaria,* and *Tabellaria* in the spring maximum. Collectively, the spring maximum often declines abruptly as the silica concentrations fall below 0.5 mg liter^{-1} (Fig. 14-22). The same annual pattern is illustrated for Lake Windermere, where it has been demonstrated continuously for over 30 years. Factors such as light intensity, temperature, grazing by zooplankton, fungal parasitism, and changes in other nutrients, especially nitrogen and phosphate, could not be shown to be associated with the decline of the maximum. Experimental results on silica requirements showed that the silica reduction was clearly the major factor contributing to the decline of the diatoms. The diatom succession results from interspecific differences in assimilation efficiencies and the effects of silicon concentration on growth and death. For example, in Lake Constance in southern Germany, silicon depletion in *Asterionella formosa* did not stop cell division but led to the death of most of the population (Sommer and Stabel, 1983). In *Fragilaria* and *Stephanodiscus,* however, cell division stopped but cells did not die and population growth continued at reduced levels after the concentrations of dissolved silica had increased later in the season.

To generalize from these situations would be misleading since, even though this sequence occurs rather commonly, numerous other interacting factors are involved. Silica concentrations and their biogenic reduction from epilimnetic waters, however, are certainly major factors in diatom-community regulation. In lakes where silica levels remain high, even though severely reduced during the summer productive period (e.g., Lawrence Lake, Fig. 14-21, *upper*), the spring diatom maximum persists longer into the summer and is overtaken gradually by a predominance of green algae. In very productive lakes, a maximum diatom peak can be found in the fall and early winter, as, for example, in Wintergreen Lake (Fig. 14-21, *lower*), during which time a competitive advantage to diatoms is apparent until the silica levels decline to very low concentrations (<100 μg liter^{-1}). After spring overturn, diatom growth is very short-lived in this lake, followed by a brief dominance of green algae until inorganic combined nitrogen

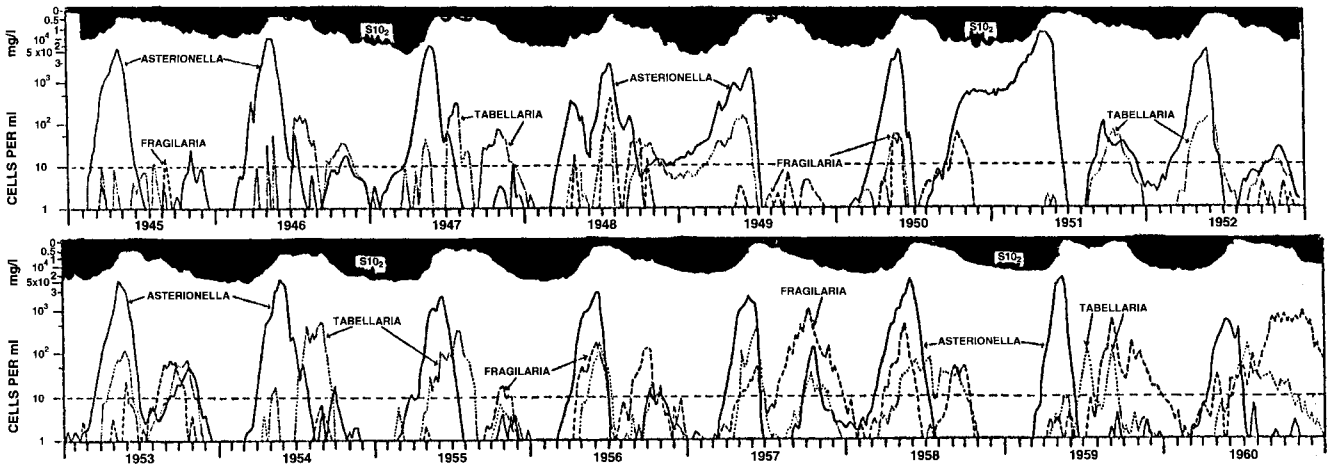

FIGURE 14-22 The periodicity of the diatom algae *Asterionella formosa, Fragilaria crotonensis,* and *Tabellaria flocculosa* in relation to fluctuations in the concentration of dissolved silica, 0–5 m in Lake Windermere, England, 1945–1960. (From Lund, J. W. G.: *Verhandlungen Int. Ver. Limnol. 15*:37, 1964.)

sources are depleted. Nitrogen-fixing cyanobacteria then quickly dominate and persist until the combined effects of increased inorganic nitrogen, reduced light and temperature, and renewed silica reoccur during circulation in late summer and early autumn.

The succession sequence of different species of diatoms can be seen not only within a composite spring maximum but also in the patterns of diatom periodicity as lakes become more productive. In lakes in which silica concentrations are moderate to low (e.g., <5 mg liter^{-1}), progressive long-term enrichment with phosphorus and nitrogen can lead to rapid biogenic reduction in silica levels so that diatoms cannot effectively compete and are replaced by nonsiliceous phytoplankton (Kilham, 1971). A common response to nutrient loading in northern temperate lakes, reservoirs, and even rivers under some circumstances is an increase in diatom growth and biomass. Nutrient enrichments commonly lead to increases in concentrations of total P and total N, but not Si. Such nutrient loading can lead to increased diatom production. The greatly increased sedimentation of diatoms can result in rapid depauperation and even depletion of silica in trophogenic zones. As the reductions of silica from the photosynthetic zones continues over a number of years, more silica is removed to the sediments than is replenished from external sources and regeneration from the sediments (Schelske and Stoermer, 1971; Schelske, 1985, 1988; Schelske *et al.*, 1988; Conley *et al.*, 1993). Under such circumstances, diatoms are gradually outcompeted and excluded by green algae and cyanobacteria during the summer period, and if persisting over long periods of time, permanently as dominant components of the phytoplankton.

A strong interaction can exist between the population level of littoral diatoms and the development of planktonic diatoms. For example, in Furesø, the spring maximum of the planktonic diatoms, primarily *Stephanodiscus,* reduced the silica concentrations to <40 μg liter^{-1}, levels experimentally demonstrated to inhibit the growth of these algae (Jørgensen, 1957) (Fig. 14-23). An immediate increase in epiphytic diatoms growing on submersed portions of the emergent macrophyte *Phragmites* accompanied this decrease. The *Phragmites* stems were shown to possess large quantities of easily dissolved silica, and their silica content decreased during the development of the epiphytic diatoms.

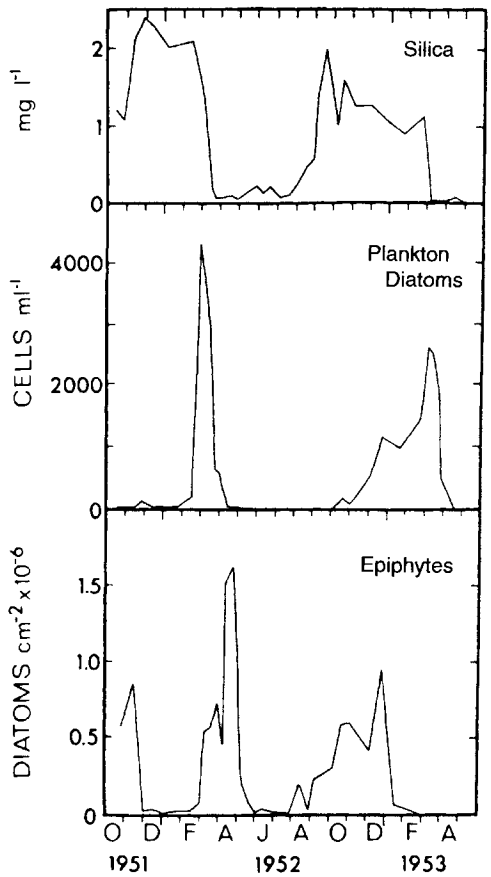

FIGURE 14-23 Variations in numbers of the dominant phytoplanktonic diatom (*Stephanodiscus hantzschii*), silica concentrations at the surface, and epiphytic diatoms per cm^{-2} of *Phragmites* stems at a depth of 20–30 cm, Furesø, Denmark. (After data of Jørgensen, 1957.)

VIII. SUMMARY

1. The biogeochemical cycling of essential inorganic micronutrients is regulated to a large extent by changes in oxidation-reduction (redox) states, which are governed largely by photosynthetic and bacterial metabolism.
   a. By conversion of light energy into chemical bonds, photosynthesis produces reduced states (negative E_h) of high free energy and nonequilibrium concentrations of carbon, nitrogen, and sulfur compounds. Respiratory and fermentative reactions of nonphotosynthetic organisms tend to restore equilibrium by catalytically decomposing the products of photosynthesis. The nonphotosynthetic organisms obtain free energy for their metabolism from this process.
   b. Complete redox equilibrium conditions do not occur in natural aquatic ecosystems because most redox reactions are slow and consist of a composite of many redox reactions of different reaction rates. In addition, continuously changing inputs of photosynthetic energy occur, which disrupt the tendency toward equilibrium.

c. The predominant reactants in the redox processes in natural waters are carbon, oxygen, nitrogen, sulfur, iron, and manganese. Under anaerobic conditions, each predominant terminal electron-accepting reaction has an identifiable range of H_2 concentrations, which in sediments allows evaluation of the redox conditions.

d. Redox remains positive (300–500 mV) as long as some dissolved oxygen (>1 mg liter^{-1}) is present. Temperature and pH changes have only minor effects on redox. As oxygen concentrations approach zero, E_h decreases precipitously.

2. Concentrations of ionic iron are exceedingly low in aerated water. Most iron in oxygenated water occurs as ferric hydroxide in particulate and colloidal form and as complexes with organic, especially humic, compounds. The solubility of manganese is considerably higher than that of iron, but it is analogous to iron in the way it reacts.
   a. Under conditions of both low pH and low redox potential (approximately 250 mV), ferrous and manganous ions diffuse from the sediments and accumulate in anaerobic hypolimnetic water of productive lakes (Fig. 14-3).
   b. Under strongly reducing conditions of very low redox potentials (<100 mV), sulfate is reduced to sulfide. Highly insoluble metallic sulfides, particularly ferrous sulfide (FeS), form under these conditions. Therefore, in hypereutrophic lakes, high concentrations of hydrogen sulfide resulting from bacterial decomposition of sulfur-containing organic matter and from reduction of sulfate can lead to significant decreases in dissolved iron (but not the more soluble manganese) as sulfides form during the latter portion of stratification.
   c. Iron complexes with numerous organic compounds, particularly dissolved humic substances, which can increase iron solubility and availability to organisms.
3. Iron and manganese are micronutrients that are essential to freshwater flora and fauna.
   a. Under certain conditions of restricted availability, photosynthetic productivity can be limited by these elements. Manganese is clearly involved in the seasonal succession of certain algal populations.
   b. Certain chemosynthetic bacteria can utilize the energy of inorganic oxidations of ferrous and manganous salts in relatively inefficient reactions involving CO_2 fixation. Other autotrophic and heterotrophic iron-oxidizing bacteria deposit oxidized iron and manganese. These bacteria are restricted to zones of steep redox gradients between reduced metal ions and oxygenated water (Figure 14-9).
4. Quantitative information on the dynamics of other essential metallic micronutrients—zinc, copper, cobalt, molybdenum, vanadium, nickel, and selenium—is limited. The cycling and availability of micronutrients are governed largely by biogeochemically mediated redox processes: organic matter production and degradation, Fe and Mn redox cycling, and sulfide precipitation. These reactions can be altered by metal complexation with organic, particularly humic, substances.
   a. In most natural waters, micronutrient concentrations and availability are usually adequate to meet metabolic requirements within the constraints of light, temperature, and macronutrient availability. A few clear cases of limitations to photosynthetic productivity by micronutrient deficiencies or physiological unavailability have been demonstrated.
   b. The dynamics of copper are strongly affected by redox conditions similar to those of iron. Cobalt, zinc, and molybdenum dynamics are more closely related to microbial metabolism and transport of the seston and to the effectiveness of complexing with organic compounds. Molybdenum exhibits greater mobility than do the other micronutrient ions.
   c. Inputs of many trace elements and heavy metals to fresh waters are increasing as a result of pollution from industrial and combustion emissions to the atmosphere and subsequent deposition via precipitation. Metal enrichments to toxic levels are particularly widespread for cadmium, lead, mercury, and aluminum.
5. Sulfur is nearly always present in quantities adequate to meet high requirements for protein and sulfate ester synthesis. The dynamics of sulfate and the hydrogen sulfide produced by decomposition of organic matter, however, alter conditions in stratified, productive waters that affect the cycling of other nutrients, productivity, and biotic distribution.
   a. Atmospheric sulfur compounds originating primarily from combustion of coal and oil return to land by precipitation and dry fallout of particles. This sulfur constitutes a major global source of sulfur to fresh waters that in many natural waters exceeds inputs from rock and soil weathering and transport in surface runoff and ground water.
   b. Sulfate is the primary dissolved form of sulfur in oxic waters; hydrogen sulfide accumulates in

anoxic zones of intensive decomposition in productive lakes where the redox potential is reduced below about 100 mV.

c. Most of the sulfur in lake water is stored as dissolved sulfate and hydrogen sulfide. Sestonic sulfur-containing proteins and sulfate esters and dissolved sulfides are primary constituents of the sediments. Appreciable quantities of organic volatile sulfur compounds, largely organic sulfides, can evade to the atmosphere from shallow waters.

d. Although oxygen is obtained from sulfate by sulfate-reducing bacteria, the H_2S generated readily oxidizes and utilizes oxygen upon transport or intrusion into aerobic strata.

e. Sulfur-oxidizing bacteria consist of two general types:
   i. Chemosynthetic aerobes that oxidize reduced sulfur compounds and elemental sulfur to sulfate, and
   ii. Photosynthetic sulfur bacteria that utilize light as an energy source and reduced sulfur compounds as electron donors in the photosynthetic reduction of CO_2.
   iii. The redox requirements of the sulfur-oxidizing bacteria, especially those requiring light, are rather specific, and distribution of species is often restricted to zones of steep gradients between anoxic and aerated water strata.
   iv. When conditions are optimal, the photosynthetic bacteria often develop in extreme profusion and may contribute significantly to the annual productivity of lakes.

6. Silica occurs in relative abundance in natural waters as dissolved silicic acid and particulate silica. Much of the particulate Si is biogenic Si associated with living or dead diatom frustules.
   a. Diatom algae assimilate large quantities of silica and markedly modify the flux rates of silica in lakes and streams.
   b. Utilization of silica in the trophogenic zone of lakes by diatoms reduces the epilimnetic concentrations (Fig. 14-20) and induces, along with other factors, a seasonal succession of diatom species that have different assimilation efficiencies for Si and growth rates.
   c. When the concentration of silica is reduced below about 0.5 mg liter^{-1}, many diatom species cannot compete effectively with nonsiliceous algae, and their growth rates decline until silica supplies are renewed, usually during autumnal circulation.
   d. Eutrophicational nutrient enrichments of P and N often lead to increased diatom production and removal of Si by sedimenting diatoms at rates faster than renewed by inputs. Diatoms are gradually outcompeted and replaced by algae and cyanobacteria not dependent on Si availability.

XV. Summary

The algae of the open water of lakes and large streams, the ***phytoplankton,*** consist of a diverse assemblage of nearly all major taxonomic groups. Many of these forms have different physiological requirements and vary in response to physical and chemical parameters such as light, temperature, and nutrient regimen. The photosynthetic cyanobacteria, formerly the blue–green algae, constitute a major component of the

photoplankton and are discussed throughout this treatment as functionally similar to the planktonic algae. Despite these diversities, both taxonomic and physiological, many algal and cyanobacterial species coexist in the same water volume. However, dominant genera in algal groupings change not only spatially (vertically and horizontally within a lake) but seasonally, as physical, chemical, and biological conditions change in the water body. A general pattern of seasonal succession of phytoplankton has been correlated with environmental factors of many lakes, although the precise reasons for many of these changes are not well known.

Phytoplankton ecology has been one of the most popular areas of aquatic ecology in recent decades and many inroads have been made in understanding algal requirements for light, temperature, and nutrients, buoyancy regulation, competition, productivity, and the effects of predation and parasitism on phytoplankton. However, large voids still exist in our knowledge of the many complex mechanisms that result in the wide array of planktonic algal communities observed worldwide. Further investigations, particularly in the areas of algal–microbial, algal–algal, and algal–herbivore interactions, are greatly needed.

I. COMPOSITION OF THE ALGAE OF PHYTOPLANKTONIC ASSOCIATIONS

A. Morphological and Physiological Characteristics

Before summarizing the algal and cyanobacterial associations and population dynamics of phytoplanktonic communities, a few of the major morphological and physiological characteristics of the primary algal groups should be emphasized. The systematics of algae comprising the phytoplankton are treated well in a number of detailed works but are continually being revised and improved (e.g., Medlin *et al.*, 1993, 1997; Sorhannus *et al.*, 1995; van der Hoek *et al.*, 1995). In this functional physiological and ecological treatment, it is defeating to become engrossed in discussion of whether certain groups are truly algae in a strict sense. In many respects, the cyanobacteria (Myxophyceae) are physiologically similar to the algae. Many motile and colonial flagellates are classified as Protozoa on the basis of certain morphological and reproductive characteristics. The important characteristic, however, is that autotrophic photosynthesis is the primary mode of nutrition and results in a major synthesis of new organic matter. Therefore, these photoautotrophic microbiota are treated collectively with the true algae of the phytoplankton.

The emphasis in the following synthesis is functional, from the standpoint of interactions of physiological characteristics with environmental variables and the effects of these interactions on growth, primary productivity, and resultant population successions within communities and other trophic levels.

B. Pigments

A primary algal characteristic is the presence of photosynthetic pigments—the chlorophylls, carotenoids, and biliproteins. Chlorophyll *a* is the primary photosynthetic pigment of all oxygen-evolving photosynthetic organisms and is present in all algae and cyanobacteria (Table 15-1) and photosynthetic organisms other than the photosynthetic sulfur bacteria (discussed separately in Chap. 14). Chlorophyll *a* has two *in vitro* absorption bands, as discussed on page 67, in the red-light region at 660–665 nm and at lower wavelengths near 430 nm.

Chlorophyll *b*, although common in higher plants, is found only in the green algae, euglenophytes, and certain minor groups (Table 15-1). Chlorophyll *b* is a light-gathering pigment that transfers absorbed light energy to chlorophyll *a* for primary photochemistry (reviewed in Govindjee and Brown, 1974). Maximum absorption bands are approximately 645 nm and 435 nm. Chlorophyll *c*, consisting of three spectrally distinct components, is probably an accessory pigment to photosystem II. Maximum extraction absorption bands are at about 630–635 nm, and in the dominant blue portion of the spectrum at about 583–586 nm and 444–452 nm (Meeks, 1974). Chlorophyll *d*, of no known function, is a minor pigment component found only in certain red algae. A fifth chlorophyll (*e*) has been isolated from a xanthophycean alga, but whether it exists *in vivo* is uncertain (Strain, 1951).

Among the many carotenoids of algae, the carotenes are linear unsaturated hydrocarbons, and the xanthophylls are oxygenated derivatives of carotenes (Goodwin, 1974). As is the case with chlorophyll *b*, light energy absorbed by carotenoids and biliproteins is transferred to chlorophyll *a*, leading to fluorescence and excitation of chlorophyll *a* molecules. β-carotene is the most widely distributed of the carotenes and is replaced by α-carotene only in certain green algae and in the Cryptophyceae. The biliproteins are water-soluble, pigment–protein complexes occurring in the cyanobacteria and, to a lesser extent, in certain cryptophytes and red algae.

C. Cyanobacteria

The cyanobacteria (blue–green algae) have been among the most studied of all planktonic groups. Previously classified as algae in the division Cyanophyta [*cyano* (Greek) = blue–green] or Myxophyceae [*myx* (Greek) = slime], these organisms are true bacteria

[a] From Morris (1967), Meeks (1974), Goodwin (1974), and van den Hoek *et al.* (1995) from numerous sources.
[b] These chromoproteins consist of distinctly different types in the groups in which they occur. Differentiation is based on their absorption spectra (cf. Goodwin, 1974).

with a simple prokaryotic cell structure. Prokaryotic cells lack certain membranous structures, including a nuclear membrane, mitochondria, and chloroplasts. The chloroplasts of other algae and plants originated from cyanobacteria by endosymbiosis. The cells do contain cellular inclusions, which in some cases assume similar functions to eukaryotic organelles such as pigment-bearing lamellae, a plasma membrane, and a nuclear region containing chromosomal material. The cyanobacteria, like most other bacteria, have murein in the cell wall, reproduce by binary fission, and do not divide by mitosis as algae and higher organisms do. However, the cyanobacteria are distinguished from other bacteria by the presence of chlorophyll *a*, which is common to chloroplasts of eukaryotic algae and higher plants and different structurally from bacteriochlorophyll. Cyanobacteria are also able to use water as an electron donor in photosynthesis, which is evolutionarily more advanced than bacterial photosynthesis. Therefore, cyanobacteria possess the enzymatic and pigment capability to photosynthesize under oxygenated conditions as higher plants. In effect, cyanobacteria are structurally and physiologically like bacteria, but they photosynthesize functionally like plants in aquatic systems.

Cyanobacteria occur in unicellular, filamentous, and colonial forms, and most are enclosed in mucilaginous sheaths either individually or in colonies. Most planktonic cyanobacteria consist of members of the coccoid family Chroococcaceae (e.g., *Anacystis* = *Microcystis, Gomphosphaeria* = *Coelosphaerium,* and *Coccochloris*) and filamentous families (e.g., *Planktothrix, Limnothrix,* and *Tychonema,* all formerly classified within the genus *Oscillatoria*), Nostocaceae

(e.g., *Anabaena, Aphanizomenon,* and *Nodularia*), and Rivulariaceae (e.g., *Gloeotrichia*).

In filamentous cyanobacteria, cells are arranged end to end to form long trichomes. Trichomes are usually contained within a mucilaginous sheath. Although vegetative reproduction by fragmentation of trichomes is common, some cells are differentiated and specifically involved in reproduction and perennation. Akinetes (nonmotile, resistant cells) form in a number of species as enlarged, thick-walled cells that accumulate proteinaceous reserves in the form of cyanophycin granules (cf. Fogg *et al.,* 1973; Stanier and Cohen-Bazire, 1977; Adams and Carr, 1981). Under favorable conditions, akinetes germinate directly into a trichome or into hormogonia. Hormogonia are short, slightly modified pieces of trichome that fragment from the parent trichome and move away by means of gliding motions to develop into a new filament. In a few species, hormogonia develop within the parent sheath as multiple trichomes. A few other spore structures develop in species that do not form hormogonia; in these species, development continues without resting stages.

Heterocysts are differentiated cells unique to cyanobacteria. Heterocysts can occur in many filamentous species but are absent from those in the Oscillatoriaceae; they are the major sites of nitrogen fixation (Chap. 12). Heterocysts develop from vegetative cells, which form a thick envelope over the cell wall except for a pore at each pole where the heterocyst is connected to adjacent vegetative cells. The envelope provides a barrier to diffusion of gases into the cell. It is through this pore that the plasma membranes are adjoined and the exchange of metabolic products occurs. In contrast to vegetative cells, heterocysts lack phycobilins, which are the primary light absorbers in cyanobacteria, lack an oxygen-evolving photosystem, and show higher reducing activity. The rate of oxygen diffusion into the heterocyst from outside is reduced by waxy layers in the envelope, though sufficient N_2 gets through to support nitrogen fixation (Walsby, 1985). Therefore, the internal environment of the heterocyst is ideal for nitrogen fixation, since the nitrogenase enzyme is inactivated by oxygen. Organic carbon from adjacent cells is transferred into the heterocyst and used as an energy source in nitrogen fixation; reduced nitrogen is, in turn, transferred out of the heterocyst and into vegetative cells (Wolk, 1968, 1973; Adams and Carr, 1981). The interaction of vegetative cells and heterocysts is an example of structural separation of metabolic processes (photosynthesis and nitrogen fixation) in a relatively primitive organism. Nitrogen fixation can also occur in some nonheterocystous cyanobacteria (e.g., *Gloeocapsa*). In this case, photosynthesis and nitrogen fixation may be separated temporally rather than structurally (Gallon *et al.,* 1974). Recent studies indicate that cyanobacteria have circadian rhythms and that the capacity for photosynthesis and nitrogen fixation is regulated by a biological clock, reset by light/dark cues, at the level of gene expression (Golden *et al.,* 1997).

D. Green Algae

The Chlorophyta are an extremely large and morphologically diverse group of algae that is almost totally freshwater in distribution. Most planktonic green algae belong to the orders Volvocales (e.g., *Chlamydomonas, Sphaerocystis, Eudorina,* and *Volvox*) and Chlorococcales (e.g., *Scenedesmus, Ankistrodesmus, Selenastrum,* and *Pediastrum*). Many members are flagellated (2 or 4, rarely more) at least in the gamete stages; in the Zygnematales and the desmids (Conjugales or Desmidiales), the gametes are amoeboid.

Asexual reproduction by vegetative division is common to most of the green algae but is lacking in most of the Chlorococcales and Siphonales. Cell division very often is synchronized so that nuclear and cell division occurs at night. Cell division in colonial species results in enlargement of the colony; new colonies are formed by fragmentation of the colony. Among filamentous species, such as *Spirogyra,* fragmentation of the filament is common. Vegetative formation of single or multiple zoospores within a cell is also common. When liberated from the parent cell, the flagellated zoospores are actively motile and positively phototactic for varying periods of time before losing the flagellae and entering a resting spore stage.

Sexual reproduction in the green algae is diverse. In the simplest case of isogamy, the flagellated male and female gametes are morphologically similar in size and structure. In anisogamy, the flagellated female gamete is larger than the male gamete. Among more specialized algae, oogamy is common, in which union occurs between a large, nonflagellated female gamete and a small, flagellated male antherozoid. Some green algae are sexually monoecious (gametes are derived from the same cell), and others are dioecious (male and female gametes are derived from different cells).

Whereas the planktonic Volvocales and Chlorococcales are ubiquitous in distribution among waters of differing salinity within the normal limnological range, the distribution of most species of desmids of the Conjugales is limited to low concentrations of the divalent cations calcium and magnesium. Although not totally restricted to waters of low salinity (Coesel, 1983; Reif *et al.,* 1983), the desmids are most common and the species diversity is greatest in unproductive soft waters draining land forms developed in granitic or other

igneous rocks and especially in waters with a high content of dissolved organic matter. Their abundance and diversity are often greatest in bog waters that drain through deposits of the moss *Sphagnum.* Many desmids are distributed widely, but as a whole they are less cosmopolitan than most unicellular algae (cf. Hutchinson, 1967; Brook, 1981).

E. Yellow–Green Algae

The Xanthophyceae are unicellular, colonial, or filamentous algae that are characterized by conspicuous amounts of carotenoids in comparison to chlorophylls that result in their predominantly yellow–green coloration (Table 15-1). Nearly all of the motile cells possess two flagella, one of which is smooth and longer than the other, "hairy" flagellum (hence the older name, Heterokontae; the Heterokontophyta is now a large phylum that includes many major planktonic algal familes; cf. van der Hoek *et al.,* 1995). A cell wall is often absent; when present, it contains large amounts of pectin and in many species may be silicified. Asexual reproduction is usually by fission, with the formation of zoospores. Sexual reproduction is poorly understood in this group but is most often isogamous.

Most xanthophycean algae are associated with substrata, and many are epiphytic on larger aquatic plants. A few members are planktonic and include common genera such as *Chlorobotrys, Gloeobotrys,* and *Gloeochloris.*

F. Golden-Brown Algae

The chromatophores of the Chrysophyceae often yield a distinctive golden-brown coloration because of the dominance of β-carotene and specific xanthophyll carotenoids in addition to chlorophyll *a.* Most of the chrysophycean algae are unicellular; a few are colonial; and they are rarely filamentous. Flagellation is variable; most often cells are uniflagellate, but some species possess two flagella, usually of equal length. Many species lack a cell wall and are bounded only by a cytoplasmic membrane; others possess a cell surface covered by delicate siliceous or calcareous plates or scales. Vegetative reproduction by longitudinal cell division is most common, especially among the motile unicellular species. Although it has rarely been observed, sexual reproduction is isogamous: The resulting cystlike zygote undergoes reductive division under favorable conditions.

Numerous chrysophycean algae form important components of the phytoplankton. The unicellular species with a single flagellum (e.g., *Chromulina, Chrysococcus,* and *Mallomonas*) are usually very small algal representatives of the nanoplankton (Table 15-2).

TABLE 15-2 Size Classification of Plankton[a]

Term	*Size ranges (μm)*
Femtoplankton	0.01–0.2
Ultraplankton	0.2–20
Picoplankton	0.2–2.0
Nanoplankton	2.0–20
Microplankton	20–200
Mesoplankton	200–20,000

[a] Based on evaluations of Sieburth *et al.* (1978) and the reviews of Hutchinson (1967) and Fogg (1991).

Larger colonial forms such as *Synura, Chrysosphaerella, Uroglena,* and particularly *Dinobryon* are widely distributed and may become major components of the phytoplankton under certain environmental conditions, particularly in temperate, oligotrophic lakes (Hutchinson, 1967). The conspicuous development of populations of certain species of *Dinobryon* and *Uroglena* in lakes of very low phosphorus concentrations (cf. earlier discussion, p. 267) may be related to their abilities to take up phosphate effectively at extremely low ambient concentrations (cf. Lehman, 1976). In contrast, other species of *Dinobryon* and *Synura* have high phosphorus requirements. The phytoplankton of many oligotrophic lakes are dominated throughout the year by chrysophycean algae and secondarily by cryptophytes (e.g., Siver and Chock, 1986; Stewart and Wetzel, 1986). The nanoplanktonic flagellates of the Chrysophyceae and Cryptophyceae totally dominate the phytoplanktonic during the short growing season (60–100 days) of the millions of thermokarst ponds that dominate the northern tundra of Alaska, Canada, and Russia (Sheath, 1986). The chrysophytes are particularly well adapted to low temperatures and light levels (Roijackers, 1986; Sandgren, 1986). Several species of chrysophycean algae, particularly *Dinobryon,* supplement photosynthesis with phagotrophy. These algae can obtain an appreciable fraction of their energy and nutrients by ingesting bacteria (Bird and Kalff, 1986). Although the rates of water clearance are small (e.g., 0.00014 ml day^{-1}), large populations of *Dinobryon* can collectively clear water of bacteria at rates that compete effectively with those of ciliates, rotifers, and microcrustaceans.

G. Diatoms

A most important group of algae of the phytoplankton are the diatoms (Bacillariophyceae), even though most species are sessile and associated with

littoral substrata. Their primary characteristic, silicified cell walls, has been discussed in the preceding chapter. Both unicellular and colonial forms are common among the diatoms. The group is commonly divided into the centric diatoms (Centrales), which have radial symmetry, and the pennate diatoms (Pennales), which exhibit essentially bilateral symmetry. The cell wall or *frustule* of diatoms consists of two lidlike valves, one of which fits within the other; the overlapping area of the valves is connected by bands that constitute the girdle. The beautiful structures of the siliceous cell walls of diatoms are complex and used as taxonomic characteristics.

The valves of pennate diatoms exhibit various areas of cell thickenings and dilations. In some species a slit, termed a *raphe,* traverses all or part of the cell wall; in others, a depression in the axial areas of the cell wall, termed a *pseudoraphe,* is found. The four major groups[1] of pennate diatoms are differentiated on the basis of these structures: (a) the Araphidineae, which possess a pseudoraphe (e.g., *Asterionella, Diatoma, Fragilaria,* and *Synedra)*; (b) the Raphidioidineae, in which a rudimentary raphe occurs at the cell ends (e.g., *Actinelia,* and *Eunotia*); (c) the Monoraphidineae, which have a raphe on one valve and a pseudoraphe on the other (e.g., *Achnanthes,* and *Cocconeis*); and (d) the Biraphidineae, in which the raphe occurs on both valves (e.g., *Amphora, Cymbella, Gomphonema, Navicula, Nitzschia, Pinnularia,* and *Surirella*). These divisions are of more than taxonomic interest since distinct nutritional requirements favor the growth of one group over another.

Vegetative reproduction by cell division, usually at night, is the most common mode of multiplication (cf. Werner, 1977). Sexual reproduction occurs periodically when the cells reach a minimum critical size (30–40% of maximum size) through repeated cell division in the course of asexual reproduction (Edlund and Stoermer, 1997). Also required for sexual induction are a set of correct environmental conditions, often species-specific, that may include combinations of light, temperature, nutrients, trace metals, organic growth factors, and osmolarity. After sexual reproduction, size is restored. Amoeboid gametes occur in isogamous reproduction in the Pennales, whereas in the Centrales reproduction is oogamous with flagellated spermatozoids. After fusion of the gametes, an auxospore develops and divides; some of the resulting cells give rise to vegetative cells that are of the largest dimensions of the species.

[1]These groups are differentiated on the basis of morphology but are not necessarily monophyletic (e.g., Medlin *et al.,* 1993; Sorhannus *et al.,* 1995).

H. Cryptomonads

Most of the cryptophycean algae are naked, unicellular, and motile. This class is very small and most of the planktonic members belong to the Cryptomonadineae (e.g., *Cryptomonas, Rhodomonas,* and *Chroomonas*). All members are small and not a great deal is known about their ecology or physiology. The cryptomonads usually are flattened dorsoventrally, with an anterior invagination that bears two equal or subequal flagella. The one or usually two chromatophores contain a variety of pigments (Table 15-1) that can yield a spectrum of apparent colors, including olive green, blue, red, or brown. Reproduction is by longitudinal division; sexual reproduction is unknown in the group.

Cryptomonad algae and other cryptomonadlike microflagellates occur in almost all lakes, regardless of trophic state (Stewart and Wetzel, 1986). The cryptomonads are typically present in low numbers during most of the year but commonly increase intermittently (e.g., Ilmavirta, 1983; Taylor and Wetzel, 1984; Dokulil, 1988). Such increases in abundance often follow the demise of previously dominant "bloom" algal populations. Characteristics of the cryptomonads and other microflagellates include intermittent numerical dominance, high nutritional quality, short turnover times, ability to grow and reproduce at low intensities of light, and effective rapid pulse timing of growth. In combination, these characteristics implicate the cryptomonads and other photosynthetic microflagellates as an ecologically significant internal stabilizing component of planktonic communities.

I. Dinoflagellates

The dinoflagellates (Dinophyceae of the Pyrrophyta) are unicellular flagellated algae, many of which are motile. Although a few species are naked or without a cell wall (e.g., *Gymnodinium* of the Gymnodiniales), most develop a conspicuous cell wall that often is sculptured and bears large spines and elaborate cell-wall processes (the Peridiniales, e.g., *Ceratium, Glenodinium, Peridinium).* In both naked and armored types, the cell surface has transverse and longitudinal furrows that connect and contain the flagella, whose movements create water currents providing for weak locomotion and the disrupting of chemical gradients at the cell surface. Although sexual reproduction occurs, asexual reproduction by the formation of aplanospores (in which a motile phase is omitted) predominates. These asexual resting stages or cysts can undergo considerable periods of diapause (Loeblich and Loeblich, 1984). In the large *Ceratium,* for example, the autumn

decline of summer populations in temperate regions results in the production of overwintering cysts. Emergence from benthic cysts can result in an exponential increase in the planktonic cells in the ensuing spring and summer (Heaney *et al.*, 1983; Sako *et al.*, 1985; Pollingher *et al.*, 1993). The distribution of dinoflagellates in relation to major chemical characteristics shows that, while some species are widely tolerant and ubiquitous, especially among species of *Ceratium* and *Peridinium*, most dinoflagellate species have restricted ranges with respect to calcium, pH, dissolved organic matter, and temperature (Taylor and Pollingher, 1987). The relatively large body size (ca. 400 μm) makes these algae relatively inedible to most grazing organisms.

Although many zooplankton change size and form seasonally (Chap. 16), only a few phytoplankton undergo seasonal polymorphism or cyclomorphosis. One example of phytoplanktonic cyclomorphosis is the lengthening of cellular extensions or horns in the dinoflagellate *Ceratium* as temperatures increase from spring into midsummer (Hutchinson, 1967). In *Ceratium*, the conspicuous separation of the cell wall by the transverse furrow into the upper part (epitheca) and lower part (hypotheca) is accentuated further by the development of horns. The epitheca always has one horn; the hypotheca usually has 1–3 horns. As the water warms, the cells of populations exhibit an increase in the length of the horns, a decrease in the width and general size of the cell, and a lessening of the angle of divergence of the hypothecal horns (Fig. 15-1). In midsummer, with even warmer temperatures, the development of a short, fourth horn is common. Field and experimental evidence indicates that these changes are induced primarily by increasing water temperatures. Some experimental evidence points to the fact that the sinking rate is reduced appreciably in less viscous warmer water by the reduced cell dimensions, increased divergence of the horns, and the development of the fourth horn. Presumably, these changes are of adaptive significance to *Ceratium* in that they reduce the rate of sinking out of the photic zone.

J. Euglenoids

Although the euglenoid algae (Euglenophyceae) are a relatively large and diverse group, few species are truly planktonic. Nonetheless, when conditions are favorable, the euglenoids can develop in great profusion. Almost all euglenoids are unicellular, lack a distinct cell wall, and possess one, two, or three flagella that arise from an invagination in the cell membrane. Reproduction occurs by longitudinal division of the motile cell; sexual reproduction has not yet been substantiated.

Although some euglenoids are unpigmented and phagotrophic (able to ingest solid particles) and are best treated as Protozoa, most are photosynthetic and facultatively heterotrophic. Even when phagotrophy constitutes the dominant mode of carbon assimilation among certain nonpigmented members of the Dinophyceae, Chrysophyceae, and especially the Euglenophyceae, none of these algae depends solely on phagotrophy for their major carbon requirements (Droop, 1974). Nutrition is supplemented by the uptake of dissolved organic compounds. Ammonia and dissolved organic nitrogen compounds are the dominant sources of nitrogen among most euglenoid algae.

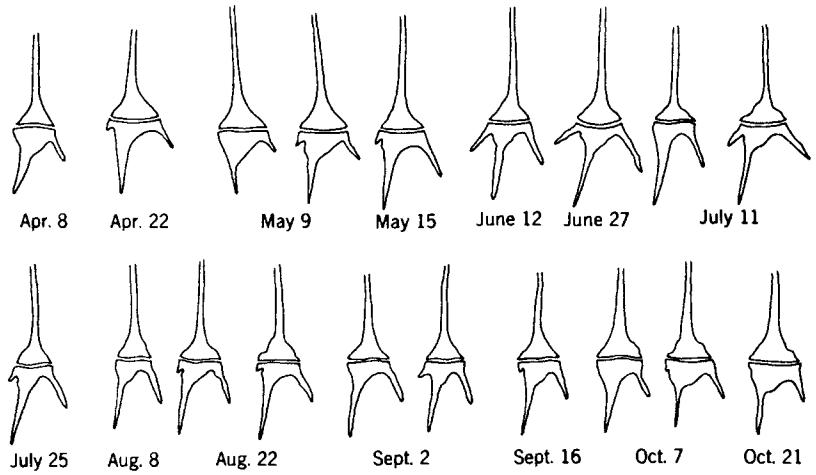

FIGURE 15-1 Seasonal polymorphism in *Ceratium hirundinella* in Kirchbergteich, Darmstadt, Germany. (From Hutchinson, G. E.: *A Treatise on Limnology*, Vol. 2, New York, John Wiley & Sons, Inc., 1967, after work of List.)

Their development in the phytoplankton occurs most often in seasons, strata, or lake systems in which concentrations of ammonia and especially dissolved organic matter are high. For example, detailed seasonal analyses of the phytoplanktonic populations at weekly intervals at each meter of depth for 16 months in hardwater Lawrence Lake in southwestern Michigan showed euglenoid algae developing for only a brief 2-week period immediately prior to autumnal turnover and in a small stratum, 1 m above the deep sediments, that was anoxic during the last 2 months of summer stratification (Stewart and Wetzel, 1986; Taylor and Wetzel, 1988). However, euglenoids are found most often in shallow water rich in organic matter, such as organically polluted lakes (e.g., Yusoff and Patimah, 1994) and farm ponds.

K. Brown and Red Algae

The brown algae (Phaeophyta) are mostly filamentous or thalloid algae, which, as a group, are almost exclusively marine. Only a few genera of this large, primitive group are represented in fresh water; those that are found in fresh water are attached to substrata, such as rocks. No species is planktonic.

The red algae (Rhodophyta) are also very sparsely represented in fresh water, and none is planktonic. A majority of the genera occurring in fresh water are found only there. The thalloid or filamentous species (e.g., *Batrachospermum)* are nearly all restricted to fast-flowing streams of well-oxygenated, cool waters.

II. THE IMPORTANCE OF SIZE: SMALL IS BEAUTIFUL AND PRODUCTIVE

An enormous variation in size is found among the phytoplankton. Early separations and classifications were based largely upon filtering devices, such as fine nets, that were available for capture of the phytoplankton[2]. A more functional basis now underlies size groupings (Table 15-2), in which major environmental parameters controlling growth and succession are coupled to size.

Minute (0.2–2.0 μm) algal and cyanobacterial picoplankton were found to be abundantly and ubiquitously distributed in freshwater ecosystems (Stockner and Antia, 1986; Stockner, 1991). These ***picophytoplankton*** consist mainly of small coccoid cyanobacteria of the *Synechococcus* type, commonly of a size less than 1 μm. These prokaryotes often exceed 300,000 cells ml^{-1} and occupy diverse habitats over a wide range of temperatures, light, salinity, and nutrients. Although less abundant than cyanobacterial picophytoplankton, the eukaryotic *Chlorella*-like picophytoplankton tend to be larger (1.2–2.0 μm) and can dominate in certain extreme habitats, such as acidic or humic-stained dystrophic waters (e.g., Søndergaard, 1991). Colonial picophytoplankton are found in oligotrophic lakes but are likely aggregations of chroococcoid cyanobacteria such as *Synechococcus.*

When the size of planktonic organisms falls below about 20 μm (the ***ultraplankton,*** see Table 15-2), the transfer of materials to and from cells is almost entirely by molecular diffusion rather than by the eddy diffusion of turbulence (Fogg, 1991, 1995). The foundational theoretical basis for this size boundary of ca. 20 μm is treated in detail by Karp-Boss *et al.* (1996). A cell radius near 20 μm is needed before sinking or swimming can be expected to increase the flux of nutrients. Macroturbulence is important, however, for moving water parcels containing the ultraplanktonic communities into the light field of the euphotic zone. The ultraphytoplankton are simple, unicellular in form, and have generation times in hours that are similar to those generation times of protistian flagellate predators (Table 15-3). The exchanges by molecular diffusion that small size makes possible, however, allows the establishment of a self-contained, dynamic community of phototrophs, viruses, heterotrophic bacteria, phagotrophic flagellates, and ciliates, in which materials are rapidly cycled with little loss by sedimentation or transfer to higher trophic levels. In such an equilibrium system, population densities are determined by internal dynamics rather than by nutrient inputs.

The larger phytoplankton (***microplankton*** of 20–200 μm; Table 15-2) are not vulnerable to control by flagellates but are inefficient in nutrient uptake and therefore develop prolifically when nutrient concentrations are relatively high. The microphytoplankton are also vulnerable to sedimentation from the photic zone. The availability of sufficient nutrients and transport to light are strongly coupled to macroturbulence (Table 15-3). Water movements are highly variable and, as a result, microphytoplankton must be able to grow and reproduce rapidly when conditions are conducive

[2]Terms were introduced long ago for small plankton components (***bioseston***) of the total particulate material (***seston***). For example, formerly *nanoplankton* referred to those plankton passing through older plankton nets of a mesh size of about 50 to 60 μm. The basis for the separations and complex terminology for separations by size are discussed in detail in, for example, Strickland (1960), Hutchinson (1967), and Sicko-Goad and Stoermer (1984). Recent studies have demonstrated the major importance of very small phytoplankton (see Table 15-2). As a result, plankton nets are inappropriate for even qualitative studies of phytoplankton and some, but by no means all, of the early studies of phytoplankton are applicable only to analyses of the largest forms.

TABLE 15-3 Comparison of Functional Characteristics of Ultraphytoplankton and Microphytoplankton[a]

Characteristic	*Ultraplankton*	*Microplankton*
Size	0.2–20 μm	20–200 μm
Main physical process determining nutrient supply	Molecular diffusion	Turbulence, motion relative to water
Form	Simple, unicellular	Elaborate, often colonial
Gas vacuoles in cyanobacteria	Absent	Present
Generation times	Hours	Days
Relative generation time of predators	Equal	Much longer
Variations in natural population densities	$10–10^2$	$10^3–10^5$

[a] After Fogg (1991, 1995).

(Reynolds, 1984; Fogg, 1991). A cell size of 60 μm or greater is needed to experience substantial gain from macroturbulence (Karp-Boss *et al.*, 1996). Equilibrium is never achieved within the microplanktonic community.

The microphytoplankton separate into two broad types of ecological strategies. Larger algae, such as many of the diatoms, are nonmotile and depend upon mixing to remain poised in the photic zone (Fogg, 1991). Another type, typified by the dinoflagellates and gas-vacuolate cyanobacteria, competes most effectively under relatively quiescent, stable water conditions where motility or buoyancy control allows positioning to optimize access to light and nutrients.

The importance of size relationships among algae and environmental parameters has been emphasized for some time (e.g., Margalef, 1955, 1959). Clearly, there is a general preponderance of small algal species in the phytoplankton of oligotrophic lakes, and the size of dominant algae often increases in more fertile lakes. A number of analyses of the photosynthetic productivity of phytoplankton in which the relative contributions of differently sized algae were determined show that a greater proportion of the total productivity is by smaller forms in less productive waters (Rodhe *et al.*, 1958; Goldman and Wetzel, 1963; Wetzel, 1964, 1965a; Wehr, 1991; others). The contributions of the smaller algae also shifted seasonally; the ultraplankton (<20 μm) can often dominate the productivity, particularly during the winter and spring. More recent studies have examined these relationships in greater detail and generally confirm these results. For example, the picophytoplankton (0.2–2.0 μm) often contributed >60% of the total algal chlorophyll *a* and over 10% of the primary productivity in the trophogenic zone of a mesotrophic upland lake in Wales (Happey-Wood, 1991; Happey-Wood and Lund, 1994) and some 50% of the total primary productivity in Lake Superior (Fahnenstiel *et al.*, 1986).

An inverse relationship is commonly found between total algal biomass and productivity per unit biomass in the phytoplankton. Communities dominated by populations of species with small cells usually have a greater primary productivity per unit algal biomass than communities dominated by populations of large algal species (Findenegg, 1965). Microautoradiographic analyses demonstrated that renewal time (generation time) is related inversely to cell size; cells that are small with a low carbon content tended to have shorter renewal times and were more metabolically active than larger algae (Stull *et al.*, 1973; Amblard, 1988). Some small species of relatively minor contribution to the instantaneous algal community biomass could therefore turn over rapidly and contribute more to the total primary productivity than larger species. The specific rates of population increase for picophytoplankton were found to be low in nature, however, with apparent generation times of several days (Happey-Wood, 1991). Hence, even though the autotrophic picoplankton are ubiquitous, caution is needed to avoid overestimating their contributions to total production.

III. PHYTOPLANKTONIC COMMUNITIES

An outstanding feature of phytoplanktonic communities in lacustrine habitats is the coexistence of a number of algal species. In some cases, one species is found in much greater abundance than others; more often, two or more algal species are codominant in the

phytoplanktonic assemblage. A large number of rarer species can always be found among the dominant or subdominant algae. The algae co-occur even though each species has a specific niche based on its physiological requirements and the constraints of the environment. Theoretically, niche overlap can lead to competitive exclusion and should result in dominance by a single species (see Chap. 8). This problem has been formally referred to as the "paradox of the plankton" (Hutchinson, 1961): An apparent multispecific, rather than unispecific, equilibrium occurs in what seem to be physically uniform conditions of the turbulent open water of lakes.

A number of explanations have been advanced to account for species diversity in phytoplanktonic communities that is much higher than would be anticipated from theory and mathematical derivations. First, in order for the relatively slow process of competitive exclusion to occur, the physical conditions must be uniform for a sufficient period of time. If environmental conditions change rapidly, the advantages gained by one species that is a better competitor may not exist long enough to result in the competitive exclusion of other species. Stated another way, differences in the efficiencies of resource utilization among species may be too small for competitive exclusion to occur before conditions change.

Second, competition can be negated partially if commensalism and symbiotic relations exist among species. As discussed later, a number of organic compounds released extracellularly by one alga can influence the metabolism of another species, although most of these compounds are inhibitory and antibiotic in nature. Also, most algae requiring exogenous sources of vitamin micronutrients are motile and small (Chrysophyceae, Cryptophyceae, Euglenophyceae, and Dinophyceae). The differences in organic micronutrient requirements and the release of the excess by species capable of their synthesis would serve as a means of encouraging mixed equilibrium populations.

Greater consumption of one species of algae than another can also promote coexistence, if the species being preyed upon has a much greater competitive advantage. Selective grazing, largely on the basis of algal size, by zooplankton is an important phenomenon and is discussed in some detail in Chap. 16.

Some species of algae are exclusively planktonic. As far as is known, their populations oscillate temporally in abundance, dominating for a period and then becoming extremely rare but nonetheless remaining planktonic (Hutchinson, 1964). Alternatively, some species enter resting stages and thereby leave the competitive arena for a period of time. Some of these species are quiescent in the littoral sediments and later develop sufficiently to form a significant component of the phytoplankton (e.g., Livingstone and Jaworski, 1980). Evidence for benthic algal populations in the littoral zone serving as a "seed" inoculum for some phytoplankton species is sparse (see Chap. 19), but when this occurs, phytoplankton species diversity is increased. This mode of opportunistic expansion into the pelagic region is certainly more common in shallow waters with extensive littoral development.

None of these mechanisms for explaining coexistence are mutually exclusive, and all factors probably operate simultaneously to a greater or lesser degree. Which one dominates at a particular time in a given body of water surely varies. The distribution of phytoplankton is not necessarily as uniform as the concepts of multispecies equilibrium would imply. For example, the phytoplankton of an alpine lake showed a high degree of patchiness for many species, which indicated that the rate of mixing was sufficiently slow relative to the reproductive rate of the algae and allowed communities of many different species to exist simultaneously (Richerson *et al.*, 1970). Under these hypothetical conditions of "contemporaneous disequilibrium," at any given time many patches of water exist in which one species has a competitive advantage relative to the others, but the patches are obliterated frequently enough to prevent exclusive occupation by a single species.

Among saline lakes, phytoplanktonic species diversity is inversely related to lake salinity (Hammer *et al.*, 1983; Blinn, 1993). In general, green algae and a few species of cyanobacteria are dominant; some diatoms are ubiquitous even in very saline lakes (>100 g salinity liter^{-1}).

A. Types of Algal Associations

A great deal of descriptive work has been devoted to the associations of algal species among differing fresh waters. Algae are extremely diverse, and many exhibit a very wide tolerance to environmental conditions found under natural limnological situations. Nonetheless, certain characteristic phytoplanktonic associations occur repeatedly in lakes of increasing nutrient enrichment. Some of the commonly observed major associations are set out in Table 15-4 based on the detailed discussion of Hutchinson (1967). Such categorizations are not very satisfactory because of the wide spectrum of intergradations often observed. Additionally, shifts occur seasonally from one type to another, especially among more productive waters. Even though such characterizations yield little insight into regulating environmental factors, they are useful from the standpoint of general correlations between qualitative and quantitative abundance of the algae and available nutrients.

TABLE 15-4 Characteristics of Common Major Associations of the Phytoplankton in Relation to Increasing Lake Fertility[a]

General lake trophy	*Water characteristics*	*Dominant algae*	*Other commonly occurring algae*
Oligotrophic	Slightly acidic; very low salinity	Desmids *Staurodesmus, Staurastrum*	*Sphaerocystis, Gloeocystis, Rhizosolenia, Tabellaria*
Oligotrophic	Neutral to slightly alkaline; nutrient-poor lakes	Diatoms, especially *Cyclotella* and *Tabellaria*	Some *Asterionella* spp., some *Melosira* spp., *Dinobryon*
Oligotrophic	Neutral to slightly alkaline; nutrient-poor lakes or more productive lakes at seasons of nutrient reduction	Chrysophycean algae, especially *Dinobryon*, some *Mallomonas*	Other chrysophyceans, (e.g., *Synura and Uroglena*); diatom *Tabellaria*
Oligotrophic	Neutral to slightly alkaline; nutrient-poor lakes	Chlorococcal *Oocystis* or chrysophycean *Botryococcus*	Oligotrophic diatoms
Oligotrophic	Neutral to slightly alkaline; generally nutrient poor; common in shallow Arctic lakes	Dinoflagellates, especially some *Peridinium* and *Ceratium* spp.	Small chrysophytes, cryptophytes, and diatoms
Mesotrophic or eutrophic	Neutral to slightly alkaline; annual dominants or in eutrophic lakes at certain seasons	Dinoflagellates, some *Peridinium* and *Ceratium* spp.	*Glenodinium* and many other algae
Eutrophic	Usually alkaline lakes with nutrient enrichment	Diatoms much of year, especially *Asterionella* spp., *Fragilaria crotonensis, Synedra, Stephanodiscus,* and *Melosira granulatea*	Many other algae, especially greens and cyanobacteria during warmer periods of year; desmids if dissolved organic matter is fairly high
Eutrophic	Usually alkaline; nutrient enriched; common in warmer periods of temperate takes or perennially in enriched tropical lakes	Cyanobacteria, especially *Anacystis* (= *Microcystis*), *Aphanizomenon, Anabaena*	Other cyanobacteria; euglenophytes if organically enriched or polluted

[a] After Hutchinson (1967).

A number of phytoplankton indices have been developed, particularly by Thunmark (1945) and by Nygaard (1955), in admirable attempts to quantify more precisely the relationships of rarely occurring and dominant algal species in relation to lake productivity. Their use is revived periodically with limited and varying degrees of success. The indices developed by Nygaard (1949) are based on the ratios or quotients of numbers of species within general groups, such as those of cyanobacteria to desmids, chlorococcalean algae to desmids, centric to pennate diatoms, and euglenophytes to cyanobacteria and green algae. His compound index was the ratio of all species of cyanobacteria and chlorococcalean green, centric diatoms, and euglenoid algae to the species of desmid algae. A general relationship was found between low compound index values of less than 1 and oligotrophic waters. Lowest values occurred in desmid-rich dystrophic lakes enriched by dissolved humic compounds. The values of the compound index increased in more productive waters and approached 50 in highly enriched eutrophic lakes.

Comparisons of these indices with more modern measurements of algal productivity show weak positive correlations, but exceptions are many. Great variations are found among different regions of the world and among lake districts. It is apparent that these indices, while having some value in determining species relationships, are much too superficial in physiological foundation to be of significant use in evaluating productivity among lakes or in elucidating causal mechanisms underlying the composite growth of algae.

IV. GROWTH CHARACTERISTICS OF PHYTOPLANKTON

Analyses and evaluations of seasonal and spatial growth characteristics of phytoplankton are sometimes difficult because of the array of environmental factors involved, the individual physiological properties of each algal species, and the magnitude of change that can occur in both. Clearly, the organisms and environment are both highly dynamic. Some important factors regulating growth and succession are (a) light and temperature; (b) buoyancy regulation, that is, means of remaining within the photic zone by alterations of sinking rates; (c) inorganic nutrient factors; (d) organic micronutrient factors and interactions of organic

compounds with inorganic nutrient availability; and (e) biological factors of competition for available resources and predation by other organisms. Each species of algae possesses a range of tolerance to these factors, and population growth proceeds most rapidly at some optimal combination of the interacting factors. The optimal combination of factors required for greatest growth and productivity is probably seldom achieved under most natural conditions. The competitive advantage of one species over another is relative and can change with changes in the physical and biotic conditions that affect growth.

A. Light and Temperature

The ecological effects of light and temperature on the photosynthesis and growth of algae are inseparable because of interrelationships between metabolism and light saturation. Qualitative factors of the selective attenuation of light energy with increasing depth have been discussed earlier (Chap. 5) in relation to photoreceptors and environmental parameters such as dissolved organic matter. Light intensity affects both the rate of photosynthesis and algal growth. Response to light intensity, however, is species-specific, and in many cases, a considerable degree of adaptation to changing light intensities occurs.

The intensity of light required to saturate algal photosynthesis commonly increases as water temperature increases (Fig. 15-2A). Below light saturation, photochemical reactions limit photosynthesis, and these reactions are relatively temperature-independent except at very low temperatures (<5°C) (Wilhelm, 1990). In the example given, exemplified by *Chlorella* (Fig. 15-2A), long-term adaptation to light intensities occurs mainly by changes in the amount of pigment per cell (Steemann Nielsen and Jørgensen, 1968a; Jørgensen, 1969). Cells adapted to high irradiance have a lower chlorophyll *a*

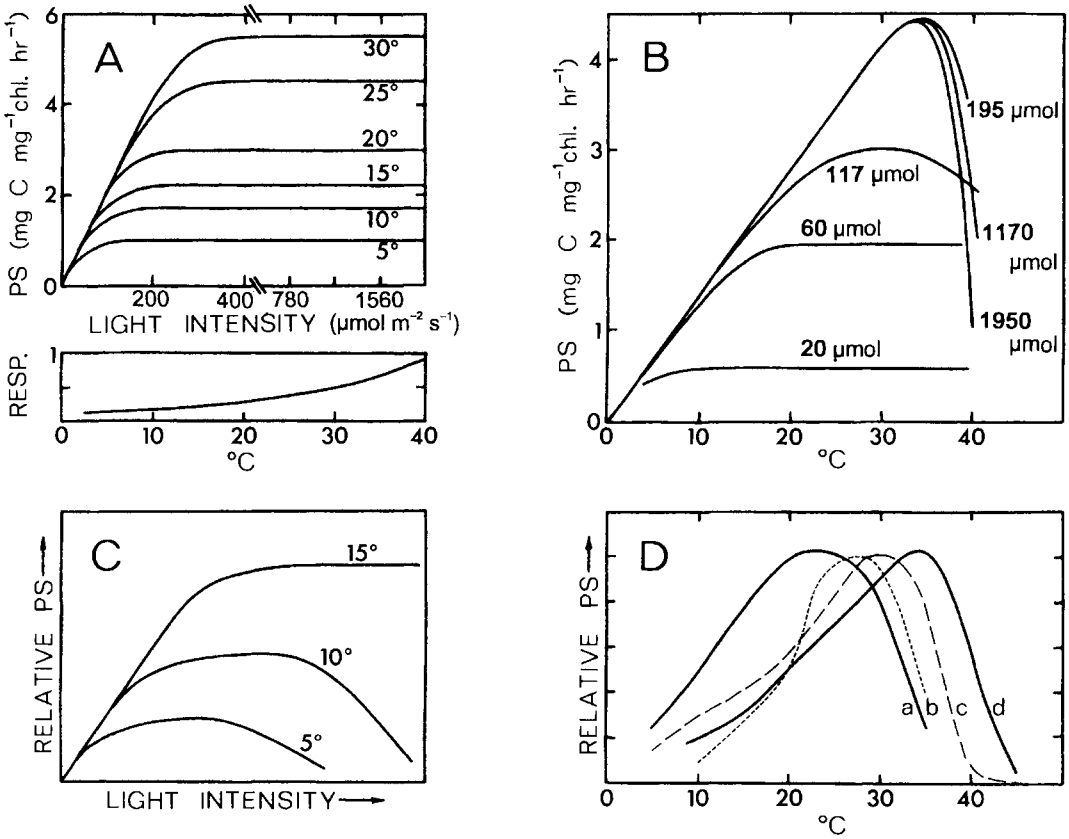

FIGURE 15-2 Interactions between photosynthesis (PS) and light intensity and temperature in plankton algae. (A) Generalized photosynthetic rates (mg C fixed per mg chlorophyll per hour) in relation to increasing light intensities and rates of respiration at different temperatures; (B) commonly observed increasing inhibitory effects of high light intensities that are accentuated at higher temperatures; (C) effects of high light intensity on photosynthetic rates of algae adapted to cold temperatures, as in arctic lakes; and (D) optimum temperatures for photosynthesis of different algae: a. *Synedra*, b. *Anabaena*, c. *Chlorella*, and d. *Scenedesmus*. (After data of Aruga, 1965.)

content per cell than those adapted to low irradiances. In *Chlorella pyrenoidosa,* for example, cells grown at ca. 20 μmol quanta m^{-2} s^{-1} have about 10 times more chlorophyll per cell than those grown at 410 μmol quanta m^{-2} s^{-1}. At high light intensities, but below light inhibition, the rate of photosynthesis per cell was not much greater than at low intensities.

In other algae, such as many diatoms, adaptation to changes in light intensity occurs by changing the light-saturated photosynthetic rate; the chlorophyll content of cells grown at low and high light intensities remains the same. The light-saturated rate of photosynthesis is generally much greater in algae grown under higher light intensities than it is for the same species grown under lower illuminance. Some algae are intermediate between the extreme types discussed here or exhibit a combination of photoadaptive strategies (cf. Prézelin and Sweeney, 1978).

Thus, the early sloping portion of light saturation curves (e.g., Fig. 15-2B) is largely a photochemical response of pigments to increasing irradiance. At light saturation, biochemical enzymatic reactions are rate-limiting and these are regulated by temperature (Davison, 1991). Some algae, such as *Skeletonema,* adapt to lower temperatures by increasing enzyme concentrations; consequently, the same rate of photosynthesis is achieved per given light intensity at high and low temperatures (Jørgensen, 1968; Priscu and Goldman, 1984). In *Skeletonema* adapted to low temperatures, the amount of protein per cell was twice as great at 7°C as at 20°C, and the size of cells was greater at low temperatures. Although rates of respiration are affected little by changes in light intensity, they do increase with increasing temperatures (Fig. 15-2A). Photosynthetic rates of planktonic algae adapted to light and temperature conditions of arctic regions can be nearly as high as those observed in temperate regions during summer under relatively high irradiance (e.g., Steemann Nielsen and Jørgensen, 1968b; Harrison and Platt, 1986).

Light of high intensities is detrimental to many algae and reduces rates of photosynthesis (Fig. 15-2B, C). Photoinhibition occurs when light exceeds physiological saturation and results in an excess of photons that are not dissipated by photosynthetic carbon fixation or by fluorescence or quenching reactions (Long *et al.,* 1994; Falkowski and Raven, 1997). The injury to enzymes and photosystem II can be repaired, and the resynthesis processes are more rapid at higher temperatures. Thus, the repair process is generally faster at higher temperatures, within the limnological range, where photosynthetic rates are higher.

Effects of high light intensities vary with the species in question, and some adaptation occurs with time. On bright days it is very common to observe a distinct depression in rates of *in situ* photosynthesis near the surface. The decrease in photosynthetic rates is associated with photooxidative destruction of enzymes, not chlorophyll (Steemann Nielsen, 1962; Steemann Nielsen and Jørgensen, 1962). The depression of enzymatic processes at high light intensities takes some time to occur. If exposure is of short duration (several hours), reactivation can occur and permanent damage is avoided. A depression of pigment concentrations often occurs at midday on bright days (e.g., Long *et al.,* 1994). Some algae, such as the diatom *Cyclotella,* adapt rapidly (<24 h) to changing light intensities and are not inhibited at very high intensities (Jørgensen, 1964). Other algae, such as natural populations of phytoplankton in Antarctic lakes exposed to continuous light in summer or in Arctic lakes after loss of ice cover in summer, are severely inhibited by high light intensities (Goldman *et al.,* 1963; Hobbie, 1964). In Arctic ponds, the phytoplankton exhibit increasing susceptibility to photoinhibition at cold (2–8°C) temperatures (Fig. 15-2C; Alexander *et al.,* 1980; Hobbie, personal communication). As water temperatures increase during the brief, 100-day period when the ponds are not frozen solid, adaptation to high illuminance occurs.

Ultraviolet light, which mediates a photooxidative alteration of the photosynthetic apparatus, is particularly harmful to planktonic algae. UV light can inactivate photosystem II, disrupt electron transport, and damage pigments, membranes, and thymidines of DNA (e.g., Gessner and Diehl, 1952; van Baalen, 1968; Karentz *et al.,* 1994; Falkowski and Raven, 1997). Detrimental effects are partly reversible if exposure is not too long, such as if plankton exposed to intensive UV irradiance at the immediate surface waters are circulated to deeper waters to which less UV penetrates (see Chap. 5). Resynthesis of damaged proteins and/or pigments can represent a net metabolic loss and affect long-term survival and cell fitness.

Interactions of light and temperature frequently result in one of several possible vertical profiles of photosynthesis in planktonic environments. In some cases, there is a zone of maximum photosynthetic rates at light saturation, which overlies a zone of near-exponential decline of rates with increasing depth (Fig. 15-3A). When light intensities exceed saturation and the photoinhibition threshold of the most productive species in the algal assemblage, a surface photoinhibition of the community photosynthesis often occurs (Fig. 15-3B). The depth at which maximum rates of photosynthesis occur varies with the transparency of the water, which is governed by the concentration of dissolved and particulate organic matter and abiotic turbidity. When densities of phytoplankton, that is, the

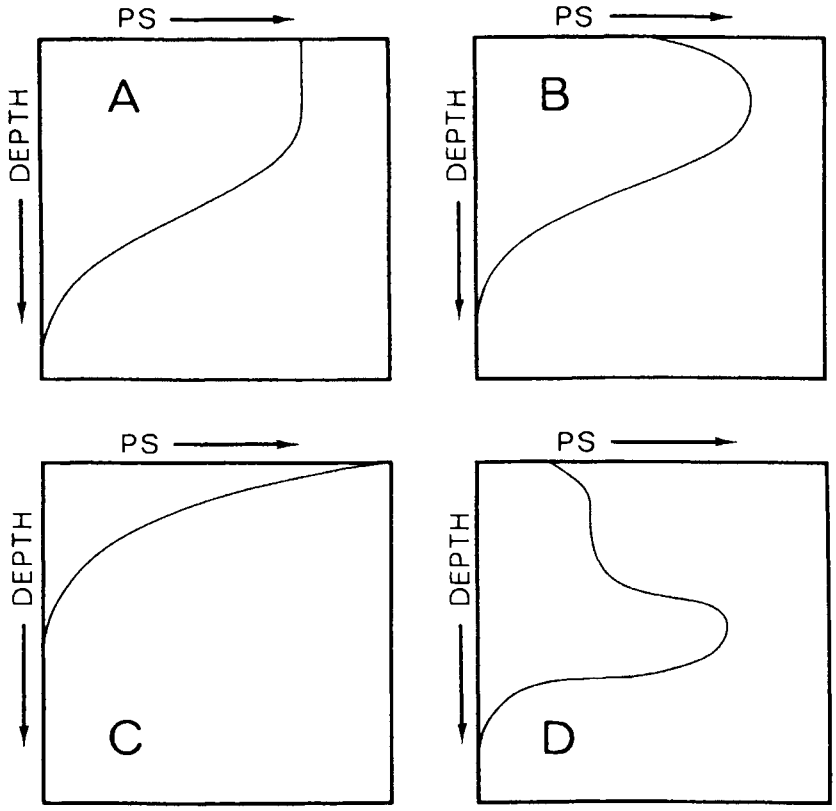

FIGURE 15-3 Generalized variations in vertical profiles of rates of photosynthesis (PS) among phytoplankton. (A) Light saturation in surface waters, without inhibition, underlain with decreasing rates as light is reduced with depth; (B) profile when severe surface photoinhibition occurs; (C) photosynthetic rates when biogenic turbidity is very high; (D) photosynthetic maximum in the metalimnion.

biogenic turbidity, are high, self-shading effects can greatly reduce light penetration and the trophogenic zone is reduced accordingly (Fig. 15-3C). Although surface photoinhibitory effects occur, rapid light attenuation through self-shading of the algal populations reduces the severity of enzymatic damage. In some cases, the algal populations adapted to relatively low light intensities of deeper layers develop greatly and have higher photosynthetic rates than those in the epilimnion (Fig. 15-3D; cf. also Fig. 9-5A).

There is great diversity in tolerances to variations in temperature among the algae (Fig. 15-2D). The minimal temperature at which photosynthesis can occur depends upon the algal species. For many diatoms, the critical temperature is about 5°C; for others, about 15°C (e.g., Rodhe, 1948). In many green algae and cyanobacteria, even higher temperatures are needed for incipient photosynthesis. The cyanobacteria as a group are generally much more tolerant of higher temperatures than are other phytoplankton. Many species of cyanobacteria have higher temperature optima than eukaryotic algae of the same waters. Further, thermophilic algae with optimal growth at temperatures above 45°C are almost exclusively cyanobacteria, and photosynthesis is known to occur at constant temperatures as high as at least 74°C (Castenholz, 1969). Respiration and especially photorespiration increase at high temperatures (Döhler and Przybylla, 1973). In the ensuing discussion of seasonal succession of algal populations, we will see again the frequently observed preponderance of diatoms at colder temperatures and the increasing variety of algae as the waters warm.

B. Flotation Mechanisms and Water Turbulence

The importance of water movements in the transport of particulate organic matter, in this case planktonic algae, has been emphasized at length earlier (Chap. 7). Not only are water movements important in the physical movement of phytoplankton into and out of the photic zone but they are critical in the transport of mineralized matter from lower depths and from the littoral regions to the open water. The degree of turbulence and water movement are obviously critical in the regulation of phytoplanktonic periodicity and production.

The importance of basin morphometry to water movements must be emphasized again in relation to

composition of planktonic algae aside from nutrient considerations. An excellent example is seen in the analyses of the spatial distribution of predominantly littoral desmid algae in several lakes in Minnesota (Bland and Brook, 1974). Many desmids occur throughout the year on and among submersed macrophytes of the littoral zone. During spring circulation, many desmid algae are dispersed, particularly to other areas of the littoral, and can colonize newly growing annual macrophytes. In small lakes, circulation in the littoral is not as intense as it is in larger lakes. Larger desmids are carried out of the littoral less frequently in these smaller lakes. The more active circulation of larger lakes, however, transports a variety of desmids into the pelagic regions from the littoral zone, and this input increases the diversity of the planktonic communities.

Various characteristics are found among plankonic algae that improve flotation or reduce sinking rates (Lund, 1959, 1965; Fogg, 1965; Hutchinson, 1967).

a. ***Density.*** The density of most freshwater planktonic organisms is slightly greater than that of the water and causes them to sink when in undisturbed water. Cells of cyanobacteria, which lack sap vacuoles, may have densities in the range of 1.02–1.09 times that of water, but gas vesicles may render them less dense than water (Thomas and Walsby, 1985; Utkilen *et al.*, 1985). Eukaryotic algae, which usually have sap vacuoles, have a density of 1.01–1.03 times that of water.

b. ***Particle Size.*** Spherical particles of a mean diameter of not more than 0.5 mm fall according to Stokes's law: The velocity of sinking varies (i) inversely with the viscosity of the medium (see Chap. 2), (ii) directly with the excess density of the particle over that of the medium, and (iii) directly as the square of the diameter or some appropriate linear dimension (reviewed by Hutchinson, 1967). Thus, in planktonic habitats, velocity of sinking is greatest for relatively large, dense particles in open water (cf. Titman, 1975). It is apparent that sinking out of the photic zone is a distinct disadvantage for phytoplankton. However, movement of a cell through water, either by its own motility or by sinking (or floating) through water has the advantage of disrupting nutrient gradients around the cell and increasing the chances, because diffusion is so slow, of contact with nutrient molecules. Consequently, the disadvantage of sinking out of the photic zone, which is usually fatal, is offset to some extent by the advantage of increased nutrient acquisition.

c. ***Form Resistance.*** Sinking rate is reduced by decreasing size and increasing surface-to-volume ratios (Table 15-5). The sinking rate of an algal cell is almost always less than a sphere of a volume and density equal to those of the alga. The effect of the shape that causes the reduction in this sinking rate is called *form resistance,* the ratio of the sinking rates of the object and a sphere of the same density and volume. Although the rough surface texture of the cell wall or membrane has relatively little effect on sinking, elongation into cylindrical or discoid shapes distinctly decreases settling rates. Projections or more elaborate protrusions such as spines decrease the settling rate by frictional resistance and, if they cause uneven weight distribution, will shift the orientation of the cell during descent.

d. ***Mucilage Production.*** The production of mucilage can alter the sinking rate. The effect on the sinking rate (U) depends on the thickness of the mucilage layer. The mucilage layer can lower the excess density, thereby reducing U, as well as increase the radius (r), which increases U in proportion to r^2 (Walsby and Reynolds, 1980). Thin layers reduce U, but if the layer exceeds a critical thickness, the velocity increases.

Gelatinous sheaths occur in nearly all cyanobacterial phytoplankton, some diatoms, and green algae, particularly most desmids with rather elaborate projections and irregular cell morphology (Boney, 1981). The mucilage generally has a density less than that of the cell, which decreases sinking velocity, but the mucilage layer increases cell size, which increases velocity. The sheath also reduces the efficiency of nutrient uptake by creating an additional diffusional barrier. Mucus secretions can cause diatoms to aggregate, however, when very abundant and accelerate sinking rates as large particles (Smetacek, 1985).

e. ***Gas Vacuoles.*** Gas vacuoles are found in the protoplasm of both cyanobacteria and many other types of bacteria. Each gas vacuole contains numerous hollow, cylindrical gas vesicles, the walls of which are composed of protein. The main cylinder and conical end caps of the gas vesicle are formed by a small hydrophobic protein arranged in ribs. The ribs are bound together by a larger hydrophilic protein, which assembles on the outer surface. Together these proteins form a rigid shell that withstands pressures of several bars. At a certain critical pressure, the structure collapses and no longer provides buoyancy. Cyanobacteria in deep lakes have evolved very narrow, strong gas vesicles that withstand pressures generated at greater depths (Walsby, 1994).

The gas vacuole membranes and the walls of the vesicles are freely permeable to gases, and the gas contained in the vacuoles and vesicles is in equilibrium with gases dissolved in the surrounding water. Water is prevented from entering the gas vacuole by surface tension at the inner surface of the membrane (cf. reviews of Walsby, 1972, 1975, 1994; Fogg *et al.*, 1974; Reynolds and Walsby, 1975).

The gas vacuoles decrease the density of cyanobacteria to below that of water, even though the volume of the vacuoles often occupies <5% of the total cell volume. Cyanobacteria possessing gas vacuoles float toward the

surface and are not dependent only on turbulence, which is required by other phytoplankton to remain in the photic zone. Changes in gas vacuole:cell-volume ratio determine whether the cells sink or float. The ratio changes as vacuole volume becomes proportionately less of the total volume in exponential growth phases. Gas vacuoles become more abundant when light is reduced and growth rate slows. Rises in turgor pressure of the cells as a result of the accumulation of photosynthate cause a collapse in existing gas vesicles and a reduction in buoyancy (Dinsdale and Walsby, 1972; Konopka, 1980; Walsby and Booker, 1980) but only in cyanobacteria that have relatively weak gas vesicles (Kinsman *et al.*, 1991). Additionally, the "dilution" of newly produced vacuoles during active cell division and the accumulation of dense carbohydrate can reduce buoyancy.

By these mechanisms, cyanobacteria are able to regulate buoyancy and undergo limited vertical migration to poise themselves within physical and chemical gradients favorable to growth, usually toward the bottom of the euphotic zone (Fogg and Walsby, 1971; Takamura and Yasuno, 1984; Klemer, 1986). The population maximum, which results from population growth and movement downward, apparently often occurs as epilimnetic nutrient concentrations are sharply reduced in summer (Klemer, 1978; Konopka, 1981). Metalimnetic populations of planktonic cyanobacteria, particularly of several species of *Planktothrix* (formerly *Oscillatoria*), often develop in strata of low light intensity during the latter portions of summer stratification. Some other filamentous cyanobacteria in the genus *Tychonema* lack gas vesicles and exhibit chromatic adaptation to the low light intensities (Utkilen *et al.*, 1985).

Gas vacuolation can increase under carbon limitation and promote cyanobacterial blooms (Booker and Walsby, 1981), whereas nitrogen limitation decreased vacuolation and contributed to deep population maxima (Klemer *et al.*, 1982; Rijn and Shilo, 1983). Light is an overriding factor regulating buoyancy, however. As with sinking, movement by floating also has the added advantage of disrupting nutrient gradients surrounding actively growing cells. The scattering of light by gas vesicles has been investigated and found to be of little, if any, benefit to cyanobacteria in that they shield the cells from excessively bright light (Shear and Walsby, 1975; Ichimura *et al.*, 1981).

The energetic costs of making gas vesicles to provide flotation have been compared with the combined smaller cost of making flagella and the additional cost of rotating them to provide movement (Walsby, 1994). The gas vesicles provide a cheaper solution in slowly growing organisms like cyanobacteria. In rapidly growing cells, however, they are more expensive because a new set of gas vesicles must be made at each cell division.

Large colonial cyanobacteria occur mainly in turbulent polymictic and epilimnetic waters, since single filaments sink more slowly than helically shaped cells (Booker and Walsby, 1979). As turbulence subsides, these cyanobacteria can adjust their position rapidly. As a result of these movements, large colonial cyanobacteria commonly form phytoplanktonic blooms (cf. Reynolds, 1978). In extreme cases, the blooms of cyanobacteria become so dense on the surfaces that scums or "hyperscums" of thick (several cm), crusted accumulations of cyanobacteria cover the water in wind-protected areas (e.g., Zohary and Robarts, 1990). These surface accumulations form cyanobacterial refuges, which help maintain large planktonic biomass during winter when growth is re-

duced but have no effect on the perennial survival of the organisms.

f. ***Accumulation of Hydrocarbons.*** The density of some algae is decreased by the accumulation of fats. Some algae, such as *Botryococcus*, can contain lipids up to 30–40% of dry weight and can float because of this accumulation (Fogg, 1965). Usually, however, fat accumulation occurs in senescent cells that are in various stages of degradation.

g. ***Ion Regulation.*** Buoyancy alteration may also be achieved in some marine and brackish-water algae by means of ion regulation (cf. Anderson and Sweeney, 1977). Ionic regulation of the contents of the large sap vacuole in large diatoms and dinoflagellates can make the cells less dense than sea water. K^+ salts replace the denser Na^+ salts and Cl^- the denser SO_4^{2-}. Positive buoyancy can be obtained by this method in sea water but not fresh water.

h. ***Swimming by Flagella.*** Swimming by flagella is common among cryptomonads and dinoflagellate algae. Despite the very small size of many of these flagellated organisms, their locomotion is adequate to move vertically within the water column for 10s of centimeters to several meters daily in response to sinking, shifting light and nutrient concentrations, and possibly predation by zooplankton, especially rotifers (Sommer, 1982, 1986; Arvola, 1984; Gasol *et al.*, 1991; Jones, 1991; Gervais, 1997; Pithart, 1997). Migrational amplitudes and maximal swimming velocities of phytoflagellates increase with body size, but relative amplitudes and relative velocities decrease with body size (Sommer, 1988). Cryptomonads commonly exhibit a regular vertical daytime ascent and a nighttime descent of between 0.5 and 1.5 m. Because the energy costs for flagellar movement in swimming nearly equal or could exceed those benefits gained by movement (Raven and Richardson, 1984), it is assumed that the benefits are in improved nutrient acquisition in heterogeneous environmental conditions of nutrient distribution. If dinoflagellates are moved by water currents into surface waters, motility and phototaxis can be strongly impaired by exposure to ultraviolet radiation (Tirlapur *et al.*, 1993).

C. Inorganic Nutrient Factors

The importance of inorganic macro- and micronutrients, particularly the two major elements, phosphorus and nitrogen, to algal nutrition has been emphasized in preceding chapters on biogeochemical cycling, so reiteration is not necessary here. Facets of algal nutrition and nutrient interactions will be discussed further in the sections on the periodicity and succession of phytoplanktonic populations.

The limiting nutrient concept, originally developed by Liebig well over a century ago as the "Law of the Minimum," has experienced considerable misuse, largely from attempts at oversimplification. Simply paraphrased, the law states that the yield of any organism will be determined by the abundance of the substance that, in relation to the needs of the organism, is least abundant in the environment (cf. Hutchinson, 1973; Talling, 1979). Algal species differ in specific nutrient requirements and optimal ratios of N:P (e.g., Rhee and Gotham, 1980; Tilman *et al.*, 1982; Borchardt, 1996). Thus, in a multispecies algal community, growth rates among different species are likely to be limited by different resources, including differing nutrients. As a result, the concept of single-nutrient limitation does not apply strictly to communities. When such limitation is in effect among dominant species in the community, or a resource such as phosphorus occurs at levels below the minimal threshold requirements of many species of the community, the limitation concept is applicable to community productivity.

Since yield is a result of growth, rate of growth has been substituted for yield in many subsequent analyses, the most important of which is the well-known Monod model for a single nutrient limitation in the growth of microorganisms (cf. Droop, 1973):

$$\mu/\mu_m = S/(K_s + S)$$

when

μ = specific growth rate (increase in biomass per unit biomass per unit time)
μ_m = maximum specific growth rate at infinite external substrate concentration
S = external substrate concentration (mass per unit volume)
K_S = saturation constant when the external substrate concentration results in half the maximal rate of uptake (i.e., S when $\mu = \mu_m/2$)

Irrespective of the internal nutrient concentration, the specific rate of uptake depends upon substrate concentration in a Michaelis function; the rate of uptake increases with increasing substrate concentration to a specific substrate level beyond which no further change in rate of uptake occurs.

Under conditions of steady state with nutrient concentrations that are not limiting, the specific rate of nutrient uptake (u, mass per unit biomass per unit time) equals the product of the specific growth rate (μ) and the cell nutrient quota (Droop, 1973):

$$u = \mu q$$

where q is a demand coefficient or cell nutrient quota (content) in the absence of nutrient excretion [(internal

substrate concentration) (mass per unit biomass)]. The specific rate of uptake and the cell nutrient quota have a linear relationship:

$$\mu q = \mu_{m'}(q - k_q) \quad \text{or} \quad \mu/\mu_{m'} = 1 - k_q/q$$

where

$\mu_{m'}$ = maximum specific growth rate at nonlimiting internal substrate concentration,
k_q = the subsistence quota (i.e., the q intercept for zero μ)

The importance of these models, which are confirmed by many studies on planktonic algae (e.g., Goldman, 1977), lies in their applicability to obtaining specific growth values from more easily determined uptake rates (Eppley and Thomas, 1969).

It is important to view nutrient uptake as it really takes place, since uptake of several nutrients occurs simultaneously. Nutrient limitations of photosynthesis can be highly dynamic both spatially and temporally (Wetzel, 1972). Of importance among the many interacting, potentially limiting nutrients is the relative position of limitations within an *intensity* spectrum, which undergoes constant change spatially and temporally. The model of Droop can be expanded to the multinutrient condition, based on the fact that a limiting parameter (in this case μ/μ'_m) is proportional to the product of two or more functions if it is independently proportional to each of them. Therefore,

$$\mu/\mu_{m'} = (1 - k_{qA}/q_A)(1 - k_{qB}/q_B)(1 - k_{qC}/q_C)(. \; . \; .)$$

is a simple polynomial in which the subscripts A, B, C, . . . , refer to various nutrients. In the latter equation, all nutrients are formulated equally; the significance of a particular nutrient in establishing the composite limiting parameter (μ/μ'_m) is determined by the relative magnitude of k_q compared with q. The parameter μ'_m is an abstract proportionality constant in this case, whose value is determined by all factors (physical, nutritional, et cetera) excluded from the equation.

The effectiveness of individual nutrient limitations has been shown in a number of studies (e.g., Droop, 1974, 1977; Rhee, 1974, 1978). Frequently, a relatively sudden shift occurs in the transition from limitation by one nutrient to limitation by another nutrient. These results demonstrate the restricted usefulness of the simple multiplicative polynominal formulation given here as a descriptor of simultaneous limitation of growth or nutrient uptake by two or more nutrients. Although the shift from one nutrient limitation to another can be expressed mathematically (Droop, 1977), the predicted growth rates are likely serious underestimates for a given algal population (Talling, 1979).

1. Resource Competition and Limitations

Nutrient resource competition functions to structure natural communities of freshwater phytoplankton. The Droop equations just discussed describe the dependence of nutrient-limited reproductive growth rates on the cellular content of the limiting nutrient (cell quota) and are applicable to populations grown to steady state, as in a continuous culture, as well as field populations (Sommer, 1991). Although the effects of external nutrient concentrations are difficult to evaluate, particularly for cell quotas (content) of nonlimiting nutrients (Kilham and Hecky, 1988), the Droop model was found to be a superior extension of the Monod model, which relies on ambient concentrations of limiting nutrients for prediction of growth rates (Sommer, 1991).

Growth experiments for algal species under substrate-limiting conditions allow one to obtain μ_m (the maximum growth rate) and K_S (the half-saturation coefficient for growth). These values allow one to estimate the concentration of the limiting nutrient (R^*) required by an alga to grow at a specific mortality or dilution (D) rate (Fig. 15-4), where:

$$R^* = D\,K_S/(\mu_m - D)$$

Species with the lowest R^* for a resource should have the competitive advantage for that resource and dominate (Tilman, 1982). The predicted outcome of competition between two species with two potentially limiting nutrients (Fig. 15-5) defines the isoclines of zero net growth (heavy lines) by the R^* for each species for each nutrient resource. The rate at which each species consumes both resources is represented by a specific consumption vector (diagonal lines), the slope of which is a species' optimal ratio. Species having the lowest R^* values become the competitive dominant under that specific potentially limiting resource. With sufficient information about the physiological capabilities of different algae, the competitive abilities of the different species can be determined in relation to resource availability, as illustrated in the examples of Figure 15-6.

Loss rates experienced by a species can be just as important as growth rates in determining species compositions of phytoplankton communities. Seasonal fluctuations in such mortality rates, as for example by differential susceptibility to grazing, would also direct the succession of populations (Fig. 15-7). Similarly, other environmental factors influencing growth and mortality rates couple to limiting nutrient resources to determine phytoplankton succession. For example, temperature affects mainly the maximal growth rate of a species. Among several species of algae, the species with the lowest R^* should be the superior competitor at a given temperature, and as a result species A should dominate at

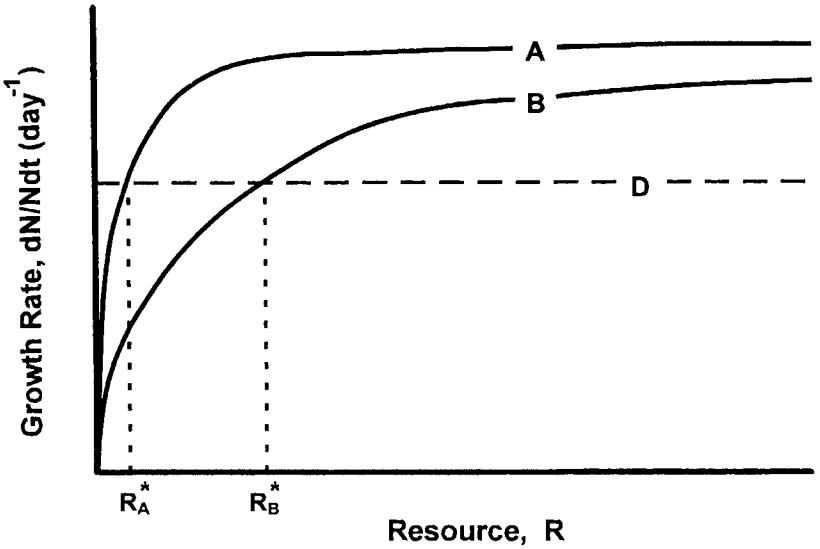

FIGURE 15-4 Monod growth curves for two species of algae (A and B). The R^* value for each species is the equilibrium resource (nutrient) concentration at specific dilution rates (D equals mortality rate at steady state). When the two species A and B compete for a single resource, the species with the lowest R^* for that resource will always win. (Modified from Kilham and Hecky, 1988.)

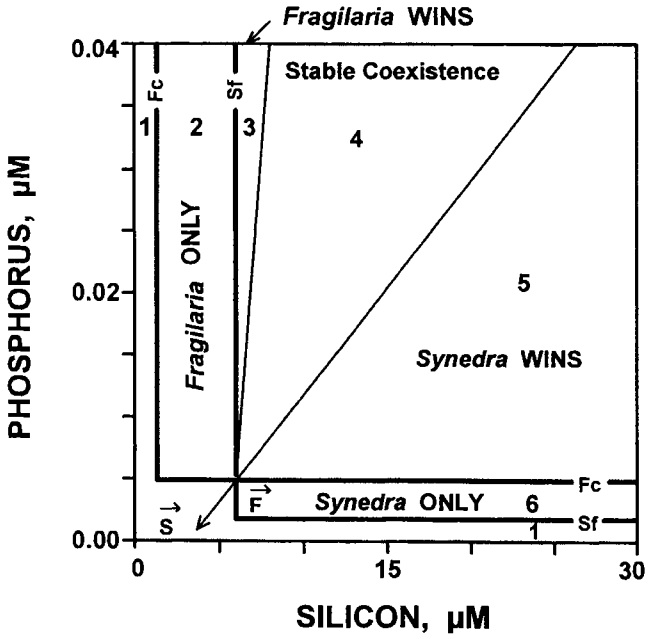

FIGURE 15-5 The predicted outcome of resource (phosphorus or silicon) competition between two freshwater diatoms, *Synedra filiformis* (Sf) and *Fragilaria crotonensis* (Fc). The isoclines of zero net growth (heavy lines) for each species cross at an equilibrium point (•). The consumption vectors (diagonal lines) for each species are labeled S → and F →. Neither species has sufficient nutrients to survive in region 1. In region 2, *Fragilaria* can survive but *Synedra* cannot. In region 3, *Synedra* is outcompeted by *Fragilaria*. Both species stably coexist in region 4. *Fragilaria* is competitively displaced by *Synedra* in region 5. Only *Synedra* can survive in region 6. (Modified from Kilham and Hecky, 1988.)

low temperatures, followed by species B and C as temperature increases, for example, seasonally (Fig. 15-8).

2. r- and K-Selection in Seasonal Phytoplankton Succession

The original concept of two types of selection to which organisms are exposed in natural environments was based on the logistic growth equation.[3] The expanded concepts now group *r*-selection with short-lived, fast-growing species capable of rapid colonization of habitats with abundant resources that are relatively unoccupied with competing species (Kilham and Kilham, 1980; Sommer, 1981; Amblard, 1988). *K*-selection favors organisms that have high competitive abilities by such means as high efficiency of resource utilization and resistance from high losses, such as predation or sedimentation. *r*-selection is commonly associated with early stages of succession following environmental change or disturbances, whereas *K*-selection is typical of more mature, stable stages. A reasonable environmental constancy persisting over some 12–16 generations is needed for the community to reach a more climactic, stable condition (Gaedeke and Sommer, 1986; Holzmann, 1993; Reynolds, 1993). Species diversity tends to increase with greater intervals of time

[3] *r* was the intrinsic rate of growth and *K* the upper asymptote of the growth curve or the "carrying capacity" of the environment for a particular species (MacArthur and Wilson, 1967).

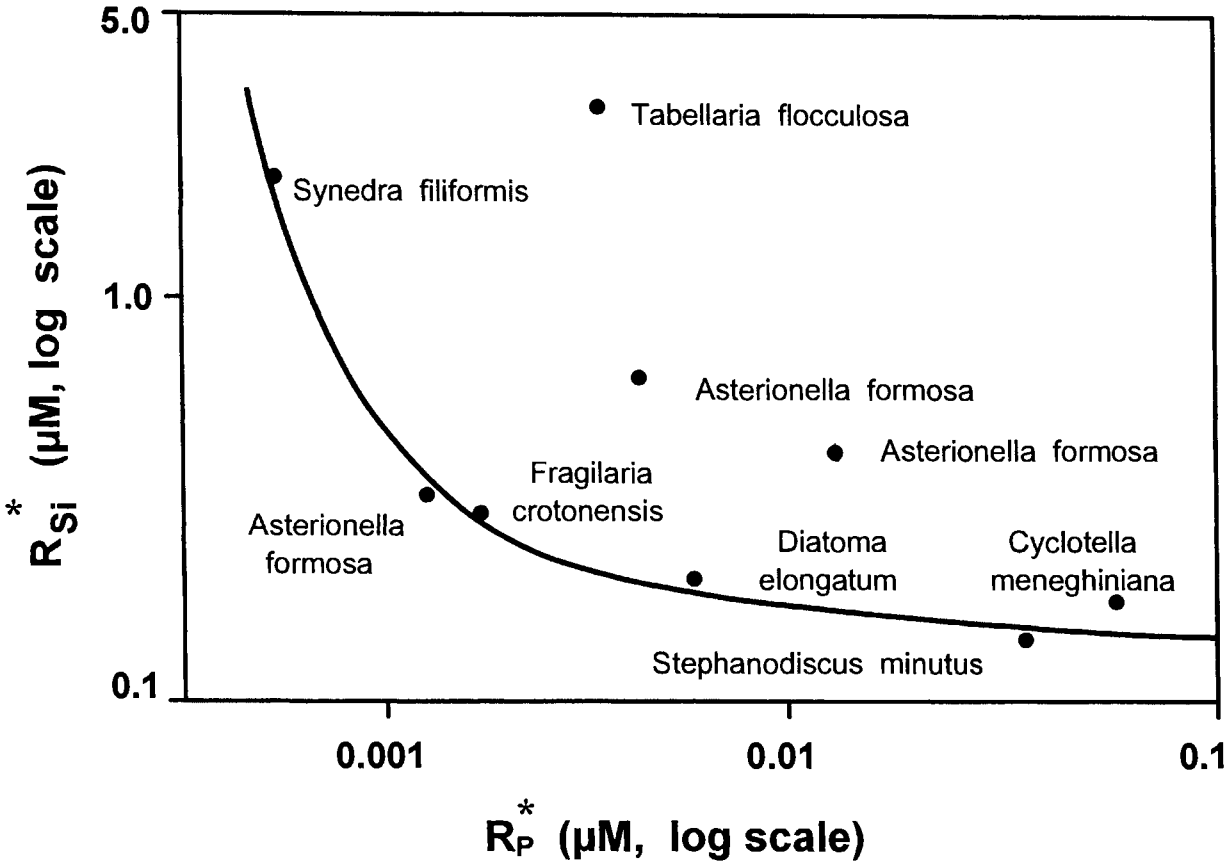

FIGURE 15-6 Differential competitive abilities of freshwater planktonic diatoms at 20°C. *Synedra filiformis*, for example, is the superior competitor for phosphate but the most inferior competitor for silicate. (From Kilham and Hecky, 1988, based on Tilman *et al.*, 1982.)

between disturbance but decrease under very stable conditions where conditions of nutrient limitations and grazing select toward few species.

There is a strong tendency toward balance between fecundity and mortality, where species with rapid growth usually also decline rapidly (Green, 1980; Sommer, 1981). Maximum values occur in the spring in temperate waters, followed by a depression in summer, an increase at the end of summer, and a slow decline in autumn. From spring to late summer, growth classes with the most rapid growth shift to the growth class with the slowest growth, and from the smallest to the largest size class. In the autumn, the developmental sequence commonly reverses.

Species of similar growth class and size class tend to be associated with each other in a community. Therefore, a common sequence is for rapidly growing, small phytoplankton of the spring bloom to shift to a slower-growing algal community with a shift from predominantly *r*-selection to largely *K*-selection. The shift is regulated by both nutrient reductions in the trophogenic zone and early grazing pressures by zooplankton (cf. Kilham and Kilham, 1980). When resources are scarce, the ratio of resource demand (D) to resource supply (S) tends toward 1, and more *K*-selected organisms are favored (Kilham and Hecky, 1988). When D/S ratios are considerably <1, more *r*-selected organisms predominate. In the autumn, competition for nutrients declines as the thickness of the trophogenic zone increases, but light and temperature decrease as well. As a result, the biological controls shift to dominance by physical factors.

Complications in simple multiplicative predictive analyses of algal population growth also result when synergistic effects occur between nutrients. An example mentioned earlier was an enhanced rate of photosynthesis resulting from enrichment with both phosphorus and manganese, but not with each nutrient alone (Shapiro and Glass, 1975). As will be discussed later (Chap. 17), among the bacteria, nutrient uptake can be influenced by the previous substrate (nutrient) concentration. If lack of a nutrient previously has limited growth severely, the uptake sites for that nutrient can be reduced. Replenishment of the limiting nutrient may not result in an immediate response of uptake and

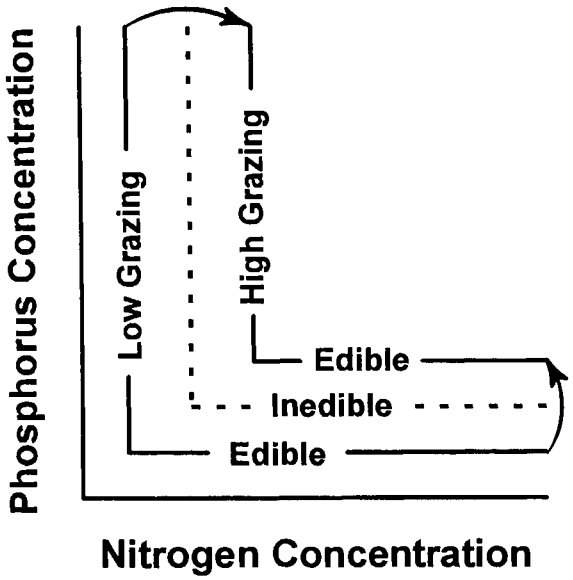

FIGURE 15-7 Hypothetical succession of algal species that results from a shift from low grazing rates to high grazing rates (arrows). The isocline of an inedible species (- - - -) does not vary with grazing pressure, but the isocline of an edible species (——) moves away from the axes as grazing pressure increases. The species with its isocline closest to the axes will be the superior competitor and will dominate. (From Sterner, 1989.)

growth. This fact has important implications for short-term enrichment bioassays since effects of the added nutrient may not be realized in population growth for a considerable period, possibly longer than the duration of the experiment.

In fresh waters of low nutrient concentrations and slow turnover rates, it is metabolically advantageous to be both small and motile. Small size (ultraplankton, <20 μm) increases the ratio of absorptive surface area to cell volume (Table 15-3). Since growth rates among microphytoplankton (>20 μm) are slow and may not be adequate to offset mortality by sedimentation and predation, small size is further advantageous in reducing the settling rate and possibly predation by many grazers. Motility also is effective in disrupting nutrient gradients surrounding cell membranes during active growth. These relationships suggest that one would anticipate a greater percentage of the algal populations of oligotrophic lakes to be small and motile. In most oligotrophic lakes, this relationship is indeed the case. Usually a much larger percentage of the total rates of primary productivity derives from ultraplanktonic algae of oligotrophic lakes than from larger algae. In some extreme cases, all phytoplanktonic primary productivity is by algae <30 μm.

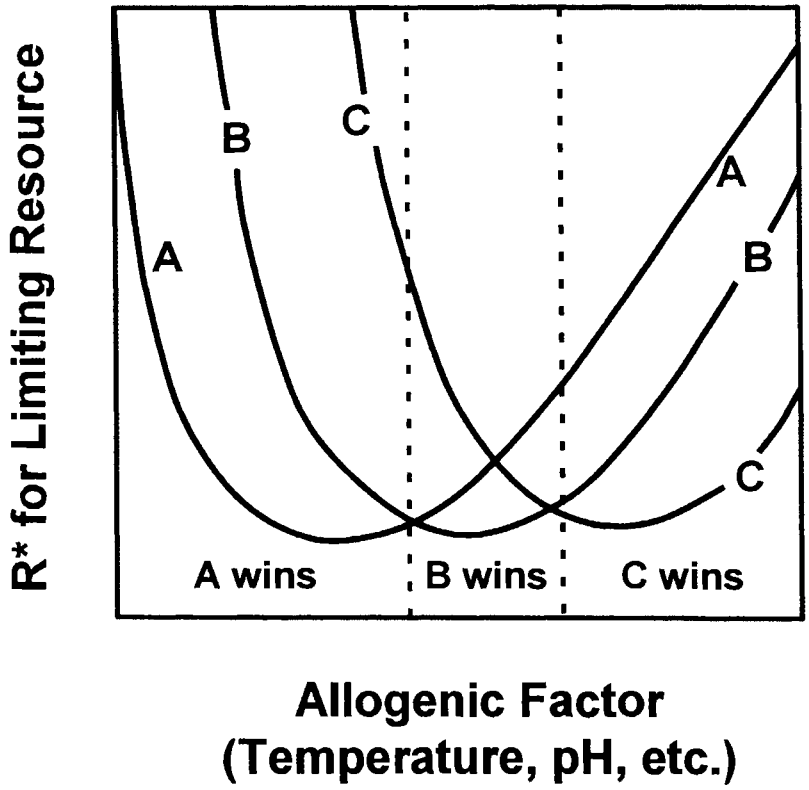

FIGURE 15-8 Competition for one limiting resource in relation to an allogenic factor such as temperature or pH. The species with the lowest requirement (R^*) for the resource at a given level of the allogenic factor should competitively displace the other species. (Modified from Tilman *et al.*, 1982.)

3. Organic Matter and Algal Growth

Dissolved organic matter is intimately coupled with the nutritional requirements of algae for organic growth factors. In addition, the availability of certain organic compounds is dependent upon the quantity and types of dissolved inorganic cofactor compounds that are present. Furthermore, a number of algae can supplement primary photosynthetic autotrophy by the uptake and utilization of organic substrates. Algae capable of synthesizing required organic growth factors (e.g., vitamins) have a distinct competitive advantage over algae that must rely on exogenous supplies synthesized by other microorganisms.

In addition to direct utilization as a micronutrient or utilization as supplementary energy and carbon sources, organic compounds can function as nonessential accessory substances that may stimulate growth of the algae. Growth substances or nonessential organic micronutrients include a large group of hormones known to be produced by algae and effective in growth regulation and cell development (Bentley, 1958a,b; Conrad and Saltman, 1962; Provasoli and Carlucci, 1974). Little is known of the physiological mechanisms of these substances in freshwater algae, although they are probably of some significance in the success and succession of certain more specialized algae under natural conditions.

4. Lipid Production in Algae

Algal lipids are critical in aquatic ecosystems because they provide a high-density source of energy and essential fatty acids (EFA) for aquatic animals. Lipids can also be vectors for the movement of hydrophobic materials, including many organic contaminants (Landrum and Fisher, 1999). Many planktonic and attached algae and cyanobacteria are major synthesizers of lipids. Lipids can constitute 30–50% of the dry mass of lake seston of a size <50 μm in diameter at certain times of the year (Kreeger *et al.*, 1997).

Lipids undergo modest seasonal changes in concentration that are proportional to the percentage of photosynthate allocated to lipids. This relation is directly coupled to light intensity and is proportional to the efficiency of carbon fixation, with greater production in summer than in other seasons (Wainman and Lean, 1992; Arts *et al.*, 1997; Kreeger *et al.*, 1997). In summer, the lipid content as a percentage of production is about 15–30% of total photosynthesis at light saturation (P_m); in winter, the lipid production is 5–20% of P_m. No clear seasonal trend in the lipid percentage of areal photosynthetic production was evident, however, with an annual mean of ca. 17% (Rai *et al.*, 1997; Wainman *et al.*, 1999). This seasonal constancy suggests lipid synthesis is constitutive and not susceptible to "luxury storage," except potentially when the algae can increase lipid synthesis (30–40% of total production) when severely nutrient-limited (e.g., Parrish and Wangersky, 1987; Kilham *et al.*, 1997). Nutrient limitation tends to depress the rate of cell division more than it does of carbon accumulation through photosynthesis. As a result, nutrient limitation should thus result in algae that are rich in carbon storage products as lipids or carbohydrates (Ahlgren *et al.*, 1997; Rai *et al.*, 1997; Olsen, 1999). As noted later, however, essential nutrient limitations can alter the specific production of essential fatty acids in algae, which in turn affects metabolism in both the algae and in the zooplankton that consume them. Light and carbon limitation, however, can limit cell division and should result in a lower level of storage lipids in algae. Also, slow growth in any algal species often leads to a rapid removal of that alga from the plankton through grazing.

Lipids contain some 16 subclasses. Triacylglycerols, in which three fatty acids are esterified to a glycerol molecule, are important intracellular energy stores that are used for generating ATP for respiration and anabolic reactions. Sterols, of similar ring structure, are also neutral lipids associated with membrane structure. Phospholipids, also critical as structural constituents of cellular membranes, are polar and similar functionally to the glycolipids that contain one or more sugar molecules (Parrish, 1999). Glycolipids are major components of the thylakoid membrane in chloroplasts. Nomenclature for fatty acids is based on the total number of carbon atoms (e.g., "18" of 18:2ω6), the number of *cis* double bonds (e.g., "2"), and the position of the first double bond (e.g., "ω6," where the "6" is the position of the first double bond counted from the methyl end of the molecule). Lipids with *trans* double bonds are largely unknown in fresh waters, and only plants can desaturate fatty acids at the ω3 and ω6 positions.

Polyunsaturated fatty acids (PUFA) of algae and cyanobacteria are important biochemical markers because they include some essential fatty acids that animals must assimilate in their diets. The distribution of fatty acid markers in the major groups of freshwater algae and cyanobacteria shows some specificity, but the variations are sufficiently large that fatty acid profiles can be used to distinguish algae at the class level only (Ahlgren *et al.*, 1992; Napolitano, 1999). However, some groups, such as the ω3-PUFAs, are important fatty acid markers of algal biomass because they are virtually absent in most bacteria and terrestrial plants. Among the bacteria, PUFA and fatty acids with a chain length longer than 18 carbon atoms are usually absent

in procaryotes. In contrast, eukaryotic algae contain large proportions of fatty acids with 20–22C and 3 to 6 *cis* double bonds. Lipids of terrestrial and higher aquatic plant origins tend to contain longer chain (≈C26) fatty acids than do phytoplankton (≈C16). Thus, the C16/C26 fatty acid ratio in lipids of the particulate organic matter in sediments of lakes can be seen to increase with distance from the land and littoral areas (e.g., Meyers *et al.*, 1984; Boon *et al.*, 1996).

Pronounced differences in fatty acid profiles exist among species and larger taxonomic groups of algae. Dinoflagellates are rich in docosahexaenoic acid (22:6ω3; DHA). Diatoms are rich in eicosapentaenoic acid (20:5ω3; EPA). In general, large quantities of ω3 fatty acids, including EPA and DHA, are far more common in marine than in freshwater algae (Olsen, 1999). Chrysophytes have variable ω3 profiles with either 18:3, 18:4, EPA, or DHA as the dominant ω3 fatty acid. The green algae are more diverse and have variable profiles with 18:3, 18:4, or EPA as the dominant ω3 fatty acids (Ahlgren *et al.*, 1990, 1992, 1998; DeMott and Müller-Navarra, 1997; Desvilettes *et al.*, 1997; Olsen, 1999). Among the cyanobacteria, one group (*Planktothrix, Microcystis*) was similar to green algae, with higher amounts of 18C components of the ω3 acids, whereas the other group (*Anabaena, Spirulina*) contained mostly ω6 acids. The taxonomically diverse flagellates were characterized by high amounts of long-chained (20–22C) polyunsaturated fatty acids. Alterations in growth conditions tend to change the total lipid content rather than specific ratios of fatty acids. Increased lipid content in stressed algae was largely the result of increased saturated fatty acids and ω6 acids, whereas the ω3 acids were relatively unchanged. Branched-chain fatty acids are usually considered a characteristic of cyanobacteria (Mancuso *et al.*, 1990).

There is some evidence that algae, stressed by UV-A (Arts *et al.*, 1999) and/or UV-B radiation, allocate less carbon to lipids and have altered fatty acid profiles (Goes *et al.*, 1994; Wang and Chai, 1994). Relative increases in short-chained, and decreases in polyunsaturated, fatty acids have been observed in phytoplankton exposed to moderate UV (Hessen *et al.*, 1997). Critical membrane fatty acids, such as eicosapentaenoic (20:5ω3) and docosahexaenoic (22:6ω3) acids, can experience peroxidation or reduced biosynthesis under stress of UV radiation.

V. ORGANIC MICRONUTRIENT REQUIREMENTS

Knowledge of the specific requirements of phytoplanktonic algae for growth factors or essential organic micronutrients, especially the vitamins, is extensive (cf. reviews of Provasoli, 1958; Hutner and Provasoli, 1964; Provasoli and Carlucci, 1974). Although most higher plants do not require vitamins (Roth *et al.*, 1996), many algae do; species that require vitamins for growth are termed ***auxotrophic.*** In the case of auxotrophic growth, the requirements for specific organic compounds are low and these compounds do not contribute significantly to the total cell carbon. Only three water-soluble vitamins are known to be required by algae: vitamin B_{12} (cobalamine), thiamine, and biotin. Vitamin B_{12} and thiamine are required alone or in combination by a majority of the auxotrophic algae, and B_{12} is required more often than thiamine. Biotin is known to be required by a few chrysomonads, dinoflagellates, and euglenoid algae.

TABLE 15-6 General Requirements for Vitamins among the Algae and Cyanobacteria[a]

Algal groups	*Biotin*	*Thiamine*	*Vitamin B_{12}*	*Predominant vitamin requirements*
Cyanobacteria	0	0	++	B_{12}
Rhodophyceae	0	0	++	B_{12}
Bacillariophyceae	0	+	++	B_{12}
Xanthophyceae	0	0	0	None
Phaeophyceae	0	0	+	None
Chlorophyceae	0	+	++	B_{12}
Chrysophyceae and Haptophyceae	−	++	+	Thiamine
Cryptophyceae	−	−	+	None
Dinophyceae	+	0	++	B_{12}
Euglenophyceae	−	−	+	None

[a] After discussion of Provasoli and Carlucci (1974).
++ = required in many species; + = few species; − = requirement rare; 0 = no known requirement.

There is no strict taxonomic correspondence to the known distribution of the requirement for external vitamins (auxotrophy) among different algae. The differences, however, are sufficient to permit some generalizations. On the basis of relatively few analyses in pure cultures, a significant number of cyanobacteria, diatoms, green algae, and dinoflagellates require exogenous sources of vitamin B_{12}, that is, they are auxotrophic (Table 15-6). Only a few groups show any significant requirements for thiamine. Only the xanthophycean algae exhibit no apparent need for these major water-soluble vitamin growth factors, although in several other groups the requirements are rare (Table 15-6). The cyanobacteria, Chlorophyceae, Xanthophyceae, and Phaeophyceae exhibit the least number of species requiring vitamins. Most of the species in these groups are strictly autotrophic in metabolism. In contrast, a clear predominance of auxotrophic species occurs in the Chrysophyceae, Dinophyceae, Cryptophyceae, and Euglenophyceae.

When algae are unable to synthesize an organic micronutrient, the need for an exogenous source of the correct chemical moiety is obvious. Most of the vitamins are synthesized by bacteria and certain algae and are released to the water during active growth and upon death (Carlucci and Bowes, 1970; Aaronson *et al.*, 1977; Grieco and Desrochers, 1978; Nishijima *et al.*, 1979). Appreciable concentrations of vitamins derived from airborne soil particles, pollen, or active microorganisms (Parker and Wachel, 1971) can enter aquatic ecosystems from precipitation (Table 15-7). Although very low concentrations of organic micronutrients, especially vitamin B_{12}, exist in fresh waters (Table 15-7), these concentrations yield little insight into rates of turnover between supply sources and demand. All assays of the absolute vitamin requirements of algae are necessarily based on bacteria-free cultures and in most cases indicate that the requirements are much lower than observed concentrations in fresh waters.

Studies of seasonal variations in concentrations of vitamin B_{12}, thiamine, and biotin have demonstrated large changes with time (Tal, 1962; Kashiwada *et al.*, 1963; Daisley, 1969; Kurata *et al.*, 1976, 1979a; Cavari and Grossowicz, 1977; Nishijima and Hata, 1977; Parker, 1977). In many cases, concentrations of

vitamin B_{12} and thiamine, but seldom biotin, were negatively correlated with densities of phytoplankton, particularly small algae (<30 μm). Concentrations of the water-soluble vitamins commonly decrease with increasing water depth. In the surficial profundal sediments, vitamin concentrations are 100–1000 times greater than in the overlying water (e.g., Nishijima and Hata, 1978; Kurata *et al.*, 1979a). Concentrations of vitamin B_{12}, thiamine, and biotin also change diurnally, with higher concentrations occurring in the morning than in the evening (Kurata *et al.*, 1979b). Presumably these differences result from algal utilization in daylight exceeding inputs from synthesizing organisms. Concentrations of the water-soluble vitamins have been found to be consistently higher in the littoral zone than in the open water (Kurata *et al.*, 1979a). The data suggest that epiphytic microorganisms associated with submersed macrophytes are major net exporters of vitamins, especially B_{12}, to the open water.

Concentrations in natural waters are so low that they must be determined by bioassay organisms of known growth responses to concentrations of the micronutrients. Concentrations utilizable by the assay organisms may not be equally utilized by algae. Moreover, evidence indicates that some or many of the natural organic micronutrients may not be readily available for assimilation. Photosynthetic rates and cell numbers of natural phytoplanktonic populations frequently increase markedly by additions of vitamin B_{12} or thiamine (see, e.g., Wetzel, 1965a, 1966b, 1972; Hagedorn, 1971). The concentrations needed, especially in hardwater lakes, to increase the populations in this way are often greatly in excess of those generally known to be required by algae in pure culture. White and Wetzel (1985) have shown experimentally that much vitamin B_{12} is adsorbed to particulate calcium carbonate and is removed from the trophogenic zone by coprecipitation and sedimentation. Other losses are likely. For example, some species of algae produce a glycoprotein exudate that competitively inhibited vitamin B_{12} and suppressed the growth of an algal species that requires B_{12} for competitive species succession (Messina and Baker, 1982). It is doubtful whether the rates of vitamin synthesis generally are limiting to total growth and productivity of phytoplankton of lakes. However, large spatial and seasonal fluctuations occur, and these organic micronutrients probably play a significant role in the succession and competitive success of phytoplankton populations.

VI. HETEROTROPHY OF ORGANIC CARBON BY ALGAE AND CYANOBACTERIA

Photosynthesis dominates metabolism among algae and cyanobacteria. Most algae are obligate ***photoautotrophs:*** Cell carbon is obtained by reduction of carbon dioxide to carbohydrates from transformations in which light energy obtained by light-receptor pigment systems is converted to chemical energy (Table 15-8). The products of photosynthesis (ATP and organic carbon compounds) provide chemical energy as well as organic compounds needed for cellular synthesis. If light is inadequate or unavailable, the cells generally either die after storage compounds are used or they become metabolically inactive in a dormant state until light again becomes available.

In pure culture, an appreciable number of algae assimilate and utilize dissolved organic compounds as a source of carbon and energy both in the dark and in the light. ***Heterotrophy*** or chemo-organotrophy in algae implies the capacity for sustained growth and cell division in the dark; energy and cell carbon are obtained from the metabolism of an organic substrate(s). Heterotrophy in algae occurs by means of aerobic dissimilation, and carbon dioxide may or may not be required. Excellent reviews on the physiology and biochemistry of heterotrophy by algae are given by Droop

TABLE 15-8 Metabolic Processes Utilized by Algae and Cyanobacteria in the Synthesis or Modification of Organic Matter[a]

Metabolic processes	*Energy sources*	*Carbon sources*
Photoautotrophy (photolithotrophy)	Solar radiation	CO_2 only[b]
Photoheterotrophy (photoorganotrophy)	Solar radiation	CO_2 and organic C
Heterotrophy:		
Chemoautotrophy (chemolithotrophy)	Oxidation of inorganic compounds (usually only in certain bacteria)	CO_2 only[b]
Chemoheterotrophy (chemoorganotrophy)	Organic compounds	Organic C only

[a] Modified from Tuchman (1996).
[b] From free CO_2 or HCO_3^-.

(1974), Neilson and Lewin (1974), and Tuchman (1996).

A few algae are ***mixotrophic*** and assimilate carbon dioxide in small amounts simultaneously with organic compounds both in the light and especially in darkness. In other words, photoautotrophy in the light can be supplemented by the assimilation of organic compounds in the dark. In comparison to bacteria and fungi, heterotrophic algae can utilize only a few substrates, such as acetate and related compounds (pyruvate, ethanol, lactate, and higher fatty acids), glycolate, hexose sugars, and amino acids. None of the algae known to grow heterotrophically can do so under anaerobic conditions. The ability to utilize organic substrates requires specific enzymes for transport across cell membranes, and many algae are deficient in these enzymes. In certain species that possess the enzymes, organic substrates still are not utilized because of an apparent impermeability of the cells or an inability to couple their dissimilation to the generation of adenosine 5′-triphosphate (ATP).

It must be emphasized that in most cases in which algal heterotrophic utilization of organic substrates has been demonstrated, concentrations of substrates were very high, often several orders of magnitude greater than those found in most natural waters. Furthermore, culture conditions have been bacteria-free, which eliminates the competitive interactions of bacteria that possess much more efficient active uptake mechanisms. Nearly all analyses *in situ* with natural populations have led to the following conclusions: (a) At naturally occurring substrate concentrations, the low affinity of algae for simple organic substrates makes heterotrophy a relatively inefficient and unimportant process in comparison to photoautotrophy; (b) algae generally cannot compete effectively with bacteria for available substrates (e.g., Wright and Hobbie, 1966). This subject is discussed at greater length later on (Chap. 17).

Although it is obvious that photoautotrophic metabolism is the primary means of synthesis among algae and cyanobacteria in lake systems, it is incorrect to dismiss heterotrophic metabolism in natural populations of algae as unimportant. Indeed, there is evidence that heterotrophy and photoheterotrophy can be instrumental in subtle but important ways in the survival, competition, and succession of algal and cyanobacterial populations. Under conditions of light limitation, as occur deep in the hypolimnion, in turbid reservoirs, under heavy snow and ice cover, at extremely high latitudes at which total darkness exists for a period, or when very dense populations lead to shading, an ability to be facultatively heterotrophic (mixotrophy) is competitively advantageous. Observations of apparently viable and even reproducing phytoplanktonic algae under ice in northern Scandinavia during almost total darkness are incompletely explained (Rodhe, 1955). Some evidence exists that phytoplankton can compete with bacteria for acetate, but not glucose, under low light conditions (Maeda and Ichimura, 1973; Vincent, 1980; Vincent and Goldman, 1980). Certain deepwater cyanobacterial populations, especially *Oscillatoria,* are facultatively heterotrophic under very low light conditions (Saunders, 1972c). Earlier remarks should be recalled on the possible utilization by these populations of extremely low light intensities to generate ATP by photophosphorylation without concomitant CO_2 reduction, which could be potentially important in maintaining viability without significant growth.

If abundant concentrations of organic carbon substrates are present in the environment, the light-independent biochemical reactions of the Calvin cycle may be blocked (Sheen, 1990) and ATP utilized to transport extracellular organic substrates into the chloroplast or cell, in the case of cyanobacteria. True ***photoheterotrophy,*** in which organic substrates serve as a significant source of cell carbon during growth, is more restrictive in that different metabolic pathways are involved. When organic loading is very high, such as in sewage oxidation ponds, algae such as *Chlamydomonas* can assimilate most of the acetate (generated by anaerobic bacteria) by photoheterotrophy, which involves photosynthetic production of ATP and reducing power (Eppley and Macias, 1963). Although photoheterotrophy is generally not of quantitative importance in most natural waters, evidence indicates that it can amount to at least 20% of total inorganic carbon fixation at low light intensities in certain oligotrophic lakes (McKinley and Wetzel, 1979). Two periods of relatively high photoheterotrophic uptake activity were observed: one during spring turnover and a second during the late summer stratified period. The greatest photoheterotrophic contributions to overall carbon cycling occurred during morning-to-midday periods and at intermediate depths of the lower metalimnion. Microautoradiographic techniques have demonstrated selective utilization of organic substrates by algal and bacterial species (cf. Ellis and Stanford, 1982). Slight supporting evidence suggests that glucose can improve survival of algae by photoheterotrophy under light-limited conditions (Amblard *et al.,* 1992). Photoheterotrophy could potentially augment photoautotrophy among algal and cyanobacterial communities attached to surfaces (Tuchman, 1996). Exogenous dissolved organic substrates are certainly more concentrated within these periphytic communities than is the case among phytoplankton. Steep environmental gradients, particularly of light (e.g., Losee and Wetzel, 1983), within the attached communities could enhance photoheterotrophic utilization of organic substrates released by active and senescing microbiota.

VII. OTHER EFFECTS OF DISSOLVED ORGANIC MATTER

The extracellular production and release of antibiotics or growth inhibitors have been suggested in numerous cases from observations of the inhibitory effects of one alga on another in both mixed cultures and natural populations (Proctor, 1957; Krauss, 1962; Lefèvre, 1964; Hellebust, 1974). The chemical composition of these compounds is poorly understood. Inhibitory compounds include peroxides of fatty acids and possibly polyphenolic substances, such as humic acids. Stimulatory compounds include a number of weak organic acids, especially glycolic acid. The effectiveness of antibiotics is governed in part by species specificity, relative concentrations, and rates of bacterial degradation. Such substances may play important roles in the succession of species under natural conditions and are a fertile field for investigation.

Other effects of dissolved organic compounds include a number of ways in which the organic substances affect the availability of inorganic micronutrients (Saunders, 1957; Wetzel, 1968). Chelation of metal ions, an equilibrium reaction between a metal ion and an organic chelating agent, results in the formation of a stable ring structure incorporating the metal ion. Chelation can function in several complex ways in accordance with environmental conditions. The extent to which chelation of metallic ions occurs within a heterogeneous solution, such as lake water, is governed by the bonding characteristics of the organic compounds, the ratio of chelator to metal ions, and stability constants of chelates for different ions. Temperature, hydrogen ion activity, and the concentration and ionic strength of various anions further influence the extent of complexing (Brezonik, 1994). Other organic and inorganic compounds present in fresh waters function as sequestering agents for metals and cations (cf. Chaps. 10 and 14). Complex formation occurs with pyrophosphate, and metals are bound by the complex formation with macromolecules such as proteins (Povoledo, 1961) and by the formation of peptidized metal hydroxides of yellow humic substances (Shapiro, 1964).

Organic complexing of metal ions and major cations can influence the specific composition and succession of algal populations. Examples of some of the mechanisms involved include (a) increases in the availability of inorganically reactive ions, such as iron and manganese (Chap. 14); (b) modifications of membrane permeability and osmoregulation by complexing of cations, which results in changes in monovalent:divalent cation ratios (Chap. 10); (c) reduction of the concentration of a trace metal toxic to a particular organism below the threshold of toxicity by excessive complexing of the metal ions by organic compounds; (d) under certain circumstances increasing the concentration of the toxicant to harmful levels by the complexing and effective completion of organic compounds with a metal ion that is antagonistic to a toxicant; in addition, as discussed earlier (p. 261), evidence exists for the formation of organophosphorus–humic compounds that may reduce phosphorus availability to phytoplankton (Stewart and Wetzel, 1982).

VIII. SEASONAL SUCCESSION OF PHYTOPLANKTON

In spite of the number of pervasive generalizations about the common seasonal succession of phytoplanktonic algal populations in fresh waters, close inspection of existing data shows a great diversity of patterns. Some of the disparity is related to the choice of study methods employed. For example, many of the older analyses were based solely on number of organisms, which is an extremely biased indicator in comparison to biomass because of great differences in size among algae. Furthermore, early investigators often used plankton nets of fairly large mesh size to capture algae through which significant and variable portions of the algae were lost.

Descriptions of the seasonal succession of phytoplankton in north temperate, dimictic lakes frequently include correlations of changes in dominant algal species, biomass, numbers, and rates of photosynthesis with alterations in physical and biotic factors. From these descriptions, a general pattern of phytoplankton succession has emerged. However, many variations on the general succession theme exist, particularly in lakes of other geographical regions (tropical, alpine, and polar). Although correlations are useful in pointing to possible areas of interaction for intensive study, they do not provide specific information on causal mechanisms. Briefly, the temperate pattern of phytoplankton succession involves a winter minimum of small flagellates adapted to low light and temperature, a spring burst of diatom activity and biomass, followed rapidly by a smaller development of green algae, and a transitional lull between spring and summer. Summer populations vary in relation to the trophic status of the lakes but can include either another diatom development in less productive lakes by late summer and early autumn or increases in nitrogen-fixing cyanobacteria in eutrophic lakes.

The discussion that follows integrates a detailed description of phytoplankton succession, correlations with changes in environmental parameters, and recent information on mechanistic explanations of observed

patterns. In this latter area, our knowledge is still incomplete.

A. Seasonal Successional Patterns and Periodicity of Phytoplankton

Distinct seasonal patterns and periodicity in the biomass of phytoplankton are observed in polar and temperate fresh waters. Many detailed descriptions of phytoplankton succession have been correlated with changes in environmental parameters, particularly in temperature, light, nutrient availability, and mortality factors such as grazing and parasitism. Because seasonal succession is strongly keyed to meteorological and stratification-mixing processes, patterns in temperate ecosystems differ considerably from those of tropical waters. Each will be discussed separately with the caveat that the processes are similar but the timing can differ considerably.

Generalizations are difficult to make because of the great variability observed among phytoplanktonic numbers and biomass from lake to lake. Several patterns are reasonably consistent, however:

a. The seasonal periodicity of phytoplanktonic biomass is reasonably constant from year to year. If the freshwater ecosystem is not perturbed by outside influences, such as human modifications of the watershed, nutrient loading, et cetera, the seasonal changes in phytoplanktonic populations are similar from year to year.
b. The extent of change in phytoplanktonic numbers and biomass through the seasons is usually very great, on the order of a thousandfold in temperate and polar fresh waters. Seasonal variations in tropical waters are much lower, often as little as fivefold (Fogg, 1965).
c. Maxima and minima of numbers and biomass of phytoplankton often are out of phase with rates of primary production. Primary productivity usually follows closely the annual cycle of incident solar radiation in temperate lakes.

A periodicity of species composition continuously accompanies seasonal changes in total biomass. On an annual basis, algal communities consist of a composite of perennial species (***holoplanktonic***) that persist throughout the year in the plankton and of intermittent species (***meroplanktonic***) that periodically undergo some type of diapause in resting stages. In both cases, but much more markedly in the latter type, an interplay of environmental conditions results in fluctuations in growth and competition among other species. Among the perennial species, population numbers can decrease to extremely low levels, but cells are present in the water in sufficient numbers to re-inoculate the community when growth conditions improve.

The patterns of phytoplanktonic population dynamics discussed below of lakes in the temperate and polar zones are generally in accord with those proposed by Hutchinson (1967), Margalef (1983), Reynolds (1984, 1990, 1997), Harris (1986), Sommer *et al.* (1986), Stewart and Wetzel (1986), and Blomqvist *et al.* (1994). Those patterns of tropical lakes are generally in agreement with the summaries of Lewis (1987, 1996).

B. Dimictic Lakes in the Temperate Zone

The seasonal succession of biomass of major phytoplankton groups in dimictic temperate and arctic lakes is generally separable into eight periods:

1. In ***midwinter,*** low temperatures, high water column stability, reductions of light by snow, moderate nutrient availability, and low zooplankton grazing prevail. The low biomass of phytoplankton is dominated by ultraplankton (<20 μm), particularly by flagellates of the Chrysophyceae and Cryptophyceae (Fig. 15-9). The major structuring environmental factor is light availability, which is low as a result of high reflectance from snow and high attenuation under ice. Concentrations of inorganic nutrients are relatively high, especially near the sediments, from microbial remineralization in excess of utilization and from minimal mixing to strata above.

If nutrients are adequate, growth is limited to species that are adapted to low temperatures and low light irradiance. Population accrual by slow growth often is offset by respiratory losses, secretion of organic compounds, and sedimentation of cells from the limited photic zone under ice cover. In polar regions, inappreciable or zero growth exists under conditions of midwinter near-total darkness and very heavy ice and snow cover. At lower latitudes, within the temperate zone or at latitudes influenced by maritime amelioration of winter conditions, snow and ice are less thick and opaque, allowing more penetration of light.

The community of winter algae beneath ice is usually dominated by small and often motile algae. Cryptophyceans, such as *Rhodomonas* and *Cryptomonas,* are particularly common, as well as pyrrophyceans *(Gymnodinium),* small green algae (*Chlamydomonas*), chrysophyceans (*Dinobryon, Mallomonas, Chrysococcus,* and *Synura*), some diatoms (*Synedra, Tabellaria, Fragilaria),* and euglenophyceans *(Trachelomonas)* (Rodhe, 1955; Verduin, 1959; Wright, 1964; Tilzer, 1972; Maeda and Ichimura, 1973; and Nebaeus, 1984; among many others). The coldwater, low-light-adapted species are evidently quite species-specific in their

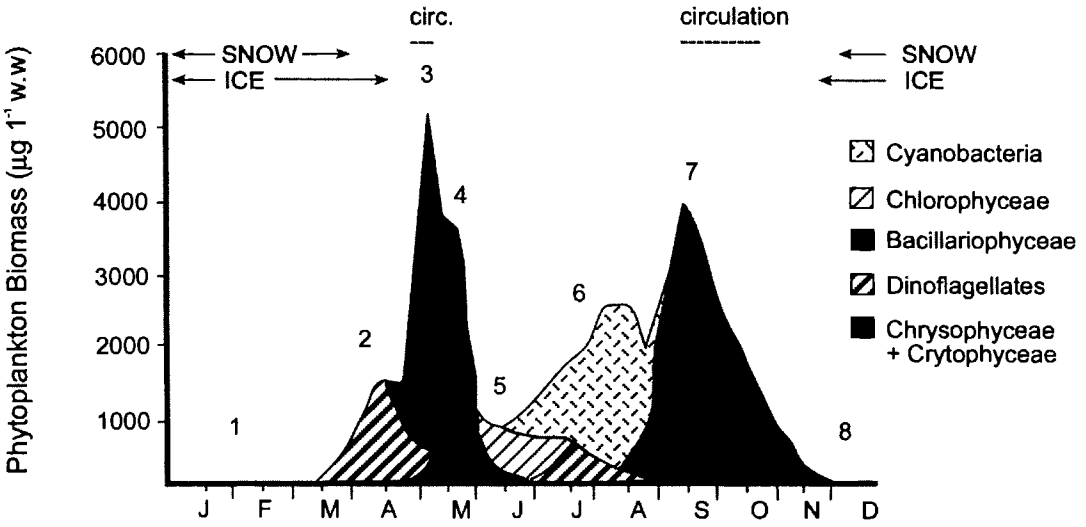

FIGURE 15-9 Model of biomass development and seasonal succession of major phytoplankton groups in a typical temperate lake of moderate productivity. Numbers refer to the eight seasonal periods discussed in the text. (Data from Lake Erken, Sweden; diagram modified from Blomqvist *et al.* (1994.)

tolerances to light quantity and quality and are found in narrow strata in the photic zone beneath the ice cover. For example, over 95% of the phytoplankton occurred in layers of the water column of an ice-covered lake of eastern Massachusetts receiving 0.5–20% of incident radiation (Wright, 1964). As discussed earlier, there is some evidence for mixotrophic growth in which photoautotrophy is supplemented somewhat by heterotrophic assimilation of simple organic substrates under darkness or very low irradiance. However, photoautotrophy dominates the metabolism of these algae, even under exceedingly low light conditions. Changes in light, as occur with snowfall on ice, result in a rapid vertical shift in the distribution and rates of photosynthesis (Fig. 15-10).

Algal blooms occur frequently under winter ice cover in shallow lakes (Nebaeus, 1984). A combination of environmental conditions of light penetrating the ice, particularly clear ice with little snow cover, high nutrient concentrations, influxes of nutrients and other growth-promoting substances from nonfrozen soils, and very low grazing losses can result in algal blooms,

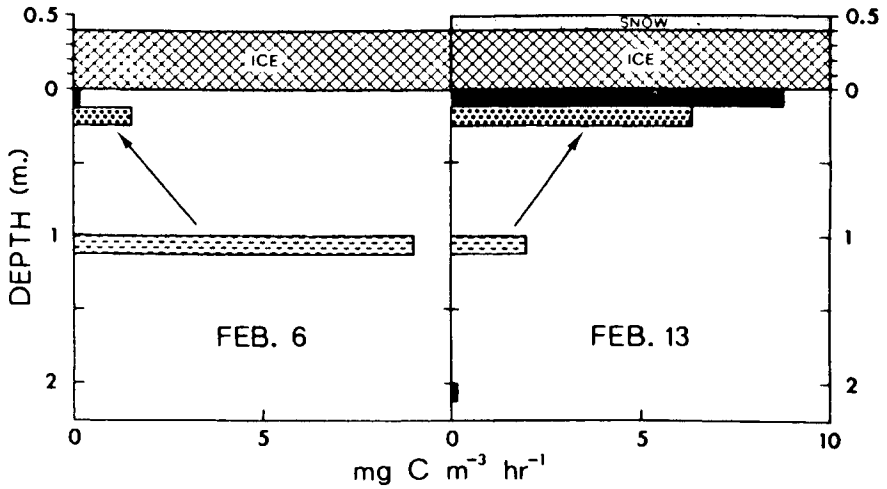

FIGURE 15-10 Rates of primary production beneath ice (6 February) and below ice and snow (13 February). Rectangles with dots are rates obtained when samples taken from 1 m were incubated alongside the surface samples. (Modified from Wright, 1964.)

particularly among the ultraphytoplanktonic (0.2–20 μm) cryptophycean and green algae. Many algae maintain reduced physiological activity under very low light conditions at temperatures of 4°C or less and are able to recover quickly once light and temperature conditions increase (e.g., Hino, 1991).

Rates of primary production under ice cover can constitute a very significant portion of the total annual primary productivity of the phytoplankton. Nearly one-quarter of the annual phytoplanktonic productivity of hypereutrophic Sylvan Lake in northeastern Indiana occurred under the 3-month period of ice cover (Wetzel, 1966a). Similar values have been found since in numerous lakes in the temperate zone, emphasizing that the widely held assumption that winter productivity is insignificant is not universally valid.

2. In ***late winter,*** conditions of low temperature, high water column stability, moderate nutrient availability, and low zooplankton grazing continue, but light availability improves not only with the seasonal (increased intensities and longer photoperiods) but often with less or no snow cover on the ice. Despite the low temperatures, phytoplankton biomass increases rapidly, particularly among the dinoflagellates that can migrate vertically and small centric diatoms (Fig. 15-9).

If temperate lakes are monomictic and circulate throughout the winter without ice cover (e.g., large lakes, subtemperate lakes, lakes at high latitudes but with moderate climate, as in Great Britain), phytoplanktonic growth is very low (e.g., Sommer, 1985). Not only is the seasonal light availability very low but phytoplankton are circulated to water depths of little or no light for long periods of time. Even though nutrient availability is high and grazing is almost nonexistent at these times, low light and movement to sites of low or no light limit photosynthesis. Only when stratification occurs, either under ice or during thermally induced density changes in the spring, can the phytoplankton achieve sufficient duration of stability to develop.

3. During the ***spring circulation,*** temperatures are still low but increasing, the water column is mixing with low stability, light conditions are highly variable but on the average low, and nutrient availability is generally high. Growth and increases in biomass, particularly by diatoms, are very rapid and usually result in the annual maximum of phytoplanktonic biomass (although usually not the maximum productivity, see p. 377). Grazing by herbivorous zooplankton is still low, although in early stages of rapid growth, during this commonly brief period of circulation.

As ice cover is lost in the spring and the season progresses, circulation of the water column results in the mixing of nutrient-laden water from lower depths with surface strata, which have more light. In shallow lakes in which the light penetrates throughout much of the water column, the spring algal maximum is often initiated by coldwater, *polyphotic*[4] species under ice in late winter. These species flourish and develop throughout the period of circulation and may persist for a time after summer stratification begins. The circulation of small lakes is commonly weaker and of shorter duration than it is in larger lakes with larger fetch distances. Among large lakes, net growth of phytoplankton can be significantly suppressed during circulation if mixing occurs at such a rate and to such a depth that the algae are carried out of the photic zone faster than they can multiply. The effects of circulation are accentuated in regions, such as much of the United Kingdom, in which lakes rarely freeze or do so for only brief periods. In these areas, circulation can continue practically all winter, with a significant loss of phytoplankton occurring as a result of outflow and other mechanisms (e.g., Lund *et al.*, 1963).

There is little question that increasing light in the spring is the dominant factor contributing to the development of the spring "outburst," because water temperatures are still low. The spring maximum is frequently dominated by one species, a diatom, such as *Asterionella* discussed earlier (Fig. 14-18), *Cyclotella,* or *Stephanodiscus* (see, e.g., Pechlaner, 1970). Although a lag phase often is not seen before the dominants reach exponential growth phases, it obviously exists and is observed if one samples frequently (e.g., Lund, 1950). In Lake Erken, Sweden, some lag in the response of the algae constituting the spring maximum to the increase in radiation was caused by the necessity for light adaptation, even when the intensities of photosynthetically usable energy were still low (Pechlaner, 1970).

The relative rates of increase[5] of the dominant algae during the spring maximum of exponential growth are usually much less than rates of increase observed in cultures grown under "optimal" conditions of light and temperature (Fogg, 1965). This difference

[4]Adapted to a wide range of light intensities.

[5]The relative rate of increase is a function of the generation time (G), that is, the mean doubling time if the cells divide by two or

$$G = \frac{\log 2}{k'} = \frac{0.301}{k'},$$

when k' = the relative growth constant under exponential conditions, or

$$k = \frac{\log_{10} N - \log_{10} N_0}{t}$$

when N_0 is the initial concentration of cells, N is the final cell concentration, and t the time interval.

is variously attributable to restrictions of light, temperature, nutrients, and losses of cells by sedimentation and other causes.

The combined effects of nutrient limitations and suboptimal temperatures on the growth of diatoms and green algae in cultures showed that the algae required more nutrients as temperatures declined from their optimal temperature range (Rhee and Gotham, 1980, 1981a). The optimum atomic ratio of nitrogen and phosphorus contained in the cells (i.e., the ratio at which one nutrient limitation shifts to another) increased at suboptimal temperatures. The combined effects of nutrient limitation and suboptimal temperature on growth were greater than the sum of the individual effects and were not multiplicative. The larger species, such as major spring diatoms, have generation times of about 4–8 days, which is somewhat longer than those of smaller species under natural conditions. The specific growth rates of the dominant species are considerably higher than those of the entire algal assemblage combined (e.g., Pechlaner, 1970). Continuous cultures simultaneously limited by light and nutrients also showed that the combined effects of these two factors on algal growth were greater than the sum of individual effects and that the effects were not multiplicative (Rhee and Gotham, 1981b). Under both nutrient-limited and nutrient-sufficient conditions, the cell-nutrient quota needed for growth increased as irradiance decreased, indicating that nutrient requirements increase as irradiance decreases.

It should be noted that cold- , low-light-adapted species of algae that are well developed under winter conditions can be severely limited in the spring or develop only in deeper strata in which temperatures and irradiance remain low. Population development in deep strata may result from actual migratory movement, as occurs among the dinoflagellates of alpine lakes, or the development of populations in lower strata through sedimentation of cells from shallower strata, as is the case among some ubiquitous cyanobacteria (e.g., *Oscillatoria rubescens*). Findenegg (1943), and others since, demonstrated the characteristic weak development of *Oscillatoria* in upper layers under winter conditions. Before, during, and after spring circulation, the *Oscillatoria* population weakens in the upper strata and increases in the deep, cold layers of the lower metalimnion and upper hypolimnion.

In high mountain lakes above the tree line, the ultraplankton (0.2–20 μm) dominate the phytoplankton and are autotrophic throughout the long winter (Pechlaner, 1971). These algae are adapted to the low light intensities that penetrate heavy ice and snow cover. Both the concentration of algae and rates of *in situ* photosynthesis shift from the surface layers in winter to deep water strata during spring and summer. Immediately before ice breakup the increasing light induces a downward migration of predominating dinoflagellates.

4. During the ***initial summer stratification,*** temperatures increase rapidly as the water column stability returns, light availability increases, and nutrient availability declines. Phytoplankton biomass declines precipitously in the beginning largely as a result of sedimentation of diatoms. Enhanced sedimentation, photoinhibition, and phosphorus limitation are factors that may slow net diatom accumulation before the onset of silicate limitation (Neale *et al.,* 1991a,b; Poulíčková, 1993). Species-specific differences in mortalities are also known. For example, high death rates of the diatom *Asterionella formosa* in Lake Constance, Germany, in late spring were associated with silicon depletion, whereas the decline of the diatom *Fragilaria crotonensis* was enhanced by fungal parasitism, as discussed later (Sommer, 1984). Rapid growth of small flagellate algae compensates for some of the community losses, but grazing by zooplankton increases rapidly.

5. In the early ***summer "clearwater" phase,*** algal populations decline precipitously under conditions of high temperatures, high water column stability, high light availability, and markedly reduced nutrient availability (Fig. 15-9). Herbivorous zooplankton increase from the hatching of resting stages and from the high fecundity associated with the relative abundance of edible algae. The planktonic herbivores with short generation times (rotifers and ciliates) increase their populations first and are followed by slower-growing species (cladocerans and copepods). Algae <40 μm are particularly vulnerable, and the grazing losses result in community filtration rates that exceed phytoplankton reproductive rates. This "clearwater" phase can result in accelerated microbial nutrient regeneration from zooplankton grazing and can persist for several weeks until less readily grazed and inedible algae develop to significant population sizes.

The decline of the spring maximum of phytoplankton and onset of summer populations in temperate lakes is associated with a complex interaction of physical and biotic parameters. In many straightforward cases, reduction of nutrients in the photic zone of the epilimnion is responsible for slowing the growth of populations of the dominant as well as rarer algae. Since diatoms are often the dominant component of the spring maximum, especially in temperate fresh waters, silica concentrations are often reduced after extensive growth. The reduction of silica concentrations to limit-

ing levels (<0.5 mg liter^{-1}; cf. Kilham, 1975) has been shown repeatedly in many fresh waters but is especially well documented in the northern British lakes, in which maximum concentrations are low (2–3 mg liter^{-1}) (Fig. 15-11; see also Fig. 14-22). Reduction of silica to limiting concentrations occurs in less than two months when turbulence is low and sedimentation of diatom frustules occurs rapidly (Fig. 15-11).

In calcareous lakes in which silica concentrations are naturally high (>10 mg liter^{-1}), silica levels can still be reduced appreciably during the spring and summer in the epilimnion (e.g., Fig. 14-21, *upper*). Utilization by diatoms continues throughout the period of the summer stratification. As hardwater lakes become more productive, the rapidity of silica reduction increases. For example, in extremely eutrophic Windermere Lake (Fig. 14-21, *lower*), concentrations are reduced to and below generally accepted inhibiting levels in both winter and spring periods.

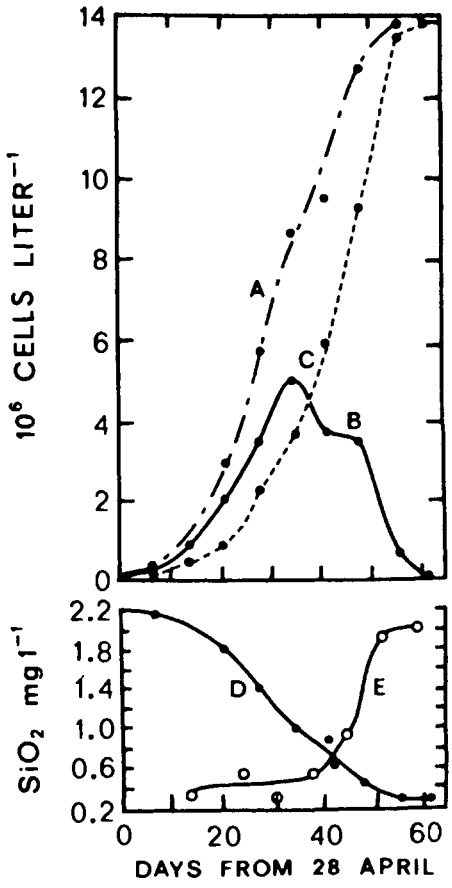

FIGURE 15-11 Production and loss of *Asterionella formosa* in the epilimnion of Lake Windermere, England, from 28 April to 30 June 1947. (A) Cumulative total of cell production computed from silica uptake; (B) mean concentration of cells in epilimnion; (C) cumulative loss of cells from the epilimnion (A minus B); (D) epilimnetic silica concentration; and (E) relative rates of loss of cells from the population. (Modified from Lund *et al.*, 1963.)

The correlations between the observed decline of the diatom maximum with diminishing silica concentrations and the experimental results using bioassays are so distinct that the relationship appears to be predominantly causal. Factors of light intensity, temperature, nitrogen, phosphorus, zooplankton grazing, and fungal parasitism contribute to but are not necessarily instrumental in the decline. Much more complex interactions of both physicochemical and biotic factors undoubtedly exist in the seasonal succession of diatom populations when silica concentrations are not reduced to levels limiting to exponential growth. For example, the decline of the dominant spring diatom *Asterionella formosa* of a small mesotrophic lake was correlated more with combined nitrogen limitation than with depletion of silica (Lehman and Sandgren, 1978; Lehman, 1979).

Much insight into the competitive interactions among dominant spring blooms of algae has been gained from detailed experimentation in cultures (the general methodology of competitive nutrient kinetic analyses is reviewed by Kilham, 1978). Nutrient kinetic parameters of two common spring diatoms, *Asterionella formosa* and *Cyclotella meneghiniana,* showed that maximal growth rates of the two species were not significantly different (Tilman and Kilham, 1976). *Asterionella* was able to grow significantly better, however, at low concentrations of extracellular phosphate, and *Cyclotella* grew better at low concentrations of silica. Using the resource-based competition models (Titman, 1976; Tilman, 1977, 1978) discussed earlier (p. 349), the outcome of nutrient competition between these two species showed that (a) under conditions in which both species were phosphate-limited, *Asterionella* would be dominant; (b) under conditions in which both species were silica-limited, *Cyclotella* would be the competitive dominant; and (c) under intermediate conditions in which the growth rates of each species were limited by different nutrients (*Asterionella* by silica and *Cyclotella* by phosphate), both species would coexist stably. The model was verified for these species both experimentally and in natural populations along nutrient gradients (Kilham and Titman, 1977; Stoermer *et al.*, 1978). These studies indicate that a species is growth-limited by only one nutrient at a time and that where two species are growth-limited by different nutrients simultaneously, they can coexist.

Gradients in nutrients and in the ratios of different nutrients exist both spatially (e.g., from nearshore to

openwater areas) and seasonally when utilization or losses exceed inputs. Concentration of a nutrient is important to growth and phytoplanktonic community structure but so is the supply rate of one nutrient relative to other potentially limiting nutrients. Competitive dominance of species populations will develop along nutrient gradients according to the species' maximal growth rates, their half-maximal growth rates (half-saturation constants of nutrient uptake), and their species-specific mortality rates (Kilham and Kilham, 1978; Tilman, 1978, 1980; Kilham and Tilman, 1979). For example, *Asterionella* is a successful competitor at high Si/P ratios, *Fragilaria* can dominate at intermediate ratios, and *Stephanodiscus* grows well when Si/P ratios are low.

6. The ***latter part of summer stratification*** exhibits conditions of high temperatures, high water column stability but a progressive erosion and deepening of the metalimnion, high but declining light availability, and low nutrient availability. Herbivorous zooplankton become food-limited, and their collective biomass declines precipitously from decreased fecundity and greatly increased fish predation. The greatly reduced grazing pressures and increasing nutrient availabilities from processes such as erosion of the metalimnion and parts of the hypolimnion result in a more diverse phytoplanktonic community. Chrysophytes, cryptophytes, and colonial green algae frequently become abundant, and their growth often reduces availability of phosphorus and commonly also combined nitrogen (NO_3^- and NH_4^+) to limiting concentrations.

If silica is abundant, the green algae are often replaced by large diatoms. Commonly, however, silica levels are reduced in the trophogenic zone in late summer. Under these circumstances of silica depletion (<0.5 mg SiO_2^- liter^{-1}), dinoflagellates and cyanobacteria dominate (Fig. 15-9). As summer algal growth utilizes combined nitrogen to very low concentrations, filamentous cyanobacteria capable of fixing molecular nitrogen often dominate, a very common sequence in temperate lakes (cf. earlier discussion; Dokulil and Skolaut, 1986; many others). The ability of many cyanobacteria to migrate by buoyancy alterations (cf. p. 347) between lower depths of relative nutrient abundance and upper strata of light abundance (e.g., Gamf and Oliver, 1982), as well as the ability to fix molecular nitrogen from atmospheric sources, results in a superior competitive position in relation to other species of phytoplankton. Certain cyanobacterial species can be recruited from the sediments, particularly during midsummer. For example, a significant portion of the bloom-forming cyanobacterial populations of a small reservoir was gained by migrations from the sediments into the overlying waters (Trimbee and Harris, 1984).

In shallow lakes where inputs of nutrients, such as silica and/or combined nitrogen, from the sediments or external sources exceed microbial utilization, faster-growing chlorophytes or diatoms can become superior competitors compared with the relatively slow-growing cyanobacteria (Hecky *et al.*, 1986; Jensen *et al.*, 1994). Nutrient turnover rates and availability to biota can be very high in shallow lakes, even when inorganic nutrient concentrations are low and the pH high.

The spring maximum of phytoplanktonic biomass is generally short-lived, usually less than one to two months in duration. This maximum often is followed by a period of low algal numbers and biomass that may extend throughout the summer. Among more eutrophic lakes of the temperate region, the summer minimum is often brief and phases into a late summer profusion of cyanobacteria that persists into the autumn, until thermal stratification is disrupted. Populations of phytoplankton are often low throughout the summer in temperate oligotrophic lakes but may develop a second maximum in the autumn period (Fig. 15-9). This second maximum of the autumn, which often consists predominantly of diatoms, is generally not as strongly developed as that of the spring period (e.g., Diaz and Pedrozo, 1993). The decline of the autumnal populations into the winter minimum is often abrupt and more irregular than the decline after the spring development. The limited growing season of lakes of high altitudes and in polar regions often is reflected in a conspicuous, single, summer maximum of phytoplanktonic biomass.

As silica concentrations are reduced in productive lakes, diatom populations are often succeeded by a preponderance of first green algae and later cyanobacteria (e.g., Fig. 15-9). Growth in these eutrophic lakes can be so intense that combined nitrogen ($NO_3^-$and NH_4^+) sources are reduced to below detectable concentrations in the trophogenic zone (e.g., Wintergreen Lake, Chap. 12). When this happens, often by midsummer when the warmest epilimnetic temperatures occur, cyanobacteria with efficient capabilities for fixing molecular nitrogen have a competitive advantage and can predominate (cf. Chap. 12). These lakes require, as a general rule, a reasonably sustained and heavy loading of phosphorus (cf. e.g., Moss, 1973c).

Gradients in nutrient ratios are commonly observed during and after the spring diatom outburst in eutrophic lakes because phosphorus and nitrate concentrations decline at different rates (e.g., Pechlaner, 1970). As a result, the Si/P ratio increases and the N/P ratio decreases markedly. At high Si/P ratios, diatoms can effectively outcompete cyanobacteria (e.g., Holm and Armstrong, 1981). As concentrations of silica are reduced, and later combined nitrogen declines, green

algae can compete less effectively with cyanobacteria that possess N_2-fixing capabilities.

Similar relationships have been demonstrated in many lakes (e.g., Reynolds, 1976) and occur on a much larger scale in the Laurentian Great Lakes (Schelske and Stoermer, 1971, 1972; Schelske *et al.*, 1972). Phytoplanktonic algae in the upper Great Lakes are distinctly phosphate-limited. As the loading of phosphorus to the lakes has increased, diatoms reduce the available silica (ambient concentrations about 2–3 mg liter^{-1}) to limiting levels more rapidly with each successive year. The diatoms then are replaced rapidly by green algae and cyanobacteria. Increased loading of trace metals, vitamins, and dissolved organic matter further accelerates the algal succession. Experimental additions of nitrogen and phosphorus to ponds also demonstrated the influence of these nutrients on phytoplankton succession; with nitrogen and phosphorus enrichment, chrysophyte species were replaced by green algae and cyanobacteria (DeNoyelles and O'Brien, 1978).

A series of papers by Moss (1972c, 1973a–c) is instructive in relation to both the seasonal succession and the distribution of phytoplankton. Changes in nutrient concentrations are just as important to seasonal periodicity within a lake as different nutrient concentrations among lakes are important in determining algal distribution. Working with 16 species of diverse but widely distributed phytoplanktonic algae, Moss found little effect of calcium ions above a concentration of 1 mg liter^{-1} among both oligotrophic and eutrophic species. No evidence was found to support the contention that oligotrophic desmids are calciphobic. Certain oligotrophic algae were unable to grow at pH values greater than 8.6, whereas eutrophic species able to utilize both CO_2 and bicarbonate grew well at pH values >9. Temperature optima for growth were similar to those discussed earlier: Diatoms have an extended range into lower temperatures, whereas green algae and cyanobacteria grow well at temperatures >15°C. Temperatures >15°C are common in many temperate waters throughout much of the summer and in tropical waters for the entire year. Temperature and nutrient interactions generally could be verified in experimental bioassays using a variety of natural lake waters ranging from oligotrophic to extremely eutrophic.

7. During ***fall circulation,*** the mixing water is characterized by progressively declining temperatures, low and decreasing light availability, declining grazing by zooplankton, and high nutrient availability from the redistribution from the hypolimnion. Large unicellular and filamentous algae, predominantly diatoms, dominate this long period (often 3–4 weeks) of mixing (Fig. 15-9).

8. During the ***late autumn decline,*** low temperatures, declining light availability, and low nutrient availability results in declining phytoplankton biomass, despite low grazing rates (Fig. 15-9).

C. Tropical Lakes

Tropical lakes are far less numerous than temperate lakes[6] and are dominated by lakes of river origin (Lewis, 1987, 1996). Greater solar irradiance with reduced annual variations result in higher minimum water temperatures. Although smaller thermal discontinuities exist between upper and lower water strata, density differences can be very large and result in high stabilities. The predominantly warm monomictic tropical lakes exhibit great regularity in seasonal mixing, which typically coincides with the hemispheric winter. Although stratification is seasonally persistent, it is less stable than in lakes at higher latitudes. As a result, intraseasonal variations in the mixing and thickness of the mixed strata are much greater than is the case for morphometrically similar temperate lakes (Lewis, 1973; Viner, 1985; Talling, 1986). The high mean temperatures and variable mixing and intrusions into the metalimnion during the stratified period result in high nutrient regeneration rates and, consequently, affect phytoplankton succession and productivity. These intermittent mixing episodes into the metalimnion disturb and reset the successional sequence. Although the successional sequence is essentially the same in tropical and in temperate lakes, more successional episodes occur per year in tropical lakes. On an annual basis, the maximum of phytoplanktonic biomass in tropical lakes often is observed during the winter.

In many tropical lakes surrounded by extensive, nutrient-buffering wetlands and receiving perennial river inflow, total phytoplanktonic biomass and productivity are often both larger and more constant seasonally than those found in temperate lakes. Abrupt changes in abiotic factors (e.g., wind-induced vertical mixing; marked seasonality in rainfall and associated nutrient loading and turbidity) can be more frequent in tropical lakes than in temperate lakes that are stratified for longer periods of time (Talling, 1969, 1986; Lewis, 1978a,b, 1996; Melack, 1979). Episodic changes are often very regular in their seasonality from year to year, and phytoplankton succession within any given episode is similar in tropical and in temperate lakes. Phytoplankton communities are no more complex in tropical lakes than in lakes of higher latitudes (Lewis, 1996).

[6]Some exceptions exist in small areas. For example, in the geologically turbulent and varied archipelago of Indonesia, containing over 11,000 islands, natural lakes are abundant, many of which are large and some are very deep (>250–500 m) (Lehmusluoto *et al.*, 1998).

Phytoplankton diversity is not markedly different than in temperate lakes.

D. Algal Succession and Productivity in Reservoirs

Within reservoirs the irregular dynamics of inflow and rapid, variable flushing rates markedly alter environmental conditions for biotic communities. A reservoir can be viewed as a very dynamic lake in which a significant portion of its volume possesses characteristics of and functions biologically as a river. Often, the riverine portion of reservoirs operates analogously to large, turbid rivers in which turbulence, sediment instability, high turbidity, reduced light availability, and other characteristics preclude extensive photosynthesis despite high nutrient availability (Fig. 15-12). Although the phytoplanktonic primary productivity of riverine sections of reservoirs can be high per unit water volume, the limited photic zone reduces areal productivity, as in large rivers (Wetzel, 1975; Minshall, 1978; Bott, 1983; Wetzel and Ward, 1992). This reduction is only partially ameliorated by turbulent, intermittent recirculation of algae into the photic zone. As turbidity is reduced and the depth of the photic zone increases in the progression through the transitional to the lacustrine reservoir zones, areal primary productivity increases with the resulting greater light penetration and depth of the trophogenic zone (Fig. 15-12). Nutrient limitations, so characteristic to the successional changes of natural lakes of low-to-moderate productivity, can then occur to varying degrees as utilization and losses of nutrients exceed renewal rates.

Light limitation is a dominant control of productivity in most reservoirs, as it is in many productive natural lakes and rivers. In many cases, light limitations in reservoirs result primarily from inorganic clay and silt turbidity. Where light limitations result from high loadings of dissolved organic matter, as in many tropical and subtropical reservoirs, the total and selective spectral light attenuations are quite analogous to those of natural lakes (cf. pp. 56–63).

The succession of phytoplankton communities of the lacustrine portion of reservoirs is generally similar to that found in natural lakes. Disturbance frequencies are much higher in reservoirs than in lakes, with rapid, often irregular and large, changes in water level, flushing rates, turbidity, and mixing (Wetzel, 1990b). In particular, the disturbances to stratification and loadings of inflowing silt that increase turbidity are dominant factors affecting phytoplankton periodicity and succession (e.g., Bettoli *et al.*, 1985; Duthie and Stout, 1986; Ramberg, 1987; Zohary *et al.*, 1996). Variations in flushing rates influence not only nutrient availabilities but also turbidity, and they can overrule the importance of other regulating factors, as is the case in shallow lakes (Bailey-Watts *et al.*, 1990). Green algae and planktonic diatoms are commonly dominant in summer during periods of short residence times, and cyanobacteria develop more strongly when water residence times are longer, such as during dry years (Lepš *et al.*, 1990; Perry *et al.*, 1990). As a result, the phytoplankton communities of reservoirs are disrupted often, which leads to increased diversity with the development of *r*-strategist species whose development and successional sequences are constantly being reset.

IX. MORTALITY OF PHYTOPLANKTON

Growth and productivity of phytoplankton populations are counterbalanced by losses by sedimentation out of the photic zone, viral and fungal parasitism, and grazing by zooplankton. As already discussed in a general way, these mortality losses couple with direct growth factors of temperature, light, and nutrients to determine succession and rates of productivity. Rates of algal sedimentation have already been discussed in relation to environmental factors influencing sinking rates of different groups.

A. Viral, Bacterial, Protozoan, and Fungal Pathogens

Viral pathogens of phytoplankton can lyse many different types of phytoplanktonic algae and cyanobacteria (Saffermann and Morris, 1963; Shilo, 1971; Suttle *et al.*, 1990). Viral particles, in the size range of 0.002–0.2 μm, reduce rates of primary production by as much as 78%. Preliminary data suggest that about 20% of heterotrophic bacteria are infected by viruses and 10–40% of the bacterial community is lysed daily by viruses (Suttle, 1994; Mathias *et al.*, 1995; Wommack and Colwell, 2000). The percentage of eukaryotic phytoplankton lost to viral lysis is likely lower on a daily basis. A diurnal periodicity in viral infectivity is likely if the viruses are exposed to natural sunlight. Viral decay rates increased markedly when exposed to sunlight (Suttle and Chen, 1992).

Viruses exhibit host specificity, and this quality suggested potential application for control of cyanobacterial blooms. Attempts to exploit this specificity for control of cyanobacterial blooms have not been very successful (Jackson and Sládeček, 1970). Cyanophage-resistant mutants can develop quickly among the cyanobacteria. Viral infections of natural blooms of cyanobacteria have apparently led to significant reductions of phytoplankton densities (Daft *et al.*, 1970; Coulombe and Robinson, 1981).

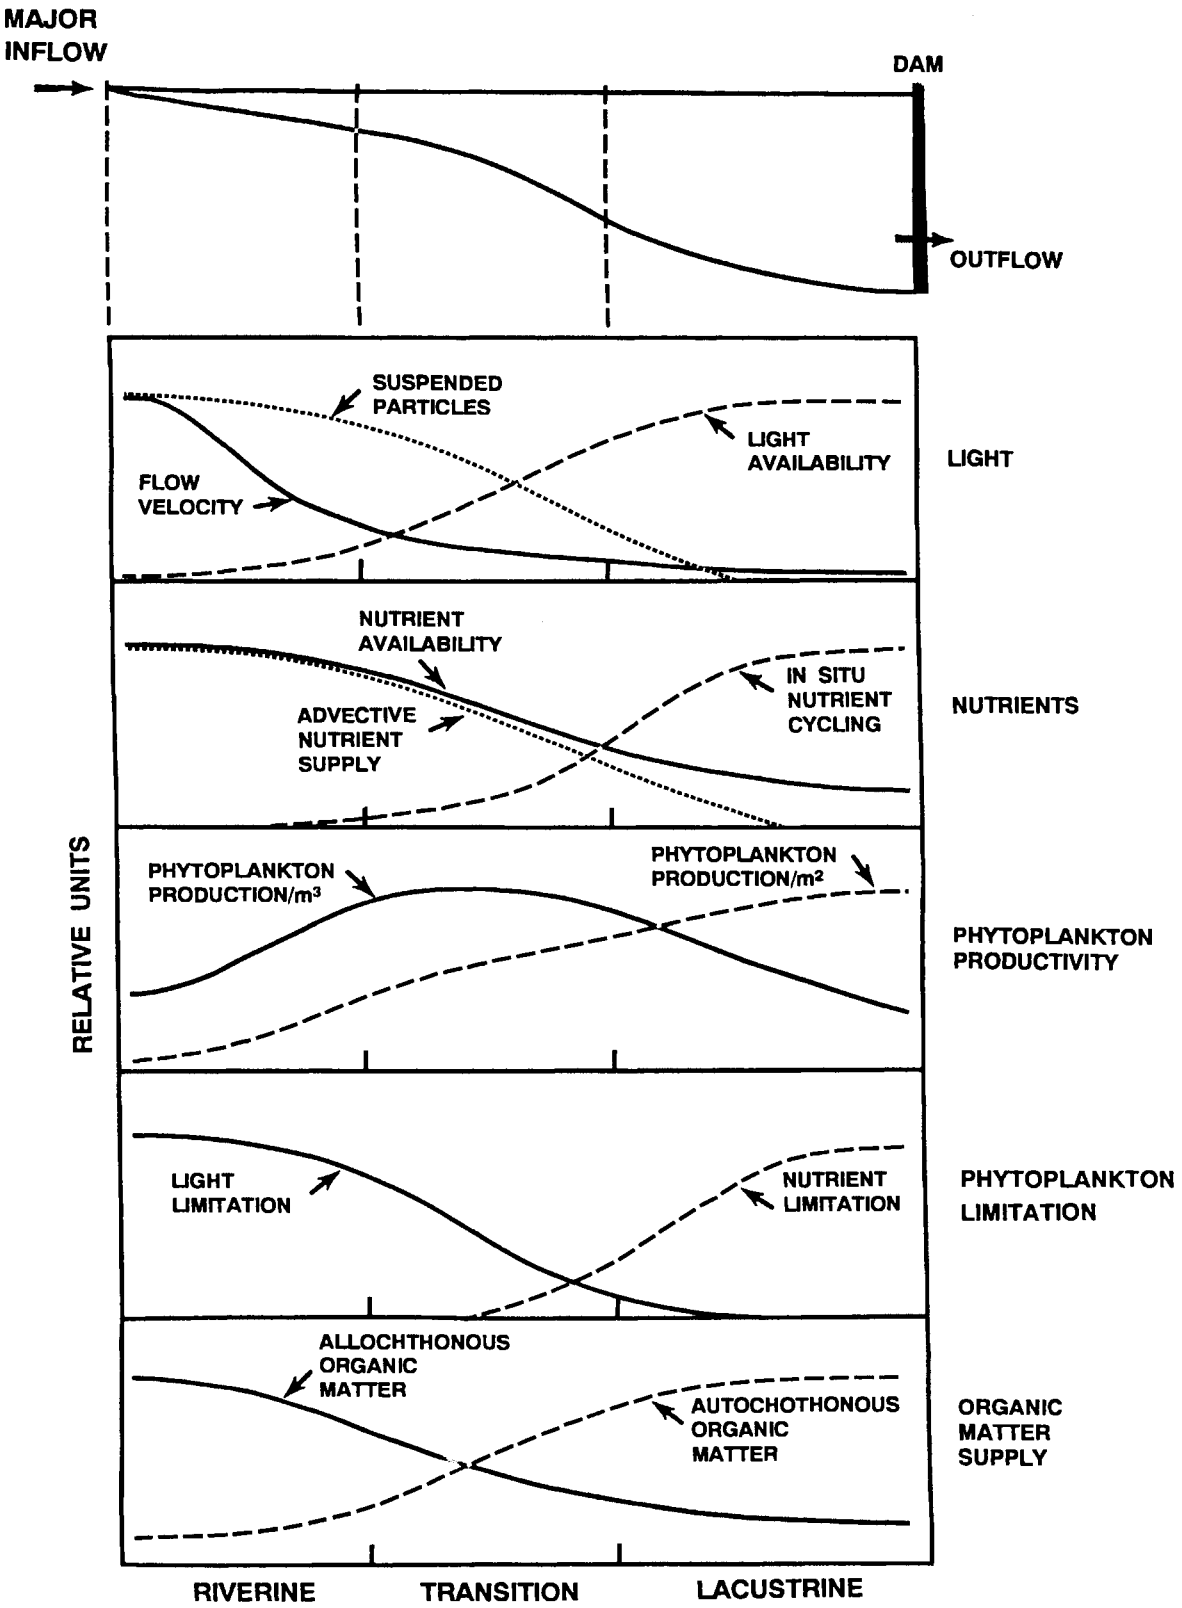

FIGURE 15-12 Commonly observed shifts in flow, turbidity, light, nutrients, phytoplanktonic productivity, and sources of organic matter in the progression through the three major zones of reservoirs. (Modified from Kimmel *et al.*, 1990.)

Bacterial pathogens, largely of the Myxobacteriales, of phytoplankton lyse many species of unicellular and filamentous algae as well as cyanobacteria (Shilo, 1970). Little is known of the significance of bacterial pathogens in the regulation of algal growth, production, and succession.

Many protozoans and related protistian organisms feed directly on algae and bacteria. These processes will be discussed with numerous examples in the following chapter. Some protozoa, however, feed upon algae with parasitic characteristics. Some species of protozoa attach to algae and extract the contents with filiform appendages or digest the contents while remaining outside the cells (Lund, 1965; Canter, 1973; Brabrand *et al.*, 1983). Certain herbivorous protozoans feeding on small colonial algae have been shown to decimate over 99% of certain chlorophycean planktonic algal populations over short periods (7–14 days) (Canter and Lund, 1968). Some of these protozoans, such as *Pseudospora*, consume only certain species of algae. The effects on seasonal succession of algal populations are obvious.

Many algal species are parasitized by aquatic fungi, mostly of the uniflagellate Chytridiales (Chytridiomycetes) that are external parasites and the biflagellate Oomycetes that are internal parasites. In the free-swimming stage of their life cycle, zoospores disperse widely (Canter, 1979; Canter and Heaney, 1984; van Donk, 1989; van Donk and Bruning, 1995). Upon the settling of chytrid fungi on an algal cell, the flagellum penetrates the cell wall and forms an internal rhizoid through which organic contents of the alga are extracted. The fungus then enlarges as a sporangium, which upon maturation produces and releases zoospores. The sporangia of biflagellate fungi are located within the algal host cells and when mature pass from the alga for final zoospore maturation.

Fungal parasitism can influence phytoplankton succession by suppression of maximum population development under the existing environmental conditions. Because most fungal parasites are host specific, infection of one algal species can favor successional development of other competing species (van Donk, 1989). Differences in the composition or amount of extracellular algal exudates likely influence the susceptibility of an algal population to fungal infection by zoospores. However, a number of environmental factors influence both the development of the fungi and their reproductive rates in relation to those of algal host species. Environmental factors, such as light or nutrients, that limit algal reproductive rates may enhance development of a fungal epidemic, as long as the same factors do not limit fungal development (Bruning and Ringelberg, 1987). Losses of host cells can vary greatly, however, as they depend on growth rates of uninfected host cells, the development times of the sporangia of the parasite, and losses of infected and uninfected host cells from processes other than parasitism (Kudoh and Takahashi, 1990, 1992; Bruning, 1991a,b). Temperature variations markedly influence the occurrence and success of phytoplankton parasitism, because at low temperatures development times of sporangia are much slower than those of many algae, particularly diatoms. Algal infection by some chytrid fungi occurs only at low temperatures (Blinn and Button, 1973). Light limitations to host algae could enhance the success of fungal parasitism (van Donk and Bruning, 1995). Nutrient limitations of the algal host could reduce the threshold host densities needed for the development of an epidemic.

Among the best studies of chytrid fungal parasitism, centered in the English Lake District, infection of desmids, diatoms, and cyanobacteria is fairly common. Even though percentage fungal infections can be very high (>70%) and chytrids can parasitize healthy, rapidly growing cells as well as declining senescent algae, parasitism usually does not greatly alter the overall seasonal pattern of periodicity of diatoms and desmids (Canter and Lund, 1948, 1969). Fungal parasitism, however, can have a significant effect on interspecific competition of algae because of the degree of specificity in the algae attacked. Reduction of dominant desmids apparently is influenced to a greater extent by parasitism, whereas the diatom decline, particularly of *Asterionella*, results from a combination of reduced nutrient and parasite interactions. Certain diatom clones react hypersensitively to chytrid parasites, which results in both the death of the host alga and the fungi and causes the demise of the parasite population (Canter and Jaworski, 1979). Parasitism likely increases in eutrophic waters, but little is known of its quantitative significance.

B. Grazing by Zooplankton

Grazing of phytoplankton by metazoan animals, particularly by the microcrustacea, can be a significant factor in the decline of algal populations under certain conditions. As a result, selective feeding contributes to seasonal succession of phytoplankton. Although most of this discussion will be deferred to the subsequent chapter on zooplankton, a few points are appropriate here.

Small phototrophic (e.g., *Cryptomonas*) and heterotrophic microflagellates in the nanoplankton size range (2–20 μm) graze on free-living bacteria and picophytoplankton (cf. many reports cited in Sanders *et al.*, 1985; Stockner and Antia, 1986). Microflagellates

are likely major grazers of picophytoplankton and bacteria (cf. Chap. 17). Many ciliates and other microzooplankton (20–200 μm) are far less efficient than flagellates and certain small ciliates in utilization of picoplankton. Although small stages of macrozooplankton can utilize algal picoplankton and some bacteria, such grazing is much less efficient than on larger nanoplankton prey.

Phytoplankton mortality and selective changes in species composition of the phytoplankton algal and cyanobacterial community are highly variable seasonally and spatially within lakes and rivers. As temperatures of temperate waters increase in the spring, reproduction and feeding of zooplankton increase markedly. In some cases, the population and grazing maxima of zooplankton coincide with the decline of algal maxima (e.g., Crumpton and Wetzel, 1982). In other cases, inverse correlations between the two processes are found, or changes in zooplankton populations correlated better with bacterial or detrital concentrations than with those of phytoplankton. Although certain studies indicated that at a few times of the year microcrustaceans could theoretically graze the total volume of the trophogenic zone in a day (cf. Chap. 16), much lower rates (3–25%) are more usual. Zooplankton grazing can have positive effects of increased growth rates of algae by means of nutrient regeneration that could potentially offset the negative effects of grazing mortality (e.g., Elser *et al.*, 1987). A degree of size and species selectivity also exists among the grazing zooplankton. Such selectivity can lead to a competitive advantage by less effectively grazed algal species (often the largest and less edible) that tend to be not or less nutrient-limited (Havens and Costa, 1985; Lehman and Sandgren, 1985). Algal succession can thus be altered by this selectivity within prevailing physical and nutrient availability constraints. In this way, invertebrates and fish possessing size-selective feeding habits on zooplankton can influence zooplankton grazing effectiveness and, in turn, algal succession (e.g., Lampert, 1978; Sterner, 1989).

An example of seasonal succession of phytoplankton and the interaction of growth rates and mortality is seen in detailed studies of a small, oligotrophic temperate lake (Crumpton and Wetzel, 1982). Weekly measurements were made of growth rates, sedimentation rates, and population densities for each of the dominant phytoplankton species and of diurnal zooplankton grazing rates on the algae. The diatom *Cyclotella michiganiana* was the dominant alga through the end of June, at which time *C. comensis* began to increase and became dominant by August (Fig. 15-13). The combined effect of greater growth rates and lower loss rates due to sedimentation of *C. comensis* resulted in its dominance over *C. michiganiana*. In late August, high grazing pressure by herbivorous zooplankton caused rapid declines of both *Cyclotella* species, which were succeeded by the larger green alga *Sphaerocystis schroeteri*. The *Sphaerocystis* species was too large to

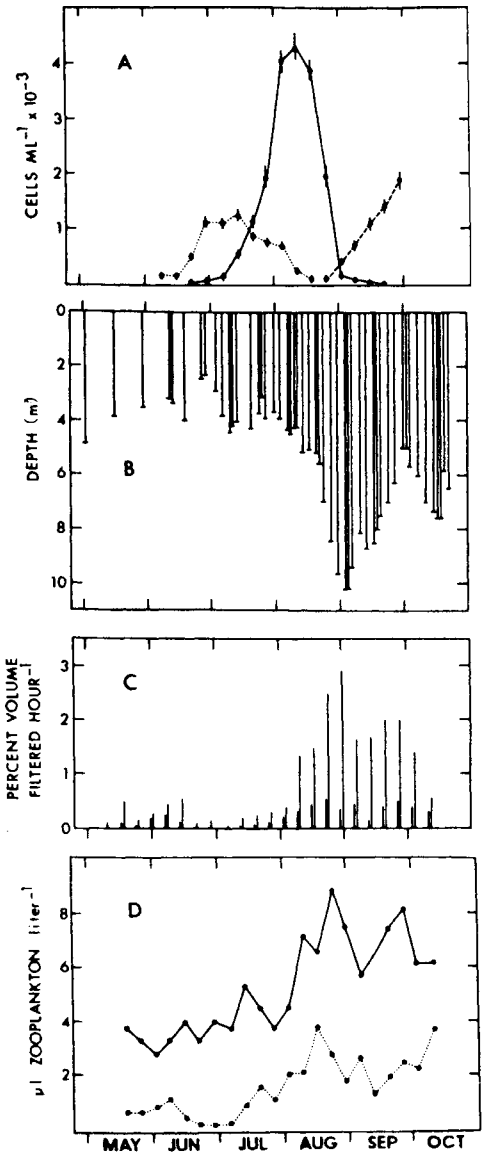

FIGURE 15-13 Dominant phytoplankton, water transparency, zooplankton grazing rates, and zooplankton biomass, Lawrence Lake, Michigan, 1979. (A) Population curves for *Cyclotella michiganiana* (- - - - -), *Cyclotella comensis* (——), and *Sphaerocystis schroeteri* (- - - -). Error bars denote 95% confidence limits. (B) Transparency (Secchi depth) in meters. (C) Grazing rates as percentage of epilimnion filtered per hour. The first of each pair of bars represents daytime rates; the second represents nighttime rates. (D) Daytime (- - - - -) and nighttime (——) epilimnetic zooplankton biomass. Dominant zooplankton were copepods (>90%) from May through July and *Daphnia* spp. (>90%) from August through October. (From Crumpton and Wetzel, 1982.)

be fed upon by the zooplankton dominating at that time. The *C. comensis–S. schroeteri* succession clearly resulted from differential mortality rather than from differences in growth rates.

Organic substances released by grazing cladocerans, such as certain *Daphnia,* copepods, and rotifers, can induce rapid morphological changes in certain algae. For example, dissolved substances released from some, but not all, species of *Daphnia,* copepods, and rotifers can induce the formation of large colonies in the polymorphic green alga *Scenedesmus* (Hessen and van Donk, 1993; Lürling and van Donk, 1996, 1997). The substances promoted a shift from unicells ($6-8 \times 4-5$ μm) to 8-cell colonies (40×6 μm), a form that is more grazer resistant and resulted in decreased grazing rates and population growth rates of zooplankton.

Some phytoplankton contain toxic organic substances that selectively alter or inhibit grazing by zooplankton. For example, the cyanobacterium *Planktothrix* contains microcystins and other toxins that are complete feeding deterrents for certain copepods and partial deterrents against grazing by *Daphnia* and other zooplankton (Kurmayer and Jüttner, 1999). Clearly, grazing deterrents can be mediated by chemical defenses rather than only by size and rigidity of the filaments.

Consumption of phytoplankton by zooplankton does not necessarily result in mortality. Some algae are resistant to zooplanktonic digestion and pass intact through the digestive tracts. Algal growth can be stimulated by the acquisition of nutrients or organic growth factors during passage (Porter, 1973, 1975, 1976; Adrian, 1987). The effectiveness of digestion during gut passage can differ depending upon the physiological status of the algae prior to ingestion (van Donk and Hessen, 1993). For example, phosphorus-saturated algae were efficiently digested by *Daphnia,* but P-limited algae passed largely intact through the gut and were likely nutrient enriched.

X. COMPETITIVE INTERACTIONS AND SUCCESSIONAL DIVERSITY

The phytoplanktonic community is composed of a diverse assemblage of algal species populations. Each of these species components and its growth dynamics are influenced by an array of environmental parameters (physical, chemical, and biotic) that undergo constant temporal and spatial variations. Some of the parameters, such as temperature, conservative nutrients, et cetera, undergo slow, periodic oscillations over an annual period. Other parameters, such as light intensity and quality, nutrients in rapid flux, et cetera, exhibit very rapid temporal, physiologically important changes in a matter of minutes or hours. The intensities of these forces greatly affect algal physiology and growth, some with regularity and others in a highly irregular fashion.

It is doubtful that an ideal species hypervolume is ever met under natural conditions. The fit of a species within an array of competing species is relative and changes constantly. The ability of an alga to store a critical nutrient imposes another time factor interaction that stresses the importance of past environmental conditions as well as contemporary ones. On the basis of the number of interacting parameters and ranges of variations tolerated by algae, it is not too surprising that (a) a species may be able to survive indefinitely provided that a suitable combination occurs with sufficient frequency and duration, and (b) the interactions are so complex and variable that, in spite of species overlap in their niche hypervolumes, coexistence can occur even though competitive interactions are in effect. Mathematical formulations of these competitive interactions are set forth in the stimulating theoretical discussions of Greeney *et al.* (1973) and Tilman (1980, 1982).

The diversity of phytoplanktonic algal species has been determined in a number of ways. The best indices of species diversity are probably those that are largely independent of sample size (cf. Chap. 8).[7] Diversity indices are often determined primarily by the proportions of the more common species (equitability) and only secondarily by the number of species, according to derivatives of the Shannon formula (Sager and Hasler, 1969; Moss, 1973d; Hallegraeff and Ringelberg, 1978). Predominance of one or two species results in low diversity values; high values occur when populations of several species each form moderate proportions of the whole. Although data are far from satisfactory because of the variations found, there is a general tendency for species diversity to decrease with increasing fertility of the water. Presumably, the slower growth rates of algae in oligotrophic lakes permit a greater number of species with reasonably similar requirements (high degree of niche overlap) to coexist than would be found in more eutrophic waters.

In eutrophic temperate lakes, the tendency is for algal diversity to increase in summer and decline during winter (Moss, 1973d). However, when the relationship between species diversity and season is examined closely, one can find considerable variability (cf. Hallegraeff and Ringelberg, 1978). Nutrient availability and water temperature may account for much of the

[7]Increasing sample size tends to reveal a greater number of species, as more and more of the rarer species are encountered. Many of the rarer species are of littoral-zone origin and not true members of the phytoplankton (cf. Symons, 1972; Moss, 1973d). Algal species diversity is much greater, commonly by a factor of 10, in the littoral zone than it is in pelagic areas.

observed pattern; during and immediately after spring circulation, nutrient concentrations are high, and progressive depletion of nutrients usually occurs throughout the summer. Relatively few algal species are adapted to the low water temperatures found immediately after ice loss in spring, and these species rapidly come to dominate the algal community. During summer, warmer temperatures are more favorable for growth of a larger number of species but competition for limiting nutrients is likely to increase. Obviously, factors such as parasitism and predation are also involved, but the extent of influence of each of these factors on the overall pattern of succession is variable and poorly studied.

Congruous with these findings are the results of a measure of successional rate, or a seasonal rate of change of species composition. Jassby and Goldman (1974), employing a mathematically more involved but more realistic expression, showed that the rate of change in species composition per unit time decreases precipitously following the spring maximum and midsummer plateaus. Thus, when the community is disturbed by the rapid changes of spring circulation, as in this case, or is perturbed by some catastrophic event (e.g., fertilization by human activities), one would expect rapid changes in species composition and increased successional rates.

The distribution of phytoplanktonic biomass and *in situ* rates of primary productivity has received a great deal of attention and represents perhaps the most thoroughly investigated aspect of lake biota. In contrast, the growth and productivity of phytoplankton of streams and rivers is poorly understood (cf. reviews of Hynes, 1970; Wetzel, 1975b; and Wetzel and Ward, 1992).

The distribution patterns of phytoplanktonic biomass within a lake or river usually change markedly throughout the year, and site-to-site variations are also extreme. Phytoplanktonic productivity is even more variable, for it is influenced by factors that can change within a matter of minutes (e.g., light intensity). However, in spite of these differences, there are some aspects of the distribution patterns that appear to be consistent. In addition, the productive capacity of a planktonic system is bounded by certain constraints beyond which productivity cannot be increased. These considerations are addressed in the following discussion.

XI. PHYTOPLANKTON IN THE GRADIENT ALONG RIVERS, RESERVOIRS, AND LAKES: DIVERSITY AND BIOMASS

A. River Phytoplankton

Many species of river phytoplankton (potamoplankton) reproduce prolifically in rivers and achieve biomass levels of 250 μg chlorophyll *a* liter^{-1} (Friedrich and Viehweg, 1984; Gliwicz *et al.*, 1985; Reynolds, 1988, 1994; Moss and Balls, 1989; Murakami *et al.*, 1992; Reynolds *et al.*, 1994). Diatoms usually dominate in the plankton of larger rivers along with, particularly in summer, a variety of green algae. Many flagellates, chrysophytes, and cyanobacteria are suppressed where currents are vigorous; these groups can increase in significance in areas where currents are reduced. Water movements enhance gaseous and solute exchanges as well as suspension of nonmotile cells. Perenniation of phytoplankton in rivers arises from surviving periphytic and benthic populations, often of backwater areas (Reynolds and Descy, 1996). Thus, much of the phytoplankton community likely derives from attached forms of the substrata (meroplankton) in various stages of growth or dormancy. Alternatively, lake surface water flows to outlets of streams and rivers can serve as a major source of riverine phytoplankton (e.g., Chandler, 1937). Mortality of entering phytoplankton can be high, however, if molar action of rapidly moving water is high.

Successful phytoplankton species in rivers must be adapted, however, to survive frequent fluctuations in irradiance as they are moved by currents erratically through their vertical light field. Often much of the mixed layer is in effective darkness and entrained cells spend more than half their daylight hours at light levels insufficient to support net photosynthesis. Increases in discharge commonly are accompanied by increases in the suspended load of nonliving particulates (clay, silt, and organic particles) derived from the drainage basin as well as within the river from scour. The depth of the euphotic zone within rivers from nonalgal particles decreases sharply as discharge increases (Reynolds, 1988). Under high flow conditions, energy limitations can be as important in regulating the growth of river phytoplankton as is the putative effects of washout downstream. When river ecosystems are disturbed or polluted, reduction or loss of algal diversity is common, particularly through the loss of rare species (Patrick, 1988). Loss of the less common species reduces the resilience of the ecosystem to recover from both natural and human-caused disturbances.

River phytoplankton generally exhibit fast growth rates and hence tend to be smaller in size than phytoplankton of lakes and reservoirs. The generation times of river phytoplankton must be more rapid than the time of displacement downstream. Survival in rivers is aided by a number of water-retentive mechanisms, particularly backwater "dead zones" of reduced currents near and among the banks and flood plains. These backwater areas retain water sufficiently to permit additional cell divisions of suspended phytoplankton. For example, phytoplankton abundance per unit phosphorus did not differ greatly among rivers, reservoirs, and natural lakes when residence times of the water were

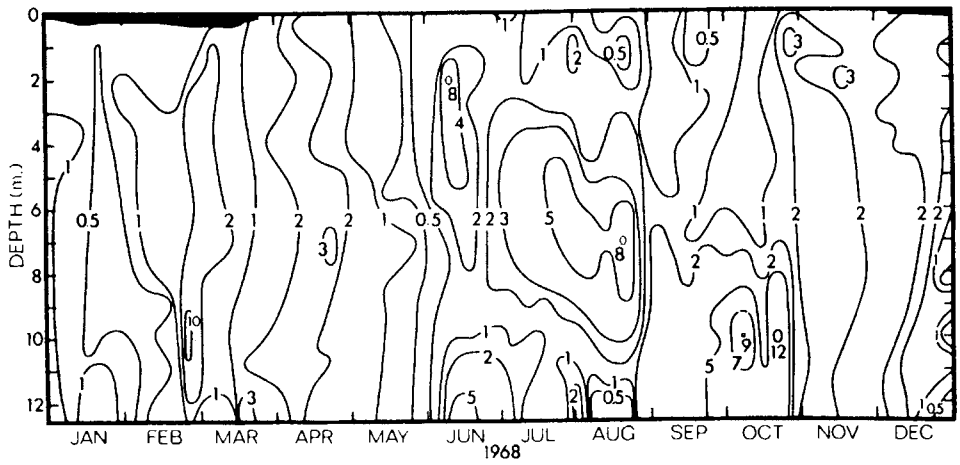

FIGURE 15-14 Depth–time distribution of phytoplanktonic chlorophyll *a* concentrations (mg m^{-3}), Lawrence Lake, Michigan, 1968. Opaque areas = ice cover to scale. Sampled at 7-day intervals at each meter of depth. (From Wetzel, unpublished data.)

similar (Søballe and Kimmel, 1987). In addition, zooplankton in rivers tend to be significantly fewer than in lakes, which would result in less efficient herbivory of phytoplankton in river ecosystems.

B. Vertical Distribution of Biomass in Lakes and Reservoirs

The vertical distribution of phytoplanktonic biomass varies greatly from season to season with shifts in species composition. If the depth–time distribution of phytoplanktonic pigments of an oligotrophic hardwater lake of southern Michigan is taken as an example, conspicuous temporal changes can be seen. In the seasonal depth distribution of chlorophyll *a* concentrations (Fig. 15-14), corrected for pigment degradation products, values were low in winter, increased conspicuously in the spring maximum, and then increased in different strata during the period of summer stratification. Detailed analyses of the phytoplankton community (some 150 major species) revealed that cryptomonads and small green algae predominated in the winter (Taylor and Wetzel, 1988). The composition then changed to predominantly diatoms in the spring and green algae in June and late August during this particular year. The metalimnetic maximum in summer was largely composed of green and non–nitrogen-fixing cyanobacterial populations with lesser percentages of diatoms. The development of a deep chlorophyll maximum (10–11 m) in the later portion of summer stratification was related to very dense populations of euglenoid algae just at the aerobic–anaerobic interface about 1 m above the sediments. Concentrations of chlorophyll *b* were very much lower throughout the year and were irregularly distributed, except in the lower hypolimnion during late summer and autumn. Chlorophyll *c* concentrations were most abundant in algal populations dominated by diatoms. The total composite plant carotenoids, which are somewhat more stable than the chlorophyllous pigments, exhibited a vertical depth distribution seasonally similar to that of chlorophyll *a* (Fig. 15-15).

Pigments must be used with caution as estimates of phytoplanktonic biomass (e.g., Cullen, 1982; Granberg and Harjula, 1982). It is also important to emphasize that a significant portion of the algal cells within the water column is nonviable, that is, is particulate detritus in various stages of decomposition. Chlorophyllous pigments can be corrected for degradation products (e.g., Wetzel and Likens, 2000). Concentrations of these heterogeneous phaeopigments give some insight into the magnitude of nonfunctional pigments in the particulate fractions. Using the same data for Lawrence Lake, Figure 15-16 sets forth the concentrations of phaeopigments with depth over the year. At many times of the year, the phaeopigment concentrations equal or exceed those of chlorophyll *a*. Moreover, the phaeopigment concentrations are often displaced to slightly greater depths and to slightly later times in relation to the functional pigments. The importance of this detrital particulate matter of algal origin to lake metabolism is discussed at length later (Chap. 23). It is important to realize that cell integrity and pigment concentrations can persist for several days after cell death (e.g., Gusev and Nikitina, 1974). Chlorophyll *a* degrades most rapidly upon death and when corrected for more stable phaeopigment degradation products, is an estimate of biomass (cf. Desortová, 1981).

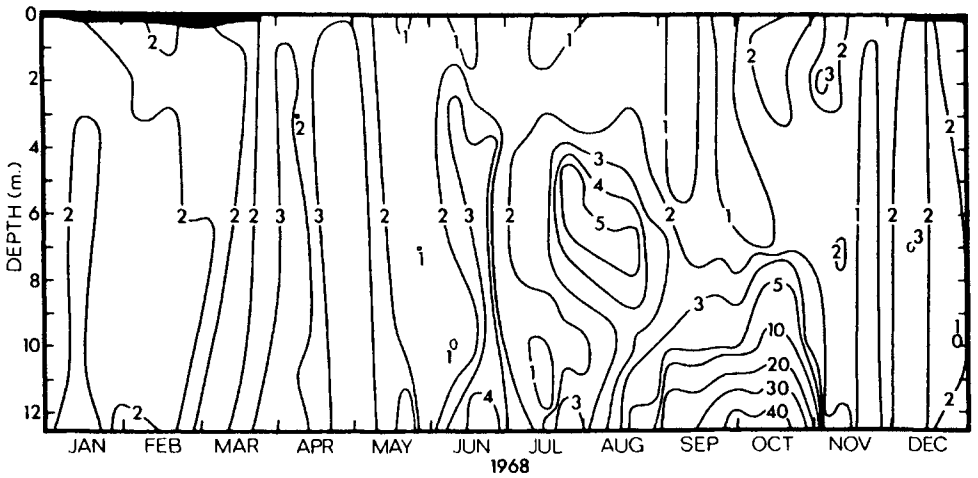

FIGURE 15-15 Depth–time distribution of phytoplanktonic total plant carotenoids (ca. mg m^{-3}), Lawrence Lake, Michigan, 1968. Sampld at meter depths at 7 day intervals; opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

XII. VERTICAL DISTRIBUTION AND MAXIMUM GROWTH IN LAKES AND RESERVOIRS

The pigment–biomass values just discussed are low, which is typical of a rather oligotrophic lake. Considerably lower concentrations, about 1 mg chlorophyll *a* m^{-3}, are not unusual among pristine arctic and alpine oligotrophic lakes. Among alpine oligotrophic lakes and larger oligotrophic lakes in general, high concentrations of chlorophyll are commonly found deep into the upper hypolimnion and into aphotic zones (e.g., Brook and Torke, 1977; Tilzer *et al.*, 1977; Richerson *et al.*, 1978). Analyses have shown that many of the phytoplankton in these deep layers are adapted to low light intensities and that, during circulation periods, aphotic algae can augment phytoplankton growth of the euphotic zone upon reentry into the upper waters. For example, phytoplankton populations can develop in deep waters of some oligotrophic lakes immediately after the ice-free stratification period forms (e.g., Priscu and Goldman, 1983). These photoautotrophic algal communities form a "deep chlorophyll layer" that can persist for months until fall circulation. Redistribution of these algae during the autumnal overturn can

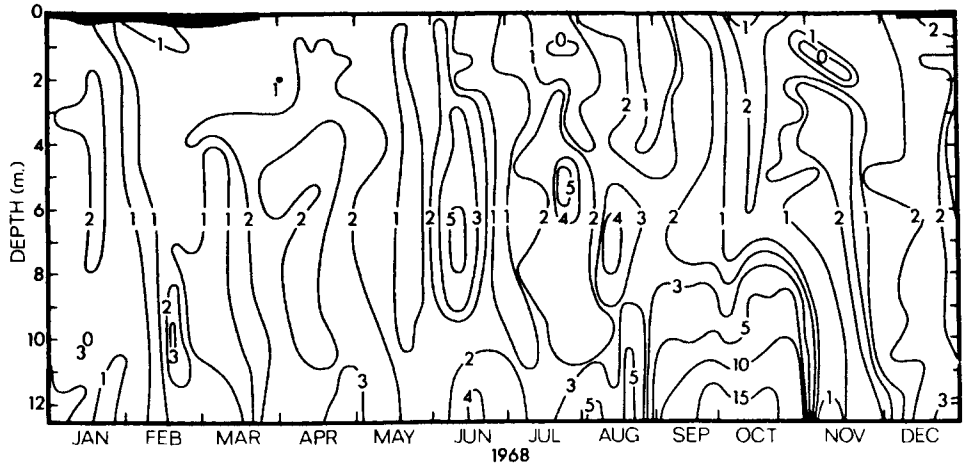

FIGURE 15-16 Depth–time distribution of phytoplanktonic phaeopigment concentrations (mg m^{-3}), Lawrence Lake, Michigan, 1968. Sampled at meter depths at 7-day intervals; opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

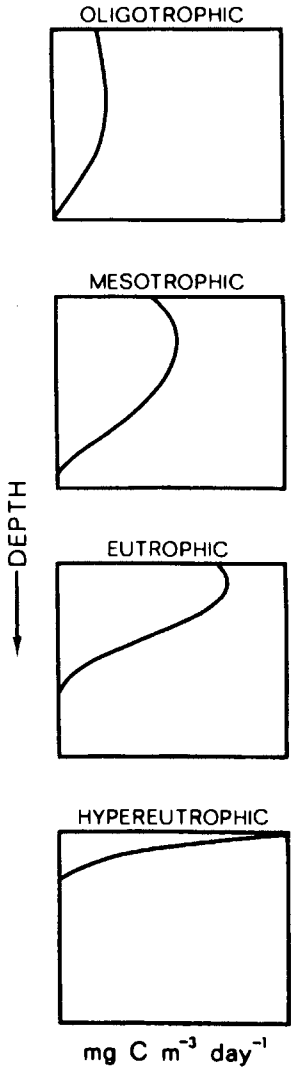

FIGURE 15-17 Generalized increases in productivity of phytoplankton per unit volume of water, with simultaneous reduction of the thickness of the trophogenic zone, in a series of lakes of increasingly greater fertility.

increase algal biomass concentrations of the euphotic zone and potentially increase primary productivity in this zone significantly.

At the other extreme of maximum growth and pigment concentrations, light limitations restrict productivity and the masses of the algae themselves impose controls upon further growth by self-shading. Photosynthetic yield can continue to increase, given adequate nutrient availability, to a theoretical point at which total absorption of photosynthetically active incident radiation occurs. This absorption is distinct from that absorbed by the water itself, by dissolved organic matter, and by abiogenic particulate matter (cf. Talling, 1960, 1971). The theoretical maximum, as indicated by culture analyses, is approximately 1 g chlorophyll per m^3 (1 mg $liter^{-1}$) but varies among algal types, being higher among cyanobacteria and less for green algae and diatoms (e.g., Steemann Nielsen, 1962b). As the algal populations increase biogenic turbidity in progressively more fertile lakes, the productivity per volume of water increases greatly (Fig. 15-17). However, the productivity per square meter of water column does not increase proportionately, because biogenic turbidity of the increasing density of algal cells reduces light penetration. The depth of the trophogenic zone and, hence, the total volume occupied by photosynthesizing algae are consequently reduced.

Therefore, as the composite extinction coefficient of light from biogenic sources increases, the productivity per square meter of water column increases to the maximum imposed by self-shading effects of the algal densities (Fig. 15-18). Increasing the extinction coefficient further, such as by high concentrations of dissolved humic compounds or inorganic particulate and colloidal turbidity, can similarly result in a progressive depression of the maximum possible productivity of phytoplankton.

The highest recorded concentrations of chlorophyll of phytoplanktonic origin emanate from tropical, eutrophic lakes. For example, shallow (2.5 m) but large (250 km^2) equatorial Lake George of western Uganda is a highly productive lake that supports very dense phytoplanktonic populations; these populations consist primarily of cyanobacteria, with very little seasonal change in either species composition or densities. Based on *in situ* estimates of photosynthesis, the predicted concentrations of chlorophyll *a* in this lake stabilized at an algal density of about 500 mg chlorophyll *a* m^{-2} (Ganf, 1974a). Because of the shallow nature of this large lake, frequent daily mixing, and disturbance of the flocculent sediments, light penetration is reduced further by nonalgal components. Therefore, the maximum quantity of chlorophyll *a* actually measured within the euphotic zone is between 230 and 310 mg m^{-2}. However, many of the phytoplankton settling to the sediments are viable and are resuspended each day (Ganf, 1974b), so a more realistic mean algal biomass may be as high as 1000 mg chlorophyll *a* m^{-2}.

Among the maximum recorded values of algal biomass on the basis of chlorophyll content are those from two Ethiopian soda lakes (Talling *et al.*, 1973). In these extremely productive lakes, favored by high temperatures and abundant light, phosphorus, carbon, and other nutrients, the euphoric zone was less than 0.6 m in thickness and the algal populations were limited severely by self-shading. Although concentrations of chlorophyll *a* exceeded 2000 mg m^{-3} in one lake, which appears to be about the maximum possible under natural planktonic conditions (Fig. 15-19), the content of chlorophyll *a* per unit area of the euphotic

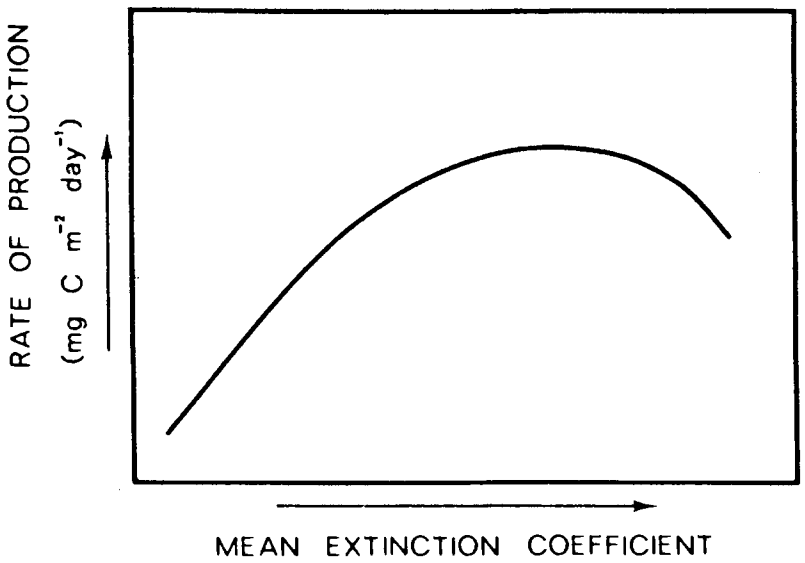

FIGURE 15-18 Generalized maximum possible productivity of phytoplankton in relation to increasing extinction of light, resulting from biogenic turbidity initially, and then combined with increasing effects of extinction by dissolved organic matter and/or particulate and colloidal inorganic matter.

trophogenic zone for these lakes was in the range of 180–325 mg m^{-2}. These values are similar to those maxima (180–450 mg chlorophyll *a* m^{-2}) that have been estimated indirectly or directly to occur in nature (cf. Westlake *et al.*, 1980).

XIII. PRIMARY PRODUCTION OF PHYTOPLANKTON

A. River Phytoplankton

Much of the control of observed primary productivity within running waters has been attributed to the availability of solar insolation reaching the water and its attenuation within the water (e.g., Wetzel, 1975a; Minshall, 1978; Bott, 1983; Wetzel and Ward, 1992; Reynolds and Descy, 1996). Nutrient loadings generally increase as the sizes of the drainage basins and stream order increase, particularly among most river valleys that have been disturbed by agriculture. As a result, nutrient limitations to primary productivity of rivers generally decrease with increasing stream order because of light limitations.

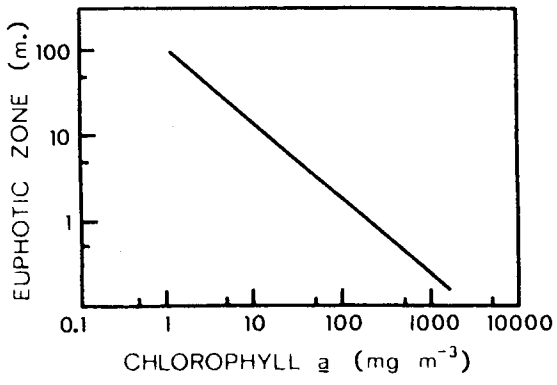

FIGURE 15-19 Generalized relationship of the depth of the euphotic zone in relation to the maximum concentrations of chlorophyll *a* per volume of water. (After data of several authors and Talling *et al.*, 1973.)

Once nutrients are provided from external and internal sources in adequate supply to support maximum rates of photosynthesis, light availability is the dominant factor regulating photosynthetic productivity. Light available *within* river channels is regulated by both the canopy cover of bankside trees and by turbidity (Fig. 15-20). Light availability is often low in small streams and rivers, at least seasonally during the active growing season of streamside vegetation, because of extensive vegetative canopy. Undisturbed rivers usually have low loads of turbidity and high water transparency as size increases downgradient (Fig. 15-20a). Unfortunately, marked alterations in the light quality of most river ecosystems have occurred as land clearance, agriculture, and other disturbances have increased (Fig. 15-20b).

Among relatively nondisturbed ecosystems, primary productivity *within* rivers is directly correlated to stream order (Fig. 15-21a). Much of the increase in stream autotrophy results from increases in production by periphytic algae associated with widespread deposition of sediment surfaces and expansion of shallow substrata with river braiding and meandering. As river ecosystems are disturbed, variance from this general

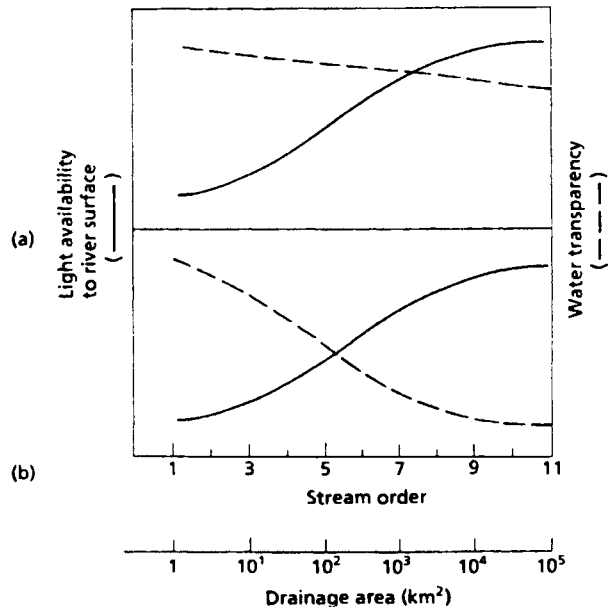

FIGURE 15-20 Changes in patterns of light penetration to the stream surface and water transparency of the stream water along a gradient of increasing stream order and area of drainage basin in (a) preagricultural nondisturbed and (b) present/disturbed lotic ecosystems. (From Wetzel and Ward, 1992.)

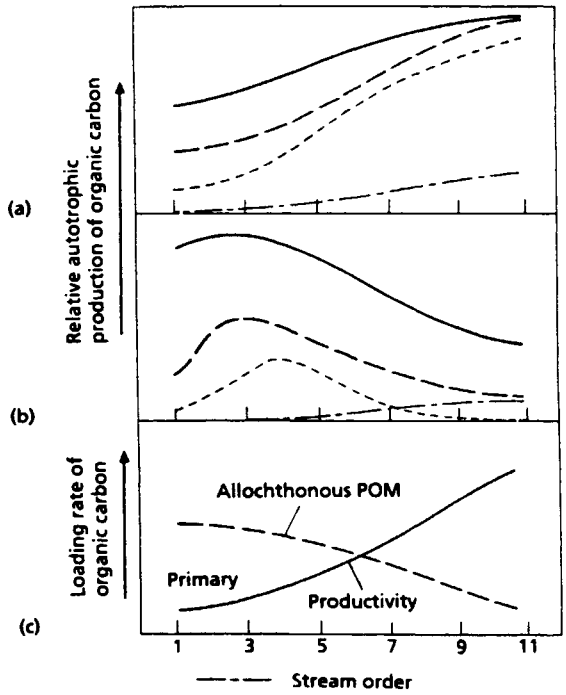

FIGURE 15-21 Changes in patterns of autotrophic production of organic carbon with increasing stream order in (a) nondisturbed and (b) disturbed lotic ecosystems. (c) Longitudinal gradient of organic carbon loading from allochthonous (upland) versus lotic ecosystem primary productivity. (———) = Photosynthetically derived *dissolved* organic matter from wetlands and flood plains; (_ _ _ _) = macrophytes; (- - - -) = periphyton; and (- _ - _ - _) = phytoplankton. (From Wetzel and Ward, 1992.)

correlation is influenced by human deforestation and agriculture (Minshall *et al.*, 1983; Naiman, 1983). Primary productivity within the rivers then generally decreases with increasing stream order because of light limitations (Fig. 15-21b). The contributions by periphyton and submersed macrophytes then decline with increasing size and turbidity.

Therefore, reductions of photosynthetic metabolism *within* the river channel per se are observed commonly along the length of the river with increasing stream order. The elevational slope decreases with increasing stream order, however, and is accompanied by increased deposition of bedloads. Colonization of these bank, wetland, and floodplain areas by higher vegetation results in very high primary productivity. Decomposition of much of the particulate organic matter produced in these sites occurs at or near the sites of production. A large portion of the organic matter synthesized by these high producers is exported to the river water as dissolved organic matter (Fig. 15-21c). As will be discussed later, that dissolved organic matter from allochthonous sources is important to the metabolism and productivity of biota within the streams and rivers.

B. Primary Production of Reservoirs

Reservoir ecosystems are intermediate between rivers and natural lakes in relation to morphology, hydrology, nutrient loadings and cycling, and sources of organic matter. Because of large water level fluctuations from flood control and hydropower operations and light limitations from abiogenic turbidity of suspended clays and silts, attached algal and rooted macrophyte development is restricted. Much of the primary production *within* reservoirs is by phytoplankton. Despite frequent high abiogenic turbidity in reservoirs, the average phytoplankton primary productivity tends to be higher than in natural lakes (Table 15-12). Because of the large drainage basins of reservoirs in comparison to natural lakes, nutrient loadings tend to be much greater. As in all inland aquatic ecosystems, however, much of the organic matter utilized within the ecosystems emanates from external allochthonous sources.

C. Seasonal Rates of Photosynthesis in Lakes and Reservoirs

Rates of *in situ* photosynthesis of the phytoplankton must be evaluated over an annual period to compensate for major differences in the length of active growing season with changing latitude and alti-

tude. Although summer productivity of an arctic or high mountain lake may be just as high as productivity per unit volume of a lake at much lower latitude or elevation, the length of the growing season is considerably less. Since evaluations of phytoplanktonic productivity must be made on an annual basis, it is necessary to look first at the magnitude of these seasonal variations.

Further, it is important to keep in mind the ecological significance of gross versus net productivity. As discussed earlier, rates of the opposing processes of photosynthesis and respiration are very difficult to evaluate in heterogeneous planktonic populations of phytoplankton, bacteria, and zooplankton. The widely used ^{14}C light and dark bottle (Wetzel and Likens, 2000) generally results in values close to net productivity under most *in situ* conditions. This method permits a further evaluation of the extent of extracellular release of soluble organic compounds during growth of the algae. Respiration cannot, however, be evaluated by the ^{14}C method. The sensitive ^{14}C method permits an estimation of the *in situ* rates of photosynthesis approximating net productivity, which is useful since it is this particulate matter that is potentially available for consumption by higher organisms. More elaborate methods, however, are required to ascertain the fate of the total productivity, since most the synthesized organic matter is not consumed by animals but instead enters the detrital food chain (cf. Chap. 23). The less sensitive oxygen-change techniques measure community metabolism, although oxygen production over time is most often the result of phytoplanktonic algae. How light-mediated photorespiration compromises the assumption that dark-bottle estimates of respiration are similar to respiration values in the light have not been evaluated satisfactorily. Similarly, bacterial respiration is assumed to be small in relation to that of the planktonic algae and to be the same in the light as it is in the dark. It can only be concluded that at best, contemporary methods provide estimates of *in situ* rates of photosynthesis that are comparable only in a general way (cf. Peterson, 1980). Nonetheless, the advantages of being able to measure rates directly *in situ* are great and are exceedingly valuable if viewed in the correct perspective.

Several examples of seasonal primary productivity illustrate the types of variations that can be encountered. The changes in productivity of the phytoplankton at depth over the season set out in Figure 15-22 for a hardwater lake of low productivity in Michigan show a common pattern. Rates are low in the winter with periodic minor surges from near-surface populations under ice, particularly toward the end of winter. Rates often decrease during spring circulation, which in this lake for this year was very brief (until early April). Rates of production increased during the spring diatom maximum, entered a low period in May, and then succeeded through a series of pulses through the summer when values were higher than during the spring. Metalimnetic maxima are conspicuous in July and late August prior to a general slow decline in the autumn. These rates of production by phytoplankton are composite values for the community of many species populations, which show a great regularity in periodicity from year to year (monitored continuously for nearly two decades).

When these data at each depth interval are integrated over a square meter of water column, one can

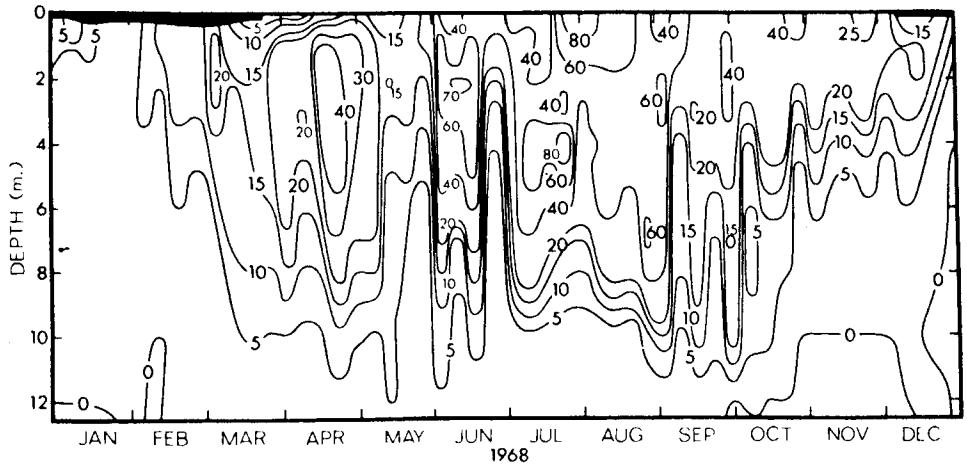

FIGURE 15-22 Depth–time distribution of the *in situ* rates of production of phytoplankton in mg C m^{-3} day^{-1}, Lawrence Lake, Michigan, 1968. Measured at meter depth intervals every 7 days; opaque areas = ice cover to scale. (From Wetzel, unpublished data.)

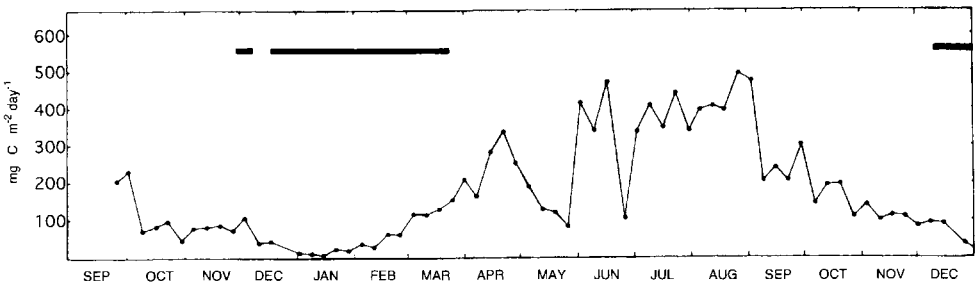

FIGURE 15-23 Integrated areal primary productivity per square meter of the pelagic zone of Lawrence Lake, Michigan, 1967–1968. Bars indicate periods of ice cover. (From Wetzel, unpublished data.)

calculate the rates of *in situ* productivity per surface area of the pelagic zone (Fig. 15-23). It is usual to integrate the areal productivity under such curves for an annual period to obtain the estimate of the total annual productivity by phytoplankton for a year (Wetzel and Likens, 1991). Division by 365 results in an estimate of the mean daily productivity for the lake. Obviously, conically shaped lake basins have much greater volume for phytoplanktonic productivity in upper strata than at greater depth within the trophogenic zone. Therefore, it is advisable to determine the annual productivity for each stratum, say at meter intervals, over the year and integrate these values before summing productivity of each stratum for the whole. In this way, the changes in volume available for productivity are taken into account.

A feature of the total phytoplanktonic productivity and the mean daily productivity for the year is their stability from year to year as long as the system is not perturbed. In spite of variations in the seasonal rates of observed productivity and numerous sources of potential error in measurement and sampling, the values are reasonably constant. Examples of this consistency can be seen in Table 15-9. Some variations are to be expected. In this case, for example, 1972 was a particularly variant year with abnormally high cloud cover and rainfall. Within this type of variation, the annual primary productivity values serve as one of the best available criteria for following changes in the metabolism of lake systems in response to alterations by human activities.

Looking at the primary productivity of phytoplankton of more eutrophic lakes of the same latitude as the previous example, three points are conspicuous (Fig. 15-24). First, the thickness of the trophogenic zone is reduced markedly to the point where most of the productivity occurs in the first 2 m of water. Second, the seasonal succession of productivity is much more irregular and exhibits marked fluctuations in comparison to less productive lakes. As discussed earlier, algal utilization and reduction of critical nutrients (Si, combined N) to levels limiting for certain algal groups progress very rapidly (a few days to weeks) and contribute to the marked oscillations in composite photosynthetic rates. Finally, the data of Figure 15-24 again emphasize the importance of primary productivity under ice and winter conditions, which should not be ignored in contemporary studies.

Because the primary productivity of hypereutrophic Wintergreen Lake is attenuated so rapidly with increasing depth by the self-shading effects of the algae, most of the productivity is restricted to the uppermost portions of the photic zone. Therefore, evaluation of the productivity of the lake on a per-square-meter-of-water-column basis throughout the trophogenic zone is similar to values for the entire lake (Fig. 15-25). Because this lake is shallow and pan-shaped, compensation for the decreasing volume of the productivity in the lower strata only has a small effect on the total lake productivity, that is, the volume of the lower strata within the trophogenic zone is small.

Seasonal climatic changes are reduced in tropical regions. The length of the active growing season is extended to the entire year. Monthly irradiances in the tropics are higher than at higher latitudes and result in higher minimum water temperatures, higher mean temperatures for the water column, and smaller thermal discontinuities between upper and lower water strata (Lewis, 1996). Tropical lakes of moderate depth are predominantly warm monomictic and exhibit regularity in seasonal mixing in the winter. Tropical lakes show more intraseasonal variations in thickness of the mixed layer than morphometrically similar temperate lakes. This periodic intraseasonal deep mixing, followed by restoration of a thinner mixed layer, results in a higher efficiency of microbial nutrient regeneration than is the case in cooler, more stable temperate lakes. The combination of efficient nutrient cycling, higher mean temperatures, and greater stability of solar irradiance results in phytoplanktonic primary production about twice as high per unit nutrient as there would be at higher latitudes (Lewis, 1996). Equatorial lakes exhibit the highest values of phytoplanktonic productivity recorded in aquatic ecosystems (e.g., Talling, 1965; Lewis, 1974b, 1996; Westlake *et al.*, 1980).

The successional clock among phytoplankton of tropical lakes is reset frequently because of irregular thickening of the mixed layer of the trophogenic zone. Definite seasonality persists even though it is not nearly as marked as is common in lakes of higher latitudes. Seasonality is reduced in very shallow tropical lakes. In shallow, nonstratified tropical lakes that have high nutrient inputs, the productivity values are not only very high but are relatively uniform throughout the year. An example is Lake George on the equator in Uganda (Talling, 1965; Ganf, 1974). Deeper tropical lakes that stratify thermally, even though weakly so, tend to

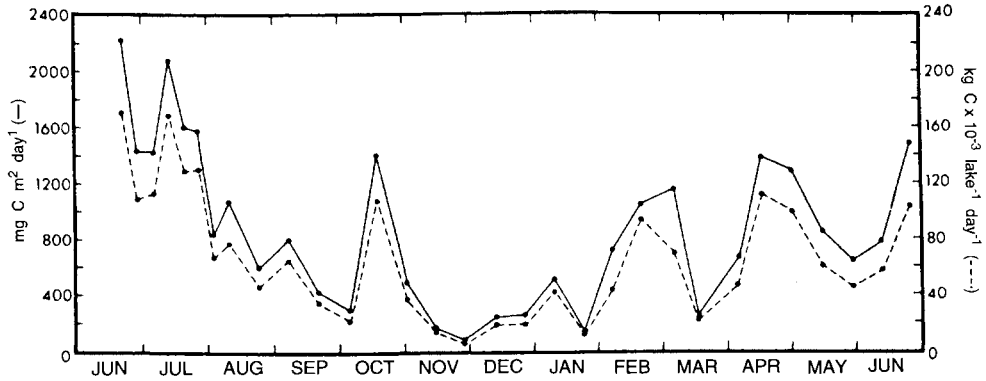

FIGURE 15-25 Integrated primary productivity of the phytoplankton of hypereutrophic Wintergreen Lake, Michigan, 1971–1972, per square meter of the trophogenic zone at the deepest point and for the lake volume with morphometric corrections. (From Wetzel *et al.*, unpublished data.)

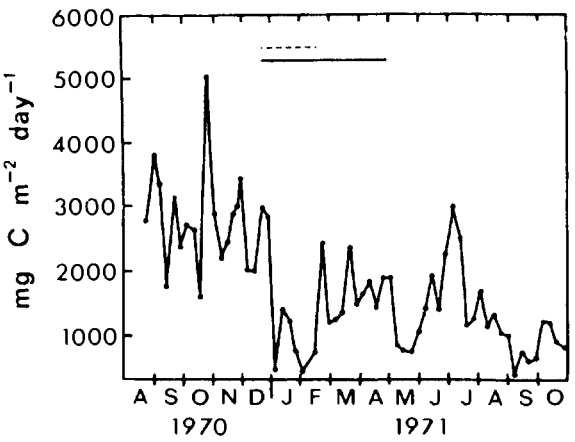

FIGURE 15-26 Net rates of primary production of the phytoplankton of Lake Lanao, Philippines, 1971–1972. The dotted line marks the period of minimum water temperature and deepest seasonal mixing; the solid line marks the period when the lake lacked stable stratification. (Modified from Lewis, 1974b.)

exhibit some periodicity in productivity. For example, in equatorial Lake Victoria of Africa, somewhat higher rates occur in the early months of the year and in June and July, when the breakdown of stratification occurs. The net primary productivity of weakly monomictic Lake Lanao (8°N) in the southern Philippines was relatively high throughout the period of stratification (May–November) but decreased precipitously during the winter period when water temperatures were lowest and deepest seasonal mixing occurred (Fig. 15-26). Respiration rates as a percentage of gross photosynthesis generally are higher (toward 50%) than the average for temperate waters (20–30% of total fixed carbon).

Therefore, when viewing the annual cycles of primary productivity in lakes in relation to latitude, seasonal variation in input of solar radiation at higher latitudes is the general controlling mechanism. Near the equator this seasonal differentiation is muted, and the incidence of vertical mixing is more important in any observed periodicity (Talling, 1969; Lewis, 1996). In some tropical lakes, as in Lake Victoria, seasonal cooling and mixing, regulated chiefly by atmospheric factors like wind and humidity, are decisive events. Nutrient supply has been implicated as a dominant controlling factor of primary productivity of Lake Lanao during stratification (Lewis, 1974b). Nutrient depletion is relieved at frequent intervals by changes in the depth of mixing associated with irregular storms.

D. Efficiency of Light Utilization

The efficiency of light utilization by algae can be estimated in several ways. All methods relate the amount of irradiance available at depth to the rate of transformation of light energy to chemical energy by photosynthesis. Existing values can be viewed only as estimates because of the difficulties in measuring the caloric equivalents of photosynthesis per unit volume at depth, or integrated for the water column, and the variable light inputs of photosynthetically active radiation at depth. In spite of these limitations, it is of great interest to see the range of values encountered in fresh waters because of the desires of some to utilize aquatic systems as potential food sources.

Phytosynthetic efficiencies of light utilization can be defined as an ecological efficiency (ϵ'), in a percentage equal to the amount of photosynthetically stored energy (PSR)[8] in a volume of water $(z_1 + z_2)m^3$ divided by the photosynthetically available radiation (PAR; 350–700 nm) absorbed or dissipated in the water layer z_1 to z_2, regardless of the variable fraction of PAR absorbed by algal pigments (Dubinsky and Berman, 1976, 1981a; Morel, 1978):

$$\varepsilon' = \frac{\text{PSR}}{\text{PAR}_{z_1} - \text{PAR}_{z_2}} \times 100(\%)$$

The difference in downwelling irradiance flux between successive water planes (z_1 and z_2) approximates light absorbance in the water column and is expressed in calories (or joules) m^{-3} h^{-1}. Backscattered light from lower depths affects the estimate of PAR dissipation in the overlying stratum only slightly. Thus, the photosynthetic efficiency is expressed as a ratio of the caloric equivalent of photosynthesis to radiation inputs.

Photosynthetic efficiency of light utilization by phytoplankton can also be expressed on an areal basis, in which the efficiencies of all the water strata are integrated throughout the euphotic zone and related to the PAR at the surface (cf. Morel, 1978; Dubinsky and Berman, 1981a; Falkowski and Raven, 1997). The areal efficiency permits more direct comparisons with photosynthetic efficiencies in other aquatic, portions of aquatic (e.g., littoral and wetland), and terrestrial ecosystems.

It is well known that the areal efficiencies of light-energy utilization by phytoplankton in aquatic ecosystems are generally much lower than photosynthetic efficiencies of terrestrial systems. Much of the irradiance is selectively and rapidly absorbed by water itself and by dissolved and particulate matter contained in it. The amount of light absorbed by the water and solutes is usually greater than the amount absorbed by plant pigments. Nearly all of the estimated efficiencies are <1%, and the highest values (approximately, 1–2%) reported for phytoplankton are from eutrophic lakes and from

[8]An approximate conversion of assimilated carbon to energy equivalents is 1 mg C assimilated = 9.33 cal, assuming all phytosynthate is glucose (Morel, 1978).

Estimates are based on different criteria of conversion; values are only approximately comparable but should be within about 30% (cf. Dubinsky and Berman, 1981b).

[b] Ice-free period only.

tropical areas (Table 15-10). The average light-utilization efficiency of a water column, based on integrated carbon fixation per unit area of water column through the euphotic zone normalized to integrated photon flux, is not constant but increases as the average daily irradiance decreases (Falkowski and Raven, 1997). Similar relationships have been found among aquatic macrophytes (e.g., Mann and Wetzel, 1998). Much of this relationship is attributed to biochemical photoinhibition by excessive light.

Variations in photosynthetic efficiencies are great, both seasonally and vertically within the euphotic zone. As light intensities increase near the surface of the water, both light utilization efficiencies and ratios of photosynthetically stored energy to the amount of PAR absorbed by algal pigments generally decrease, probably because photosynthetic reaction sites become light-saturated (Fig. 15-27; cf. Tilzer *et al.*, 1975; Dubinsky and Berman, 1981a). As irradiance decreases to values below photosynthetic light saturation, photosynthetic efficiencies usually increase. Although high efficiencies of light utilization are common at the bottom of the euphotic zone, photosynthetic rates are so low that these phytoplankton contribute little to the total primary productivity of the lake, since the absolute amount of light energy available at these depths is small. As a result, the overall areal efficiency is increased little.

As the quantity of phytoplanktonic biomass increases, the integral photosynthetic efficiencies generally increase until the maximum levels are restricted by light limitations imposed by self-shading. Therefore, the maximum areal values of photosynthetic efficiency are found in very productive waters containing dense algal populations. Exemplary ranges of photosynthetic efficiency of phytoplankton encountered in lakes of increasing productivity and of rivers are set out in Table 15-10.

It should be emphasized again that the productivity of the littoral zone and surrounding wetlands has usually been ignored as a component of aquatic ecosystems. Littoral and wetland productivity has been critically evaluated in only a few aquatic ecosystems; in every case examined, the combined productivity of

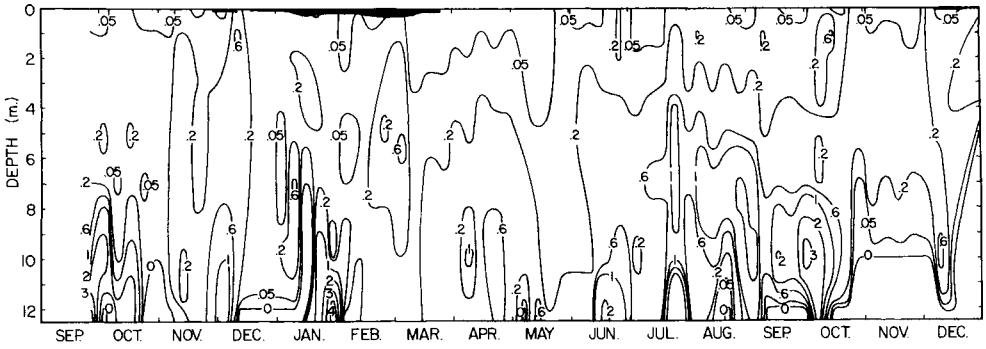

FIGURE 15-27 Depth–time distribution of estimates of the photosynthetic efficiency of utilization of photosynthetically active light income by phytoplankton of Lawrence Lake, Michigan, 1967–1968. Values expressed as per cent, most of which are much <1%. (From Wetzel, unpublished data.)

these sessile plants and their photosynthetic efficiencies of light utilization are much higher than those of the phytoplankton and constitute a major productivity component of most freshwater ecosystems (cf. Chaps. 18 and 19).

E. Extracellular Release of Organic Compounds

Algae release a large number of organic compounds into the water extracellularly. These soluble compounds include glycolic acid, carbohydrates, polysaccharides, amino acids, peptides, organic phosphates, volatile substances, enzymes, vitamins, hormonal substances, inhibitors, and toxins. Literature on this subject is large and has been reviewed by Fogg (1971), Hellebust (1974), Jüttner and Faul (1984), and Carmichael (1986, 1997).

The release of organic compounds extracellularly represents first a significant loss of carbon fixed in photosynthesis. Second, the release of such organic compounds undoubtedly is of much greater importance than is generally recognized and in a number of subtle but significant ways may modify growth, behavior of organisms, and the successional dynamics of algal and other microbial populations. For example, a number of allelopathic interactions have been found among algae, in which organic compounds released by one alga are inhibitors or stimulators to others (e.g., Proctor, 1957; Lefèvre, 1964; Keating, 1977; Wolfe and Rice, 1979; Jüttner, 1981; Gross *et al.*, 1991; Hagmann and Jüttner, 1996). The release of biologically active organic compounds, especially by cyanobacteria, is clearly implicated as one mechanism, among many others discussed earlier, that can influence fine adjustments in species succession and seasonal productivity. Fischerellin is a compound released from a cyanobacterium that can inhibit photosytem II of algae and other microorganisms in a very effective competitive interaction. Production of some of these allelochemicals can be induced when the cyanobacteria experience phosphorus limitations. Although causality is highly probable, quantitative evaluation of organic allelopathy has not yet been demonstrated in detail among natural populations of algae.

Two types of extracellular products are generally recognized (Fogg, 1971): (a) metabolic intermediate compounds of low molecular weight and (b) metabolic end products, usually of higher molecular weight. Glycolic acid, as an intermediate compound in photosynthesis, is known to be released under physiological stress conditions, especially under oligotrophic nutrient conditions and when photosynthesis is light inhibited. Glycolic acid and polysaccharides released during active growth are utilized readily by bacteria (Nalewajko *et al.*, 1980; cf. Chap. 17). Intermediate compounds of respiration that are released include organic acids, organic phosphates, and, to a lesser extent, amino acids and peptides. The liberation of end products of metabolism, usually of higher molecular weight, does not depend on equilibrium, and they are approximately proportional to the amount of growth. Included in this miscellaneous group are carbohydrates, peptides, volatile compounds such as aldehydes and ketones, enzymes, and a number of growth-promoting and -inhibiting substances.

The release of simple compounds (e.g., sugars, amino acids, and organic acids), by actively growing cells probably occurs mainly by diffusion through the plasmalemma (Hellebust, 1974). The rates of release depend on the concentration gradient of the substance across the membrane and the permeability constant of the membrane for the compound. Although active excretion of small compounds is also possible, no convincing evidence for such processes in algae exists. Large molecules, such as polysaccharides, proteins, and polyphenolic substances, probably are excreted by means of more complex processes such as fusion of intracellular vesicles containing the compounds with the plasmalemma. The rates of extracellular release depend on the physiological and environmental factors affecting membrane permeability and on intracellular concentrations (e.g., Mague *et al.*, 1980; Carmichael, 1997).

The rates of extracellular release under *in situ* conditions are quite variable. Although rates have been reported ranging from those equal to the rates of carbon fixation into cellular constituents down to <1% of rates of carbon fixation, on the average most values are <20% (e.g., Søndergaard and Schierup, 1982). For example, in the unproductive hardwater Lawrence Lake, *in situ* rates of release of organic compounds by phytoplankton monitored continuously over nearly two decades ranged from 0.0 to 22.5 mg C m^{-2} day^{-1}, with a mean of 6.5 mg C m^{-2} day^{-1}. The annual mean percentage secretion was 5.7% of net phytoplanktonic primary productivity (Wetzel *et al.*, 1972 and unpublished). Rates of release were greatest in April when production rates were low but increasing (Fig. 15-28). Secretion reached another maximum during the latter portion of summer stratification as primary productivity began to decrease while particulate organic carbon remained high. Rates of release were similar among phytoplankton in rivers. For example, Köhler (1994) found between 2.5 to 5.0% of carbon fixed in phytosynthesis was released extracellularly. The mean annual amount of released organic carbon in Lawrence Lake was highest at 1 m and decreased with increasing depth except below 10 m (Fig. 15-28). In these lower strata of very low light and low rates of photosynthesis,

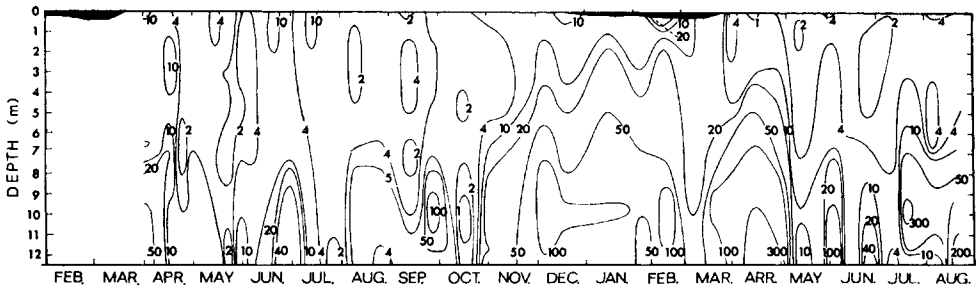

FIGURE 15-28 Depth–time isopleths of extracellular release of organic carbon by phytoplankton as a percentage of rates of carbon fixed photosynthetically, Lawrence Lake, Michigan, 1968–1969. (From Wetzel *et al.*, 1972.)

release rates, although extremely low in absolute value (cf. Fig. 11 of Wetzel *et al.*, 1972), were relatively high in relation to the low rates of primary production occurring in the deeper strata. Therefore, expressed as the mean percentage of extracellular release of all dates and samples, 23.5% of the phytoplanktonic productivity was released to the dissolved phase. Similar results have been found in many other lakes (e.g., Berman, 1976).

As lakes become more productive, the absolute amounts of organic carbon released increase markedly. For example, the annual range in hypereutrophic Wintergreen Lake, Michigan, was between 2 and 100 mg C m^{-3} day^{-1}, with the highest values in the epilimnion (Fig. 15-29). However, because of the extremely high rates of photosynthetic carbon fixation and the rapid seasonal oscillations in photosynthesis within the compressed trophogenic zone, the percentage release values are generally lower than in oligotrophic waters (Fig. 15-30).

High rates of release of extracellular products of algal photosynthesis have been shown to be a function of CO_2 limitation (e.g., by high pH), high population densities, inhibiting light intensities, low light intensities, and low cell densities and growth rates. The high percentage released at both extremes of the light and pH continuum indicates that the release of relatively large quantities of organic carbon compounds is favored by any environmental condition that inhibits cell multiplication but still permits photoassimilation to occur. Membrane permeability alteration or damage is probably the case in situations of high light intensities and other distinctly detrimental conditions. Effects of UV-A and UV-B irradiance on release of organic compounds is unclear (cf. Karentz *et al.*, 1994).

During cyanobacterial blooms, population growth of other algae can be strongly suppressed. Murphy *et al.* (1976) have demonstrated that cyanobacteria, which have high requirements for iron, can release hydroxamate siderchrome compounds, which complex iron and increase its availability, thereby favoring growth of the cyanobacteria. Simultaneously, the hydroxamate chelators have growth-suppressing effects on algae. Certain cyanobacteria, particularly *Microcystis*, produce microsystins and nodularins, a series of some 40 toxic cyclic heptapeptide compounds. Effects are numerous; some are known to inhibit protein phosphatase activity.

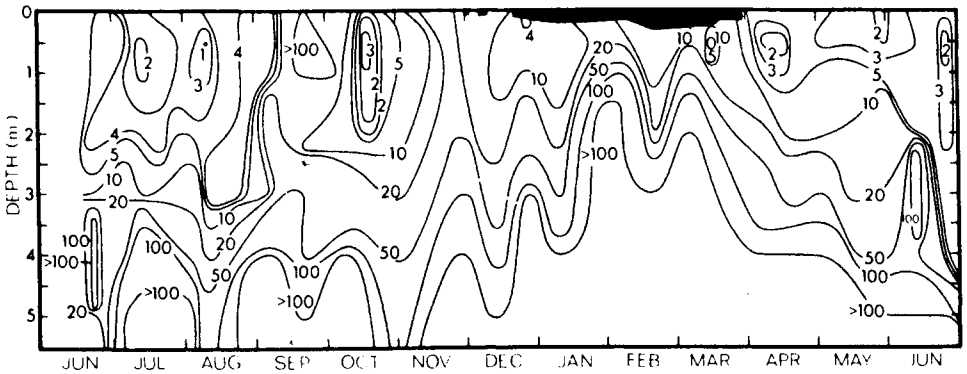

FIGURE 15-29 Depth–time isopleths of the rates of extracellular release of organic carbon by phytoplankton (mg C m^{-3} day^{-1}), hypereutrophic Wintergreen Lake, Michigan, 1971–1972. (From Wetzel *et al.*, unpublished data.)

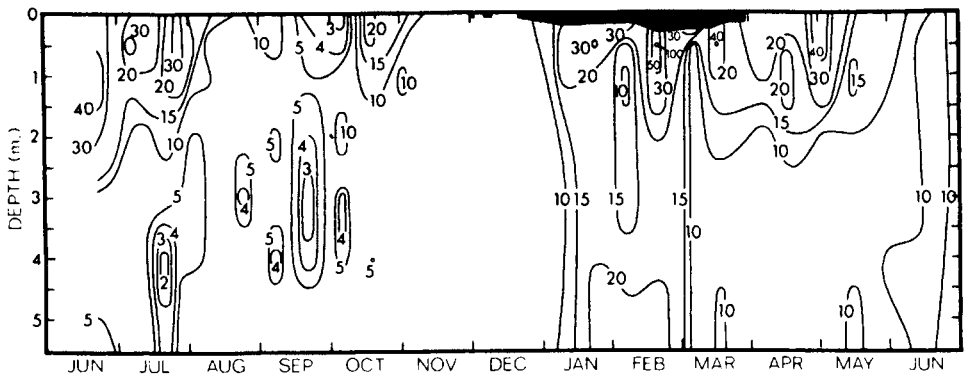

FIGURE 15-30 Depth–time isopleths of extracellular release of organic carbon by phytoplankton as a percentage of rates of carbon fixation, Wintergreen Lake, Michigan, 1971–1972. (From Wetzel *et. al.*, unpublished data.)

This large subject of cyanotoxins is reviewed in detail by Carmichael (1986, 1997). It should be noted that bacterial utilization of excreted organic compounds is extremely rapid (e.g., Nalewajko and Lean, 1972; Herbst and Overbeck, 1978; Nalewajko *et al.*, 1980; Coveney, 1981; Coveney and Wetzel, 1989, 1995). As a result, the simpler low-molecular-weight compounds are utilized and degraded rapidly and large-molecular-weight substances dominate in time because of their much slower rates of degradation by bacteria (cf. Chap. 17).

F. Diurnal Changes in Phytoplanktonic Production Rates

The diurnal periodicity of photosynthesis of phytoplankton is often not proportional to the daily insolation curve. Most studies show maximum photosynthetic rates in the morning hours, with a subsequent reduction at midday; sometimes recovery occurs in the afternoon. This diurnal periodicity is particularly acute at the surface and undoubtedly is partly related to photoinhibition and increased rates of extracellular release of recently synthesized organic compounds. However, much of this surface midday depression dissipates with increasing depth, often in <1 m, as light is attenuated and photosynthesis is undersaturated with light (Vollenweider, 1965; Jones and Ilmavirta, 1978).

Diurnal synchrony of cell division and growth has been well established in cultures of algae (Soeder, 1965), and this synchrony has been observed to take place in the same way in natural populations, particularly among small flagellates, under certain environmental conditions (Heyman and Blomqvist, 1984). As a result, the composite phytoplanktonic populations consist of various combinations of algae in (a) active, strongly anabolic growth stages in which cell numbers are increasing, especially in the morning, and overriding losses by sinking, natural death, and grazing; (b) "neutrally" active stages that are slightly anabolic, not undergoing significant positive or negative changes in biomass; and (c) inactive, catabolically metabolizing stages in which cells in resting, decaying, or degenerating stages are decreasing. Thus, depending on the combination of algae in various physiological stages of population development, and the dominant stage within the composite phytoplanktonic community, diurnal, synchronized, predawn and morning cell division often results in a pronounced photosynthetic periodicity from rapid early morning photosynthesis. For example, cell division in natural populations of the dinoflagellate *Ceratium* is phased to a brief period of the diurnal cycle (Heller, 1977; Heaney and Talling, 1980). The highest frequency of dividing cells occurred late in the dark period, with some carryover into the beginning of the following daylight hours.

It should also be mentioned that photorespiration increases at midday in submersed angiosperms and results in a midday reduction of net photosynthesis (Chap. 18). Photorespiration occurs in algae as well, but little is known as yet of its magnitude and diurnal periodicity under natural conditions.

An excellent example of diurnal biochemical coupling is seen in the bloom-forming cyanobacteria, especially one species of *Anabaena*. During daylight, carbon dioxide fixation in *Anabaena oscillarioides* is greatest in the morning period, while N_2 fixation is maximum during the afternoon hours when oxygen concentrations of the water often become supersaturated (Paerl, 1979; Paerl and Kellar, 1979). High oxygen concentrations can inactivate the nitrogenase enzyme activity of N_2 fixation. Nitrogenase-produced H_2, however, serves to remove excess intracellular oxygen

by hydrogenase, leading to the formation of water and ATP (Paerl, 1980). The ATP is used in other metabolic reactions while protecting the N_2 fixation reactions from oxygen.

Vertical migration of phytoflagellates can contribute significantly to observed diurnal periodicity in stratification and photosynthesis of phytoplankton (e.g., Nauwerck, 1963; Tilzer, 1973; Ilmavirta, 1975; Happy-Wood, 1976). In high mountain lakes, for example, the dominant flagellates (e.g., *Gymnodinium*) usually ascend in the afternoon and evening and migrate downward with increasing light intensities (maximum rates approximately 1 m hr^{-1}). Photosynthesis is reduced near the surface during the midday hours as a result of light saturation, photoinhibition, and downward migration, but at greater depths, utilization of light energy usually increases at this time.

G. Horizontal Variations in Phytoplanktonic Biomass and Productivity

It is commonly assumed when measuring phytoplanktonic primary productivity that horizontal variations within the pelagic zone are relatively minor. This assumption is probably valid in many small- to moderate-sized lakes in which variations in different parts of the lakes are relatively small (<10%). In such cases, horizontal variations in phytoplanktonic activity may be masked by larger variation associated with sampling and experimental errors of measurement. Horizontal variations in biomass and productivity of phytoplankton become much more significant, however, in very small lakes, in extremely large lakes such as the Great Lakes, in proximity to the littoral zone of most lakes, and as the morphometric complexity of the lake basins increases, particularly in reservoirs. Even in very productive tropical lakes, phytoplanktonic productivity is often greater in the pelagic zone closer to the perimeter of the lake than in the central portion of the pelagic (e.g., Talling, 1965). In very large lakes, this horizontal disparity becomes more acute (Glooschenko *et al.*, 1973, 1974a, b; Schweizer, 1997). Nutrient loading from specific regions of the drainage basins of such lakes can be sufficient to cause significantly higher, often severalfold higher, rates of primary productivity in nearshore areas or sectors of the pelagic zone.

Phytoplanktonic productivity within the littoral zone or in the pelagic immediately adjacent to it is generally reduced significantly. Within littoral areas of lakes and reservoirs that are colonized by submersed and floating-leaved higher aquatic plants, phytoplankton communities are generally very different from those of the pelagic zone. Overall phytoplanktonic algal productivity is commonly severely reduced because of competition for nutrients by the attached periphytic microorganisms on plant and sediment surfaces (see Chaps. 19 and 21). Additionally, grazing by herbivorous zooplankton is often intensive because many zooplankton have refuge from fish and large invertebrate predation amongst the greatly increased habitat complexity of the higher aquatic vegetation (e.g., Lemly and Dimmick, 1982; Jeppesen *et al.*, 1997).

Horizontal patchiness in phytoplankton distribution has also been observed in relation to wind-induced current patterns (Heaney, 1976; George and Heaney, 1978; Harris *et al.*, 1979; Heaney and Talling, 1980; Camarero and Catalan, 1991; Jones *et al.*, 1995). Light wind stress (approx. 3 m s^{-1}) can cause horizontal flow of surface layers in small lakes. These currents induce upwelling of subsurface concentrations of phytoplankton at the windward end of a lake or downwind transport of algae when concentrated in the surface waters. The direction of the gradient can be readily reversed with a shift in wind direction and circulation patterns (e.g., Jones *et al.*, 1995). Moderate-to-strong wind conditions (>4 m s^{-1}) can cause sufficient turbulent mixing to eliminate heterogeneity within the epilimnion. In large, shallow lakes, wind-induced circulation can cause concentric distribution patterns, with maximum phytoplankton concentrations occurring toward the center (e.g., Ganf, 1974c).

Many lakes and reservoirs have complex morphometry and may contain dendritic valleys with numerous large, long bays. Primary productivity within these relatively isolated bays can be quite different from that of the major basin (Table 15-11). Often the productivity of these isolated arms is higher than that of the primary basin, for they receive proportionally higher loading of nutrients per unit volume.

The primary productivity of phytoplankton of reservoirs is variable seasonally and can vary considerably from year to year as well. During periods of high runoff from the drainage basin, abiogenic turbidity can be very high in the riverine section of the basin that receives the primary influents. In this region, primary production rates often are greatly reduced (Fig. 15-12). As much of the inorganic turbidity settles out of the euphotic zone in the progression downstream along the length of the reservoir toward the dam and outlet, the depth and productivity of the trophogenic zone increase (Fig. 15-12). However, if the retention time of the reservoir is short (i.e., the flow-through rate is high) there may be insufficient time for populations to develop fully before being flushed out of the reservoir. Some reservoirs are so constructed that outflow is drawn from the hypolimnion and lower strata; the increased retention time of surface waters can then lead to a more typically lake-type of phytoplanktonic

TABLE 15-11 Variations in the Annual Primary Productivity of Phytoplankton in Different Sections of Sylvan Lake, Indiana, a Basin of Complex Morphometry[a]

community development and primary productivity. Removal of hypolimnetic water, laden with nutrients from sedimenting organic matter and decomposition, can reduce the nutrient loading of the reservoir water.

H. Annual Rates of Primary Production

The number of measurements of the primary productivity of phytoplankton in lake systems is prodigious. Only a few examples have been selected for general comparative purposes in Table 15-12, based on a rather subjective division of lakes into trophic categories. Further examples are listed in Westlake *et al.* (1980).

Among the lowest annual productivity values for phytoplankton of natural freshwater systems are those from Char Lake at latitude 74° in the Canadian Arctic. For this lake, the annual primary productivity of

Data approximated in some cases; estimates given in parentheses

phytoplankton is about 4 g C m^{-2} yr^{-1} but the productivity of mosses and epilithic algae increases this figure to about 20 g C m^{-2} yr^{-1} (Kalff and Welch, 1974; Kalff and Wetzel, unpublished). The low productivity results from low light and temperatures as well as from low nutrient availability. For example, Meretta Lake, near Char Lake, receives domestic pollution from a small village in quantities sufficient to increase primary productivity of phytoplankton by five times (Table 15-12), although lower values exist (Table 15-12). To date, all waters analyzed, even amictic, permanently ice-covered lakes, contain a limited algal flora and exhibit some net primary productivity.

A general categorization of the characteristics of lakes between the extremes of very oligotrophic and very eutrophic systems has been attempted many times. The criteria employed, largely resulting from an innate desire of humans for order in the natural world, have

TABLE 15-13 General Ranges of Primary Productivity of Phytoplankton and Related Characteristics of Lakes of Different Trophic Categories[a]

[b] Referring to approximately net primary productivity, such as measured by the ^{14}C method.

led to classification of lakes on the basis of nearly every parameter, including geomorphology, chemical constituents, nearly every type of organism from bacteria to fish, and even the waterfowl associated with different types of lakes. The most realistic parameter for such categorization, at least in a general way, is one that can be quantitatively determined as a rate of growth and one that integrates the host of environmental parameters controlling the synthesis of organic matter that enters the system. Rates of autochthonous primary production are basic to such an evaluation, and those of the phytoplankton have been proposed many times as the best existing criterion (see, e.g., Rodhe, 1969).

The ranges of primary productivity of phytoplankton commonly associated with oligotrophy and eutrophy are given in Table 15-13, along with several related characteristics of the phytoplankton. Such groupings can only be used in a general way, since there are many exceptions. The relationships, however, predominate in a majority of inland waters. The dystrophic lake category, discussed at length in Chapter 25, is very deviant and variable. Productivity of phytoplankton in dystrophic lakes is frequently attenuated by complex interactions between light, high concentrations of dissolved humic compounds, and limited inorganic nutrient availability.

The primary productivity of phytoplankton is often used as a major criterion for determining the trophic state of a lake or reservoir. The validity of this criterion, however, depends upon the assumption that dissolved and particulate organic matter inputs from littoral and allochthonous sources are small relative to those of the phytoplankton. In many cases on a global basis, littoral productivity and allochthonous organic inputs are much larger than inputs produced by phytoplanktonic productivity (Wetzel, 1990a); in such cases, phytoplanktonic productivity alone is a poor estimator of the trophic state of the lake or reservoir. One of the major objectives of Chapters 18 and 19 is to place these land–water interface components of aquatic ecosystems in proper perspective within the real world. Such analyses do not decrease the importance of phytoplankton to the metabolism and food-web structure of lakes and reservoirs. Rather, the primary productivity of phytoplankton must be viewed as a variably important contributor to overall aquatic metabolism.

XIV. PHYTOPLANKTON AMONG AQUATIC ECOSYSTEMS

Examination of the comparative characteristics of phytoplanktonic communities and their productivity among river, reservoir, and lake ecosystems indicate a number of consistent traits. Phytoplankton diversity is very low in low-order streams but increases in high-order large rivers (Table 15-14). Similarly, the diversity

TABLE 15-14 Comparative Characteristics of Phytoplankton and Their Productivity among River, Reservoir, and Natural Lake Ecosystems[a]

Property	*Rivers*	*Reservoirs*	*Natural lakes*
Phytoplankton diversity	Very low in low-order streams; increasing in high-order large rivers	Low in riverine zones; increasing in lacustrine zone	High diversity in oligotrophic lakes, decreasing in eutrophic lakes; similar in tropical and temperate lakes
Phytoplankton biomass	Very low in low-order streams; increasing in large rivers, although often light-limited	Moderately high in response to high nutrient supply in riverine sections; less in lacustrine zone where nutrients often limiting	Highly variable (to 5 orders of magnitude) in temperate lakes seasonally; much less variable in tropical lakes
Phytoplankton productivity	Low, often light-limited by advective flows and turbidity	Highest in transitional zone; reduced in riverine zone by light availability and often in lacustrine zone by nutrients; marked horizontal gradients; volumetric productivity (P_{max}) decreases from headwaters to dam; areal productivity relatively constant borizontally	Low in comparison to littoral productivity; increasing with moderate nutrient loading; declining at very high nutrient loading; seasonal and vertical gradients predominate; small horizontal gradients; light and inorganic nutrient limitations predominate

[a] Assembled from the syntheses on rivers by Ryder and Pesendorfer (1980) and on reservoirs and lakes by Wetzel (1990) and many sources cited in these papers.

of phytoplankton is low in the riverine portions of reservoirs but often increases in the more stable lacustrine zones with longer retention periods. Phytoplanktonic diversity is distinctly higher in less productive lakes than in eutrophic waters.

The biomass of phytoplankton is very low in low-order streams usually because of light limitations from shading by riverine terrestrial vegetation. Biomass can increase, despite frequent light limitation from abiotic turbidity, in larger rivers where residency times can often exceed those of the algal life cycles. The biomass of phytoplankton is usually low in riverine portions of reservoirs despite nutrient abundance because of frequent turbidity-related light limitations. Phytoplanktonic biomass fluctuates greatly in natural temperate lakes, usually by 5 or more orders of magnitude, on an annual basis, where as biomass in tropical lakes is much less variable.

The productivity of phytoplankton is low, regardless of the optimality of growing conditions, in comparison to the productivity of other photosynthetic organisms in aquatic ecosystems. The spatial distribution of phytoplankton in a dilute aqueous medium and conditions (limited light availability, sedimentation, diffusion limitations of nutrients, and others) that limit productivity have been termed an "aquatic desert" (Moeller *et al.*, 1998). Maximum rates of production of phytoplankton occur under conditions of moderate sustained nutrient availability in which the depth of the euphotic zone is large. The productivity of phytoplankton can dominate in the total productivity of some lakes where the phytoplankton themselves shade out other in-lake producer organisms. The collective productivity of phytoplankton per square meter, however, is low (Table 15-14).

XV. SUMMARY

1. The freshwater phytoplankton are composed of algae of almost every major taxonomic group and the cyanobacteria. Photosynthetic autotrophic metabolism is the sole metabolic pathway for the synthesis of organic matter among most algae. Although certain microbiota possess supplementary nonphotosynthetic means of nutrition, photosynthesis dominates and these organisms can be functionally included with the phytoplankton.
2. Light-energy-absorbing pigments are diverse among the algae. Chlorophyll *a* occurs in all algae and is the primary photosynthetic pigment. Chlorophyll *b* is found only in green algae and euglenophytes, and chlorophyll *c* occurs in many algal groups. Other accessory chlorophylls, of uncertain functions, are restricted to specialized algae. Light energy absorbed by some carotenoids and the biliproteins (phycoerythrin and phycocyanin of the cyanobacteria, cryptomonads, and red algae), as with chlorophylls *b* and *c*, is transferred to chlorophyll *a*.

3. The size of phytoplankton varies greatly. When the size is <20 μm, transfer of material to and from cells is almost entirely by molecular diffusion rather than by eddy diffusion of turbulence (Table 15-3).
   a. The ultraplankton (0.2–20 μm) are simple, unicellular in form, and have generation times in hours. These rates are similar to those of protistian flagellate predators. Small size allows establishment of self-contained, dynamic communities of phototrophs, viruses, heterotrophic bacteria, phagotrophic flagellates, and ciliates, in which materials are rapidly cycled with little loss by sedimentation or transfer to higher trophic levels. Nutrients tend to be recycled rapidly.
   b. The larger microplankton (20–200 μm) are not as vulnerable to predation by flagellates but are inefficient in nutrient uptake and develop prolifically when nutrient concentrations are high. Vulnerable to sedimentation, the microplankton depend on water movements or flotation mechanisms for transport to light and rapid reproduction to succeed. Equilibrium is never achieved within the microplanktonic community.
4. Most phytoplanktonic algae lack or have very limited powers of locomotion. As a result, most phytoplankton are dispersed by turbulent water movements. Since the density of most phytoplankton is greater than that of water, they tend to sink from the lighted, trophogenic zone. Sinking has the advantage of disrupting nutrient gradients surrounding the cells. The disadvantage of sedimenting out of the photic zone is offset to varying degrees by upward movement and turbulent water transport.

   Improved flotation or reduced sinking rates are accomplished in various ways:
   a. Reduction in sinking rate is enhanced by increasing *surface-to-volume ratios*. Deviations in cell morphology from the spherical form by protrusions and projections decrease sinking rates by increasing frictional resistance with the water. Seasonal polymorphism (cyclomorphosis) is rare among phytoplankton but is conspicuous among certain dinoflagellates. *Ceratium* alters its form and reduces its sinking rate as the viscosity of water decreases during warmer seasons (Fig. 15-1).
   b. *Production of mucilage* reduces sinking rates. Gelatinous sheaths are common among cyanobacteria and green algae, including certain desmids and diatoms. The sheaths are less dense than the cell and increase frictional resistance.
   c. *Gas vocuoles* are common in cyanobacteria and decrease the density of the cells to below the density of water. Many cyanobacteria regulate buoyancy and position in the photic zone to poise the populations within vertical physical and chemical gradients favorable to growth.
   d. A few algae reduce density by *accumulation of fats*.
   e. Certain algae can alter density by *regulation of cellular ion content*.
   f. A number of algae move vertically within the water column by *swimming by flagella*. Such movement can improve light and nutrient availability.
5. Coexistence of a number of phytoplankton species is a conspicuous feature of fresh waters. Although a few species commonly dominate a phytoplanktonic assemblage, a number of rarer algae coexist among the dominant species. Many differences in algal physiological characteristics, requirements, and tolerances, as well as seasonal and spatial variations in environmental parameters, permit the apparent multispecific equilibrium to exist for short periods.
   a. Differences in the efficiency of utilization of resources may be too small for competitive exclusion to occur before environmental conditions change.
   b. Partial commensalism or symbiotic dependency (e.g., through production and utilization of organic micronutrients) or both can reduce competition.
   c. Selective herbivory of a more successful species can reduce competition with a less successful species.
   d. Certain algae are meroplanktonic, enter resting stages often in the sediments, and do not compete for periods of varying duration with holoplanktonic (continually planktonic) species.
   e. Many or all of these coexistence mechanisms can function simultaneously.
6. Many environmental factors interact to regulate spatial and seasonal growth and succession of phytoplankton populations.
   a. Light and temperature synergistically affect photosynthesis. Although photosynthetic rates and algal growth are directly related to irradiance intensity, the response to light intensity, especially at light saturation, is temperature dependent (Fig. 15-2) and variable among species. A considerable degree of adaptation to changing light intensities occurs among algae, often by regulation of pigment concentrations per unit biomass.
   b. High light intensities inhibit photosynthesis of many algae; the effects are partly reversible if exposure is not too long (several hours) and phytoplankton are transported to regions of lower light intensities.

c. The vertical distribution of photosynthesis is strongly related to available light. A near-exponential decline with increasing depth underlies a surficial zone of maximum photosynthesis (Fig. 15-3). Photoinhibition by excessive light and ultraviolet radiation is common, with depression of photosynthesis at the surface and a subsurface photosynthetic maximum. As photosynthetic rates per unit volume of water increase in nutrient-enriched waters, the biogenic turbidity resulting from dense algal populations constricts the thickness of the trophogenic zone toward the surface.
d. Algae have definite temperature optima and tolerance ranges, which interact with other parameters to cause seasonal succession. For example, many diatoms can photosynthesize well at cooler water temperatures, whereas the temperature optima of many green algae and cyanobacteria are higher.
e. Major changes in the seasonal succession of phytoplankton in temperate lakes are related to changes in availability of phosphorus, nitrogen, and silica (cf. Chaps. 12, 13, and 14). The growth of a population under conditions of adequate light and temperature is often limited by a single nutrient. Limitation can shift rapidly from nutrient to nutrient as their availabilities change on a diurnal, daily, and seasonal basis.
f. Many algae require, but are unable to synthesize, organic micronutrients, especially vitamin B_{12}. These substances have been found to be actively assimilated by phytoplankton and, at certain times, photosynthesis is enhanced by organic enrichment; they likely play a significant role in succession and competitive success of certain algal populations.
g. Most algae are obligate photoautotrophs in which inorganic carbon is reduced biochemically with light energy. Utilization of organic substrates in the dark (heterotrophy) or in the light (photoheterotrophy) by aerobic dissimilation occurs in certain algae, and especially in the cyanobacteria. Heterotrophic augmentation occurs in some algae, but under most natural conditions of low organic substrate concentrations, bacteria are much better competitors for available substrates.
h. Dissolved organic compounds, largely of terrestrial and wetland plant origin, can influence phytoplankton metabolism by interacting with macro- and micronutrients and influencing their availability, either directly (e.g., complexation) or indirectly (e.g., altering other inorganic regulatory mechanisms).

7. Distinct seasonal patterns and successions of algal populations and biomass are observed in phytoplankton communities.
   a. In temperate fresh waters, growth is greatly reduced during winter when both light and temperatures are low. A spring biomass maximum is commonly observed as light conditions improve and often consists predominantly of diatoms and cryptophytes adapted to low light conditions. Lower biomass often occurs during the summer. Among more eutrophic waters with high phosphorus loading, silica concentrations of the trophogenic zone are commonly reduced in the spring to levels inadequate to support large diatom populations. Summer populations of nonsiliceous green algae then flourish until concentrations of combined nitrogen are reduced below replacement. Under these conditions, nitrogen-fixing cyanobacteria have competitive advantages and often proliferate.
   b. Summer phytoplankton populations of temperate oligotrophic lakes are often low. A second autumnal maximum, usually predominantly of diatoms, often develops during and after fall circulation. The limited growing season in high altitude and subpolar regions often results in a single summer maximum of phytoplankton biomass. In tropical lakes, total phytoplankton biomass is more constant (maximum often in winter) and larger than in temperate lakes. Frequent changes in abiotic factors, particularly mixing events, occur in tropical lakes that lead to more episodic changes in phytoplankton succession than in stratified temperate lakes. The succession of algae between the episodes, however, is similar in both tropical and temperate lakes.
   c. Although variability is large, the general patterns of seasonal succession of phytoplanktonic biomass are reasonably constant from year to year, if the drainage basin and lake are not perturbed.
   d. Seasonal changes in phytoplanktonic numbers and biomass are usually very large (approximately a thousandfold) in temperate and subpolar fresh waters. In tropical lakes, seasonal variations are much lower (approximately fivefold).
   e. Changes in phytoplanktonic numbers and biomass are often out of phase with rates of photosynthesis. Photosynthetic productivity usually follows more closely the annual cycle of solar irradiance in low or moderately productive lakes, especially in temperate and subpolar areas. Smaller algae with faster turnover rates often predominate at warmer temperatures.

8. Parasitism of phytoplankton, particularly by chytrid fungi and viruses, is common and can increase as algae senesce in aerobic waters. The effects of selective parasites on species succession and algal productivity are unclear.
9. Grazing of phytoplankton by rotifers and microcrusfacea influences algal populations and their succession.
   a. On an annual basis, grazing losses of phytoplankton are usually minor in comparison to losses by sedimentation out of the photic zone.
   b. Grazing losses can be highly significant during certain periods of the year, during which time the algal populations are severely reduced. In the early summer "clearwater" phase, algal populations decline precipitously under conditions of high temperatures, high water column stability, and high light and reduced nutrient availability. During this time, ciliate, rotifer, copepod, and cladoceran zooplankton often increase their populations; algae smaller than 40 μm are especially vulnerable and grazing losses often exceed reproductive rates.
   c. Much of the food ingested by zooplankton is not assimilated, but is egested and enters the detrital pool as dissolved and particulate organic matter.
   d. Selective grazing by microcrustacea, largely on the basis of algal cell size, can alter the seasonal succession of phytoplankton.
   e. Nutrient regeneration, particularly of phosphorus, can be accelerated by zooplanktonic grazing; the increase in nutrient regeneration can enhance the primary productivity of the algae.
10. As nutrient limitations of the phytoplankton of infertile waters are increasingly relieved by nutrient inputs, rates of algal production increase.
    a. The densities of the phytoplanktonic community progressively reduce the available light and decrease the thickness of the trophogenic zone. A point is reached at which self-shading inhibits further increases in productivity, regardless of nutrient availability. Productivity per unit surface area of the freshwater system is usually lower under these hypereutrophic conditions than under less productive conditions where a thicker trophogenic zone exists.
    b. Maximum photosynthetic efficiencies of light utilization by phytoplankton are low, usually $<1\%$ of radiation incident on the water. These efficiencies are considerably less than utilization of light by wetland and terrestrial plants.
    c. An inverse relationship generally exists between algal biomass and productivity per unit biomass in the phytoplankton. Often, small species of relatively minor contribution to the algal community biomass have short generation times and contribute more to the total primary productivity than do larger species.
11. A significant amount ($<20\%$) of the carbon fixed photosynthetically by phytoplankton is released extracellularly as dissolved organic compounds.
    a. Certain low-molecular-weight compounds of intermediary metabolism are released in greater amounts under conditions of stress (e.g., light inhibition, low nutrient availability).
    b. Extracellular dissolved organic carbon released as a percentage of total carbon fixed photosynthetically is usually low ($1-5\%$) in healthy, actively growing phytoplankton. The percentage release increases under very high and very low light conditions and during senescence.
12. Horizontal variations in the primary productivity of phytoplankton can be large. Spatial variations increase in significance in very small lakes, very large lakes (e.g., the Laurentian Great Lakes), in proximity to the littoral zone and inlet areas of most lakes, and as the morphometric complexity of lake basins increases.

XXI. Summary

The animals found in fresh waters are extremely diverse and represent nearly all phyla. The evaluation of their functional roles within aquatic systems requires a balanced understanding of the general modes and timing of growth and reproduction in relation to the availability and utilization of food. The population dynamics and certain important adaptive behavioral characteristics that influence these dynamics regulate the productivity of individual species populations and entire communities. Underlying all evaluations of productivity of the animals are their food or trophic relations with plants and other animals and competitive and predatory interactions that lead to a greater success of one species over another.

I. ZOOPLANKTON

In contrast to the great total biodiversity of animals in freshwater ecosystems, both the phyletic representation and species diversity of zooplankton communities is very much lower in fresh water than in marine habitats (cf. particularly Lehman, 1988). The differences are likely related to the great antiquity, depth, and evolutionary continuity found in the oceans. Even in ancient lakes zooplankton communities are not species enriched.

Planktonic animals are dominated by four major groups: (a) protists that include protozoa and heterotrophic flagellates, (b) the rotifers, and two subclasses of the Crustacea, (c) the Cladocera, and (d) the Copepoda. A few coelenterates, larval trematode flatworms, gastrotrichs, mites, and the larval stages of certain insects and fish occasionally occur among the true zooplankton, if only for a portion of their life cycles.

II. PROTOZOA AND OTHER PROTISTS

Recent studies involving electron microscopy and molecular biology have reshaped understanding of the Protista (Andersen, 1998). Phylogenetically, the Protista represent, at best, a grade, not a clade, and the kingdom Protista is not a natural taxonomic unit and is being abandoned. The Protista does, however, provide an artificial aggregation of predominantly microscopic organisms that is useful as an assemblage for ecological reasons.

Because the primary thrust of the present discussion is concerned with ecology, the protozoa are included among functionally similar phagotrophic protists. These free-living protists include the ciliates, most of the flagellates, and the sarcodines. These protists are eukaryotes, usually unicellular, that possess a nuclear envelope, eukaryotic ribosomal RNA, and endoplasmic membranes (Fenchel, 1987; Laybourn-Parry, 1992; Lee and Kugrens, 1992; Patterson, 1992). These organisms further possess eukaryotic organelles (mitochondria, chloroplasts, and flagella), histones associated with chromosomal DNA, and an ability to perform phagocytosis. Although a few protists can be colonial, they do not form tissues of specialized cells.

Most protozoa and related protists reproduce by binary fission, although multiple fission and sexual reproduction occur in a few free-living forms. Growth and generation times are highly variable among free-living protists. Maximum growth rates are found when food availability is not a constraint; under these conditions, populations generally increase directly with temperature within the limnological range and they decrease as body size increases (Taylor and Sanders, 1991). Many protists produce cysts under harsh environmental conditions (e.g., lack of food and desiccation).

Information on the functional ecology of the protists is emerging rapidly. It is becoming clear that the protistan zooplankton are the most important microbial consumers and have major functions in organic carbon utilization and nutrient recycling. Although the instantaneous biomass of the planktonic protists is small in comparison to those of the rotifers and especially the microcrustaceans, the generation rates of protists are high. The comparative rates of heterotrophic metabolism and productivity among the major groups at the ecosystem levels are presently under intensive investigation. A few examples of population dynamics and productivity estimations are presented next prior to evaluating the importance of these microbial

communities to the utilization of organic matter and nutrient recycling.

A. Dynamics of Protistan Zooplankton

1. Flagellates

Flagellates are the most abundant component of the protozooplankton. Autotrophic flagellate species have already been discussed among the phytoplankton, although many are known to be mixotrophic and to feed on bacteria as well as fix carbon photosynthetically (e.g., Sanders and Porter, 1988; Arndt *et al.*, 2000). Common forms include the dinoflagellates (e.g., *Ceratium* and *Peridinium*), chrysomonads (*Dinobryon, Mallomonas,* and *Synura*), euglenids (*Euglena*), volvocids (*Volvox* and *Eudorina*), choanoflagellates (*Astrosiga*), and the diverse large group of heterotrophic flagellates. The heterotrophic groups include heterokont taxa (mainly chrysomonads and bicosoecids), choanoflagellates, kataphepharids, and a number of species, collectively called Protista *incertae sedis*, that cannot be assigned to any of the major groups (Patterson and Larsen, 1991). The heterotrophic flagellates are differentiated into two general groups on the basis of size: (a) heterotrophic nanoflagellates (HNF) below 15 μm and (b) large heterotrophic flagellates within a range of $\geq$15–200 μm (Arndt *et al.*, 2000). Among both temperate and subtropical lakes, dinoflagellates tend to increase in dominance as the pH of the water decreases and can dominate in acidic lakes (Laybourn-Parry, 1992).

2. Ciliates

Many major ciliate genera are represented in freshwater protozooplankton assemblages across the spectrum of trophic states. Of the three major groups, the oligotrichs, particularly *Strombidium* and *Halteria,* are found worldwide in lakes across the trophic spectrum (Laybourn-Parry, 1992). The tintinnid ciliates (order Choreotrichida: *Tintinnidium, Tintinnopsis,* and *Codonella*) are also widely distributed in temperate to tropical regions. Haptorid ciliates (e.g., *Askenasia* and *Mesodinium*) are similarly distributed broadly and abundantly. Although a few ciliates are mixotrophic and supplement nutrition by photosynthesis, most are holozoic and feed on bacteria, algae, particulate detritus, and other protists. A few are carnivorous and feed on small metazoans (see discussion later). Ciliates tend to be more significant components of the zooplankton of eutrophic lakes.

A number of ciliates are common to the zooplankton, although they usually do not dominate except in certain situations (e.g., in very shallow lakes or in the deeper strata of nearly anaerobic hypolimnia). Ciliates can move much more rapidly (200–1000 μm s^{-1}) than other protozoa[1] (0.5–3 μm s^{-1} among those with pseudopodia; 15–300 μm s^{-1} among those with flagella). Such movement contributes significantly to greater dispersal and the higher feeding rates of ciliates.

3. Sarcodines

Sarcodine protozoa are poorly represented in the zooplankton of fresh waters. Even in eutrophic lakes, sarcodines occurred in modest average abundance (Laybourn-Parry *et al.*, 1980). Heliozoans are restricted vertically largely to the epilimnion and metalimnion of stratified lakes. Seasonal variations are great; for example, in Lake Constance abundances ranged from below detection limits in the spring (April to mid-June) to summer maxima of up to 6.6 cells ml^{-1} (Zimmermann *et al.*, 1996). Seasonal mean heliozoan production was, however, equivalent to only about 1% of the combined ciliate and flagellate production in this lake. Testate amoebae, particularly *Difflugia*, are occasionally abundant. For example, populations of the lobosan rhizopod *Difflugia limnetica*, a relatively common planktonic protozoan in several German lakes, increased in early summer and attained a maximum in late summer (Schönborn, 1962). Much of the population then sank as fat globules were metabolized and density increased (Fig. 16-1). Many died and decomposed, some encysted, and others remained active throughout the winter in the littoral sediments. The benthic populations of *D. limnetica* slowly increased and then in late spring became planktonic by reducing their density through formation of fat inclusions and gas bubbles. The tests of this species and some others are covered with minute sand grains; in the planktonic phase, the test may be covered instead with diatom frustules or quartz grains that are circulated into the upper strata (Fig. 16-1). Many other protozoans exhibit this type of meroplanktonic existence, in which only a portion of their life cycle is planktonic.

4. Distributions

Although nearly all protozoa and related protists are aerobic, a majority can grow very well even when oxygen concentrations are low (see, e.g., Bragg, 1960). This microaerophillic ability is conspicuous among the planktonic and benthic ciliates and is attested to by their major development in organic-rich and organically polluted waters (cf. review of

[1] The swimming rates are temperature dependent (e.g., two species of *Loxodes* averaged 270 μm s^{-1} at 10°C and 430 μm s^{-1} at 20°C (Jones and Goulder, 1973).

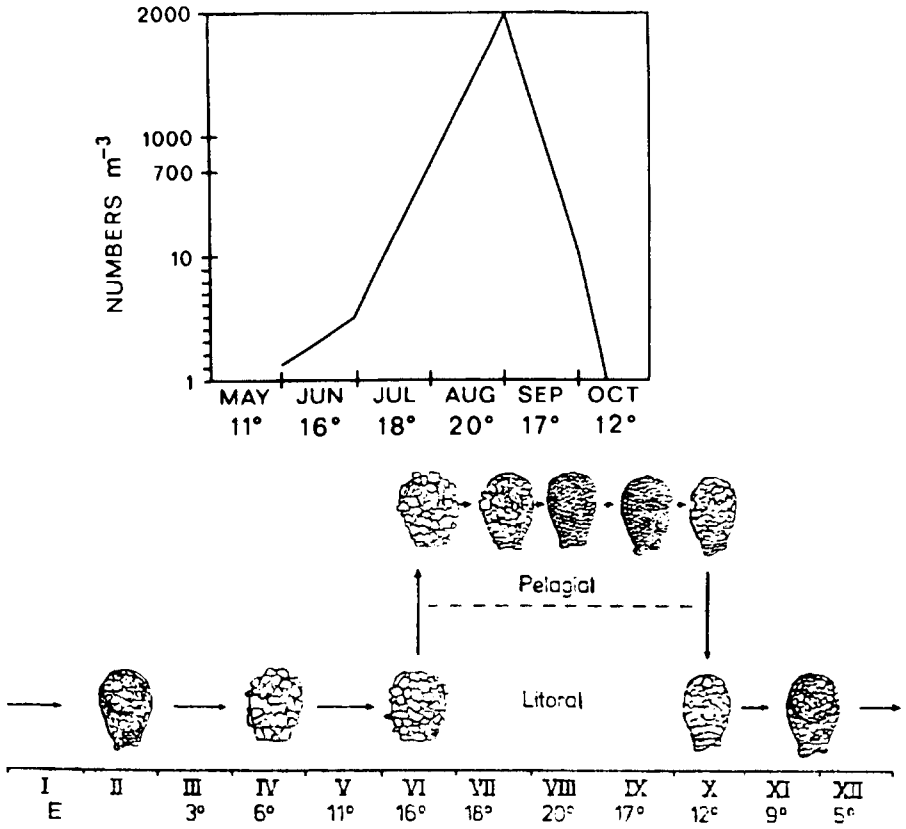

FIGURE 16-1 Changes in populations of the protozoan *Difflugia limnetica* in representative German lakes. *Upper*: Population densities per cubic meter during the planktonic phase. *Lower*: Generalized scheme of morphological changes during the population transitions between the littoral and planktonic habitats. *E* = Ice period. (Modified slightly from Schönborn, 1962.)

Curds, 1982). Various species combinations utilized as indicators of waters of different degrees of organic stress and pollution (cf., e.g., saprobic organism indices, Sládeček, 1973; Foissner *et al.*, 1991, 1992, 1994, 1995; Sládeček and Sládečkova, 1998). Populations of ciliates often develop in water strata greatly reduced in or devoid of oxygen in which bacterial populations tend to be dense, such as in the lower portions of the hypolimnia and the monimolimnion of meromictic lakes.

Four distinct types of ciliated protozoa can occur and be differentially distributed vertically in stratified productive lakes (Finlay, 1990). (1) Specialized anaerobic ciliates (e.g., *Saprodinium*) inhabit anaerobic hypolimnia, utilize particulate organic particles, and have no photosynthetic symbionts, but they do have symbiotic methanogens, which probably remove H_2 as CH_4. (2) Microaerophilic ciliates (e.g., *Loxodes*) are free of symbionts, inhabit dark and microaerobic strata at the metalimnion/hypolimnion interface, and move into lower anaerobic water, where they respire NO_3^-, when the microaerobic zone is illuminated. (3) A third group of ciliated protozoa (e.g., *Frontonia*) lives in the illuminated microaerobic zone of the metalimnion of eutrophic lakes where it benefits from upward diffusion of CO_2 and NH_4^+ that is fixed by its zoochlorellae symbionts. (4) A final group of epilimnetic ciliates (e.g., *Strombidium*) is planktonic and periodically sequesters symbiotic chloroplasts from ingested algae. Distribution of each of these ciliate types is controlled by their biochemical adaptation to anaerobic conditions, the requirements of their symbionts, and their physiological responses to light, oxygen, and gravity. Grazing pressure on anaerobic and microaerophilic ciliates by metazoa has been found to be very low or insignificant (Guhl *et al.*, 1996).

Within lakes that stratify thermally and are moderately productive, two distinct planktonic protozoo-planktonic communities develop during summer stratification. An epilimnetic protistan community of obligate planktonic species overlies a hypolimnetic community of migrants from the benthic sediments

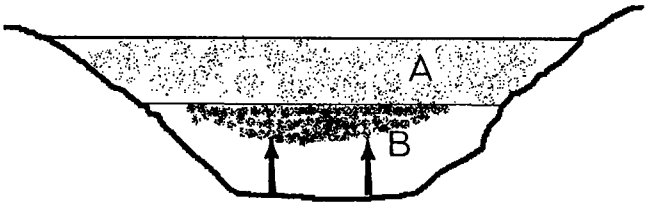

FIGURE 16-2 Distribution patterns of protozooplankton during summer stratification in a eutrophic lake. (a) epilimnetic obligate planktonic species and (b) hypolimnetic community of benthic migrants. (Modified from Laybourn-Parry, 1992.)

(Fig. 16-2). Migration of benthic protozoan communities from the sediments into the deeper strata of the hypolimnion occurred seasonally in response to reduction of dissolved oxygen. For example, two dominant species, *Loxodes* and *Spirostomum*, positioned their populations close to the 1 mg liter^{-1} oxygen isopleth (Goulder, 1974a, 1975; Bark, 1981, 1985; Finlay, 1981). Oxygen is toxic to *Loxodes* and its effect is exacerbated by light (Finlay *et al.* 1986). There is additional evidence that *Loxodes* can respire nitrate as well as oxygen. In another example, in midsummer in large Lake Dalnee, Kamchatka, Russia, flagellate and ciliate protozoans made up a substantial part of the pelagic zooplanktonic community (Sorokin and Paveljeva, 1972). Their maximal biomass was observed during the period of the decline of early summer algal populations and the simultaneous intensive development of bacterial populations. In this lake, protozoan maxima occurred in distinct layers of the water column, generally between 10 and 20 m; their biomass (ca. 3 g m^{-3}) approached the total biomass of other zooplankton at their maximum development. Protozoan utilization of planktonic bacteria in this lake in July constituted a major pathway of energy flux among the fauna in the pelagic zone (discussed further in Chap. 17). Bacterial abundances for protozoan feeding tend to be high at the metalimnetic–hypolimnetic interface (Chap. 17). At shallow sites within the lake basin above the metalimnion, no migration of these species occurs (Laybourn-Parry *et al.*, 1990b).

Mixotrophic ciliates and flagellates are typically distributed within the upper water column in relation to the depth distribution of light. The euphotic zone is shallower among eutrophic lakes, often <5 m, but extends much deeper in less productive lakes. Some flagellates, such as *Ceratium* (see Chap. 15), can migrate extensively to position themselves on a diurnal basis in relation to light, nutrient, and oxic conditions (Reynolds, 1976). Heterotrophic flagellates migrate extensively and often reach very high densities (>140,000 ml^{-1}) in anoxic hypolimnia of eutrophic lakes that contained abundant bacterial communities (Laybourn-Parry *et al.*, 1990b). Abundances of heterotrophic flagellates in most natural plankton assemblages range from 10^2 to 10^6 per liter (Table 16-1) and occur in

much greater abundance, by about 3 orders of magnitude, than the ciliates (Table 16-2).

5. Seasonal Dynamics

Seasonal variations in flagellate and ciliate abundance are variable. Cryptomonad and other microflagellates are commonly numerically dominant across a spectrum of oligotrophic through hypereutrophic lakes (Stewart and Wetzel, 1986). Having high nutritional quality, short turnover times, and ability to grow and reproduce at low intensities of light, these microorganisms function to stabilize variations in nutrient recycling in many spatial and seasonally temporal niches within lakes that are ineffectively utilized by other microbial and small metazoan organisms. For example, in a small oligotrophic lake in Michigan, small microflagellates (<6 μm) and cryptomonads constituted ca. 80% of the total planktonic units throughout the year, but their contributions to algal biomass were nearly always <10% (Taylor and Wetzel, 1988) (Fig. 16-3). Vertical stratification of species occurred but was relatively minor and most conspicuous among certain dinoflagellate and microflagellate species. Predation likely becomes increasingly important in the regulation of the abundance and community composition of protozoans and related protists as lake and river ecosystems become more productive. Where required resources for growth are abundant, the protozoan community is increasingly regulated by predation and correlated with the biomass and species composition of the metazooplankton.

Generally, ciliate abundance is coupled to maximum abundance of phytoplankton in the spring and early summer months (Beaver and Crisman, 1989;

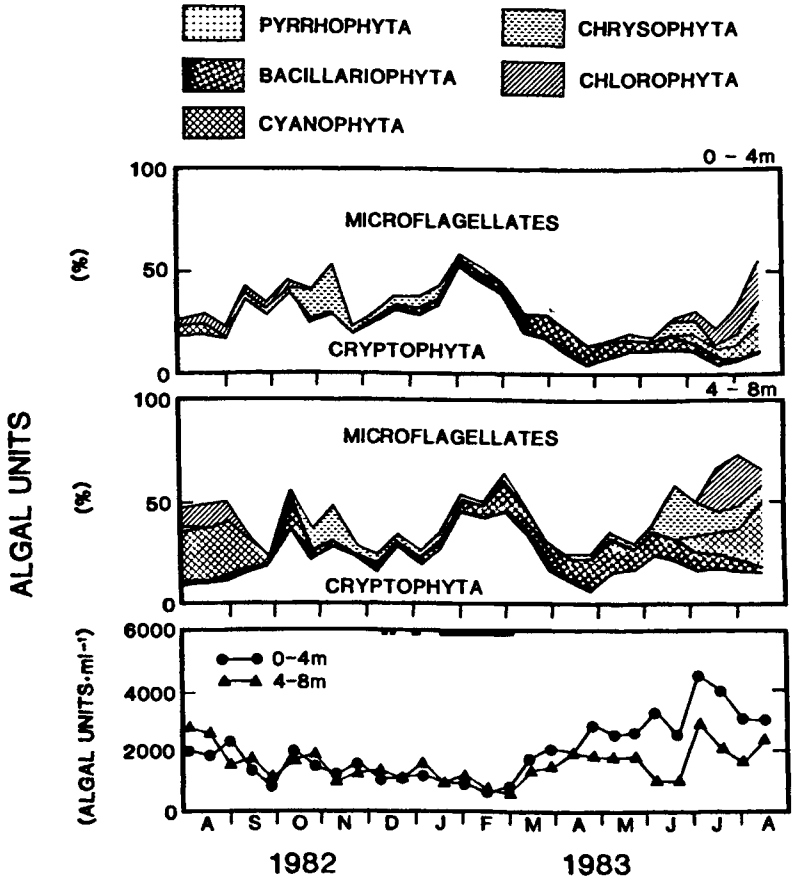

FIGURE 16-3 Percentage microbial units within major phytoplankton and protistan groups in the 0–4-m stratum (*upper*) and 4–8-m stratum (*center*), and total algal unit concentrations (*lower*) in those strata over an annual cycle in Lawrence Lake, Michigan. (From Taylor and Wetzel, 1988.)

Müller *et al.*, 1991; Laybourn-Parry, 1992, 1994). A secondary maximum in the autumn is frequently found in eutrophic and mesotrophic lakes. Species successions over the annual cycle indicate tintinnids are common spring forms in eutrophic and mesotrophic temperate lakes. The tintinnids often decrease during the summer and concentrate in the metalimnion, and later in the autumn increase again in a secondary maximum of lesser magnitude than in the spring.

This seasonal successional pattern among heterotrophic nanoflagellates is exemplified well in Lake Constance (Konstanz), Germany (Weisse, 1991). Nanoflagellate abundance and biomass were lowest in winter and highest in late spring several weeks after the phytoplankton spring maximum (Fig. 16-4). Microflagellate production was balanced through much of the year by grazing by ciliates; predation by larger zooplankton (rotifers and daphnid cladocerans) was significant only during the spring "clearwater" phase (see p. 441). The abundance and seasonal succession patterns of microflagellate communities are controlled both by food resources, particularly in oligotrophic waters, and by predatory losses. Ciliate predation on flagellates is a major regulatory mechanism, especially in more productive waters (see later discussion).

Somewhat analogous seasonal distributions were found in the detailed studies of flagellate, sarcodine, and ciliate communities of Neumühler See, Germany (Mathes and Arndt, 1995). Small heterotrophic nanoflagellates (<15 μm, HNF) were dominant in late summer and in winter, whereas large heterotrophic flagellates (>15 μm, LHF) were dominant in early spring. Ciliates, mostly oligotrichs, formed 50% of protistan biomass on an annual average, whereas HNF (mainly chrysomonads) constituted an average of 29%, LHF (mainly dinoflagellates) 19%, and sarcodines (predominantly heliozoans and testeceans) 2% of the biomass. The protistan zooplankton of these four groups constituted 21% of the annual average total zooplankton biovolume within a range of 3–78% over the year.

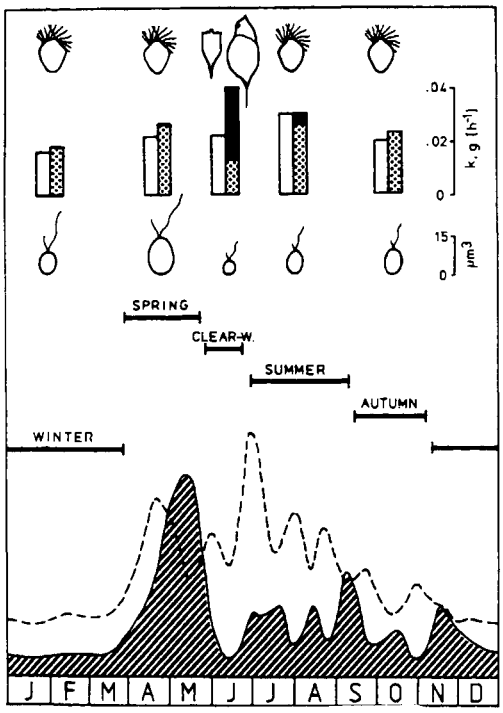

FIGURE 16-4 Seasonal cycle of biomass and cell size of heterotrophic flagellates in relation to bacterial food supply and varying micro- and macrozooplankton grazing impacts. The pictograms in the upper portion denote the major flagellate consumers in the various phases (oligotrioch ciliates, rotifer, *Daphnia*). The bars indicate gross growth rates (k, open bars) and grazing loss rates (g) by ciliate microzooplankton (stippled) or macrozooplankton (filled), respectively. In the lower part, the biomass of bacteria (dashed line) and flagellates (hatched area) are compared. Note that the flagellate biomass is five times that of the bacterial biomass. (From Weisse, 1991; The annual cycle of heterotrophic freshbwater nanoflagellates: Role of bottom-up versus top-down control. J Plankton Res. *13*:167–185, by permission of Oxford University Press.)

Among dystrophic lakes that receive very high concentrations of allochthonous dissolved organic matter, microaggregates of particulate detrital material are abundant in the plankton. These aggregates can form foci for bacteria and microflagellates and can likely serve as a significant supplemental food resource, along with bacteria and microalgae, for both microflagellates and ciliated protozoa (Laybourn-Parry *et al.*, 1992, 1994; Carrias *et al.*, 1994). The highly stained waters can attenuate light severely and restrict mixotrophy among protists.

Summer protozooplankton in eutrophic and mesotrophic lakes is dominated by *Strombidium* spp., vorticellids, and *Epistylis* (Laybourn-Parry, 1992). In Lake Tanganyika in equatorial Africa, the biomass of protozoan zooplankton often exceeded that of the phytoplankton in the euphotic zone while the lake was stably stratified (Hecky and Kling, 1981). The dominant protozoan (*Strombidium*) was, however, probably symbiotic with zoochlorellae algae and mixotrophy imposed lower demands on the available food. Mixotrophic protozoa predominate in the summer among all lake types but are particularly common in oligotrophic waters. Both heterotrophic and autotrophic flagellates commonly reach maximum abundances in midsummer.

Among subtropical monomictic lakes that are generally productive and have high average temperatures, ciliate abundances persist at high levels for longer periods of time and often exhibit a bimodal pattern (mesotrophic) or late summer–autumnal maximum (Pace, 1982; Beaver and Crisman, 1989). Some of these increases may be associated with increased nutrient loading and primary productivity during and following mixing in the autumn. Subtropical lakes maintain higher densities of protozooplankton than do lakes of comparable trophic status in the temperate zone (Table 16-2). This increase in productivity is likely related to the longer growing season and higher temperatures, which allow a sustained productivity during the winter.

B. Protistan Growth Rates and Productivity

Phagotrophic flagellates are able to grow at rates comparable to those of autotrophic ultraplankton (0.2–20 µm). Population growth rates of phytoplankton can be <1.0–2.0 day^{-1} under optimal conditions (Chap. 15). The nanoflagellates of a size range of ca. 20–500 μm^{3} can have generation times of a few hours and reproduce several times per day (Table 16-3). Dinoflagellates (size range ca. 600–50,000 μm^{-3}) rarely have generation times of less than a day, whereas ciliate (size range ca. 2000–150,000 μm^{-3}) generation times are variable in the range of 0.5 to several times per day, although most are about one to two times per day under culture conditions (Table 16-3). Growth rate is inversely proportional to cell size and directly related to temperature (Müller and Geller, 1993; Sherr and Sherr, 1994; Weise, 1997).

Estimates of production rates of protists in lakes and rivers are rare, particularly over an annual period. In a detailed study of the ciliate communities of Lake Constance, Germany, the prostome nanociliates (<20 µm) dominated numerically, while strobiliid ciliates in the size range 20–35 µm contributed most significantly to ciliate production. Ciliate community production[2] was ca. 10–15 g C m^{-2} yr^{-1} in this mesotrophic lake (Müller, 1989). Heterotrophic nanoflagellate production in Lake Constance was higher than that of the ciliates, a direct reflection of the much greater densities of flagellates by a factor of ca. 1000 (Table 16-1) in comparison to ciliates (Table 16-2)

[2]Mean daily production (P) was estimated from the intrinsic growth rates (r_m), generation times of each species, and the mean annual biovolumes (V) of the different taxa, where $P = r_m \cdot V$.

TABLE 16-3 Intrinsic Growth Rates (r_m, day^{-1}) and Minimum Generation Times (h) of Phagotrophic Protists[a]

Group	Range of temperature	Common average r_m (day^{-1})	Range of r_m (day^{-1})	Generation time (h)
Nanoflagellates	6–24	4	0.7–6.0	2.8–231
Dinoflagellates	1–27	0.8	0.3–1.3	13–72
Ciliates				
Bacteriovores	4–25	1.5	0.0–6.65	3.6–1200
Algivores	5–22	1.0	0.03–2.1	11.5–800

[a] From data summaries of Müller (1989), Chrzanowski and Šimek (1993), Müller and Geller (1993), Sherr and Sherr (1994), Macek *et al.* (1996), and Jack and Gilbert (1997).

and much greater flagellate growth rates (Table 16-3). The resulting protistan production constitutes a significant part of total zooplankton productivity. For example, in oligotrophic Lake Michigan, heterotrophic protozoan production was equivalent to 40% of the average bacterioplankton production (Carrick *et al.*, 1991, 1992). The phototrophic protozoan production represented 24% of the total planktonic primary production in the epilimnion of Lake Michigan.

C. Protistan Feeding and Trophic Interactions

Protists possess a variety of nutritional mechanisms that include both autotrophy and heterotrophy. The heterotrophic nutritional modes of free-living protists consist of

a. Uptake and assimilation of dissolved organic compounds through the cell plasma membrane (osmotrophy) or by pinching off small-sized vesicles (pinocytosis)
b. Feeding directly on living or dead particulate organic matter (phagotrophy) or by generating water currents to the cell surface where phagocytosis occurs, extending a sucking tentacle (some dinoflagellates), pseudopodial engulfment, or endocytosis within the cytosome (mouth)
c. Metabolic exchange with endosymbionts (a type of mixotrophy)
d. Combinations of the above mechanisms

(Nisbet, 1984; Gaines and Elbrachter, 1987; Sleigh, 1989; Capriulo *et al.*, 1991; Fenchel, 1991; Sanders, 1991a; Taylor and Sanders, 1991; Radek and Hausmann, 1994; Posch and Arndt, 1996).

1. Flagellates

Both phytoflagellates and zooflagellates can gain nutrition by heterotrophic mechanisms. These protists possess the following characteristics: (a) a cytosome in many species; (b) particulate food or nutrient uptake occurring by diffusion, active transport across membranes, or endocytosis; (c) mixotrophy, by which certain species can shift from autotrophic photosynthesis to heterotrophy in the absence of light or practice both simultaneously (e.g., *Ochromonas*); and (d) the use by some species of one or more flagella to create feeding currents to move food particles to the cytostome. Food capture occurs by filtration in many planktonic heterotrophic flagellates. Direct encounter and ingestion is common among benthic flagellates, likely aided by chemoreception.

Certain flagellate protists shift among trophic levels by combining photosynthesis and particle ingestion. Some flagellate photosynthetic algae, commonly chrysomonads, cryptomonads, and dinoflagellates, ingest living or nonliving particles by phagocytosis (Sanders 1991a,b). Conversely, some ciliate and sarcodine protozoa sequester chloroplasts after ingestion of algal cells. The chloroplasts, although no longer dividing, continue to photosynthesize and can contribute to the nutrition of the protist. This endosymbiotic process results in mixotrophy, in which phototrophic and phagotrophic modes of nutrition shift rapidly with changing environmental conditions. For example, the mixotrophic chrysophyte *Poterioochromonas malhamensis* immediately shifts to phagotrophy when abundant bacteria are available (Sanders *et al.*, 1990). Phototrophy was inducible in the light during starvation and is potentially a long-term survival strategy for this mixotrophic alga. The range of size of particles ingested by heterotrophic nanoflagellates extends from common bacteria to ca. 30 μm, but most particles ingested are in the range of 0.2–5 μm (Fig. 16-4).

Feeding rates among flagellates utilizing phagocytosis are highly variable. Representative average values for many lakes and stream are about 15 bacteria per individual per hour within a range of 2–53, or somewhat greater among colonial flagellates (Table 16-4). Even though the ingestion rates of bacteria by

flagellates are considerably less than those of ciliates (Tables 16-4 and 16-5), the much greater abundance of flagellates than of ciliates renders the flagellate grazing of bacteria dominant under most circumstances. Factors influencing rates include particularly the concentration and type of suspended particles utilized as prey, prey characteristics, especially size, and the velocity and characteristics of feeding currents generated by the flagellate. Feeding rates are directly correlated with temperature as well.

TABLE 16-5 General Characteristics of Suspension Feeding among Different Protists[a]

	Type of protist			
	Nanoflagellate[b]	*Ciliate*	*Ciliate*	*Ciliate*
Food type	Bacteria	Bacteria	Microflagellate	Ciliate
Range of clearance rate (body volumes h^{-1})	5×10^4–10^6	3×10^3–10^4	10^4–5×10^4	5×10^4–5×10^5
Range of clearance rate (ml h^{-1})	2×10^{-6}–10^{-5}	10^{-6}–10^{-4}	10^{-3}–10^{-2}	10^{-2}–5×10^{-1}
Specific protist example	*Ochromonas*	*Glaucoma*	*Paramecium*	*Bursaria*
Clearance rate (ml h^{-1})	10^{-5}	1.3×10^{-5}	10^{-3}	0.43
Minimum filter mesh (μm)	—	0.2	0.4	8
Range of food particle size (μm)	0.2–2	0.2–1	1–5	20–60
Minimum food particle Concentration (mg DW $liter^{-1}$)	0.5	0.8–8	0.08–1.3	0.002–0.15
Body length (μm)	7	35	200	800
Body volume (μm^3)	200	4×10^3	10^5	5×10^7

[a] From data given in Fenchel (1986, 1987).
[b] Termed "microflagellate" in the older literature.

2. Sarcodine Protozoa

Testate and naked amoebae utilize pseudopods to engulf bacteria, cyanobacteria, diatoms, flagellates, other protista, and detrital organic particles as randomly encountered (Canter, 1973; Capriulo *et al.*, 1991). A few amoeboid protozoa (e.g., *Pelomyxa*) harbor endosymbiont methanogenic bacteria (Van Bruggen *et al.*, 1983). Some small amoebae are raptors (Fenchel, 1987).

3. Ciliates

Most free-living ciliates have mouths and feed on particulate food (Fenchel, 1987; Skogstad *et al.*, 1987; Capriulo *et al.*, 1991; Posch and Arndt, 1996). Organisms ingested include bacteria, coccoid cyanobacteria, microalgae, diatoms, dinoflagellates, heterotrophic microflagellates, and other ciliates, as well as detrital organic particles in the range of 0.2–20 μm. Many modes of food acquisition occur: (a) suspension feeding in which oral membranelles may act as filters; (b) active predatory hunting by random encounter or possibly chemoreception; (c) deposit feeding of particles by phagocytosis; and (d) mixotrophy by algal endosymbionts or with functional chloroplasts (e.g., *Paramecium bursarai* with *Chlorella*). The ciliate *Mesodinium rubrum* is completely autotrophic (Lindholm, 1985).

Bacterivory can be very significant for both heterotrophic bacteria and picocyanobacteria at certain times of the year. For example, over a 5-week period in late summer in a eutrophic reservoir, ca. 70% of bacterial production was consumed by heterotrophic flagellates and ca. 20% by ciliates (Šimek *et al.*, 1995). Small (<30 μm) oligotrich ciliates ingested an average of 360–2100 bacteria and 76–210 picocyanobacteria cell^{-1} h^{-1} during this period of the year. Such ideal conditions allow high ciliate growth and doubling times of between 24 and 75 h. While only heterotrophic nanoflagellates are able to greatly impact bacterioplankton at low concentrations by grazing, many ciliates are more omnivorous (K. Jürgens, unpublished). Oligotrich ciliates feed on a spectrum from bacteria to nanoalgae and can become important bacterivores, at times exceeding bacterivory of heterotrophic nanoflagellates, which they also eat.

Smaller ciliated protozoans (<30 μm) graze upon bacteria-sized particles (Table 16-5), whereas rotifers (see later discussion) utilize both bacteria and small algae. Larger crustacean zooplankton are primarily phytophagous on small algae (Crisman *et al.*, 1981). Nutrients released when macrozooplankton graze on algae can enhance bacterial growth and thereby provide food for ciliated protozoans and small rotifers. As such, the ciliated protozoans can serve as functional links in freshwater planktonic food chains; they utilize bacteria and very small particulate detritus and provide macrozooplankton with larger particles that can be more efficiently grazed (cf. Porter *et al.*, 1979). There is some evidence that the body size of macrozooplankton (especially cladocerans) is smaller in subtropical than in temperate lakes (e.g., Crisman, 1980). Ciliated protozoans and rotifers become more important in the zooplankton among eutrophic, subtropical lakes.

Two species of benthic ciliates of the genus *Loxodes* were studied in a shallow eutrophic lake in relation to feeding and digestion of algae (Goulder, 1972, 1974a). Feeding rates were low (0.4–13 diatom cells per hour for the larger species), but there was an indication that the protozoan was able to distinguish among three species of the dominating alga *Scenedesmus* and feed selectively. Based on estimates of the feeding rates and the biomass of the algal and protozoan populations, maximum grazing by the ciliates resulted in consumption of <1% of the algal populations per day and had no appreciable effects on them. No evidence was found for interspecific competition between the two species; changes in environmental conditions affected both species in similar ways (Goulder, 1974b, 1980). These species are strongly negatively phototactic and did not migrate from the anaerobic hypolimnion to the oxygenated epilimnion. Most individuals constituting the hypolimnetic population died as the oxygen was depleted.

D. Food Utilization and Changes in Size of Bacteria

Bacterioplankton are significantly grazed by small (<5–8 μm) phagotrophic nonpigmented flagellates. These flagellates often dominate among the heterotrophic planktonic protists. Larger planktonic ciliates can also be important in bacterivory and exhibit high rates of bacterial clearance from water under both natural and experimental conditions (Table 16-4). Phagotrophic phytoflagellates also ingest bacteria at rates comparable to those of nonpigmented flagellates (e.g., Borass *et al.*, 1988; Sanders and Porter, 1988).

Bacterivory by flagellates and ciliates is influenced by temperature as well as the availability of bacterial prey. For example, at 15°C, ciliates filtered 10 times more body volume when bacteria were scarce, but the ingested bacteria were fewer than at high prey densities (Iriberri *et al.*, 1995; cf. also Peters, 1994). Size and shape of prey is important, and clearly prey geometry is the first-order determinant of ingestion through passive mechanical selection by protists. Among both flagellates and ciliates, but particularly among the heterotrophic microflagellates, there is a tendency to ingest larger bacterial cells at a frequency greater than they occur in the bacterial assemblage (Andersson *et al.*, 1986;

Chrzanowski and Šimek, 1990; Gonzalez *et al.*, 1990; Šimek and Chrzanowski, 1992), and some probability exists for chemical discrimination among prey (Verity, 1991). This size-selective grazing by microflagellates likely contributes to the frequently observed decrease in median bacterial cell volume during the summer period of temperate waters.

E. Changes in Bacterial Size and Community Structure Mediated by Interactions among Protists and Larger Zooplankton

Even though the rates of bacterivory by flagellates are smaller than those by ciliates, flagellate numbers are so much greater that their collective grazing effects on bacterioplankton can be much greater than those of the ciliates. Examples of comparative bacterivory in the plankton indicate the importance of flagellates. In contrast to the study of Rimov Reservoir where ciliates accounted for ca. 50% of bacterivory in late summer, in a monomictic reservoir in Georgia, mixotrophic and heterotrophic flagellates dominated grazing (55–99% of the total) at all times of the year (Porter, 1988; Sanders *et al.*, 1989; Bennett *et al.*, 1990). Phagotrophic flagellates are often most abundant in the epilimnion and metalimnion interface during stratification; flagellate ingestion rates tend to be greatest in the epilimnion. Ciliates were responsible for as much as 30% of the bacterivory at some depths in spring and summer, while bacterivorous rotifers were abundant only in summer. The grazing impact of cladoceran crustaceans was generally <1% in this lake, and bacterivory by adult and naupliar copepods was not detected.

Although the cladoceran and copepod bacterivory is generally small, under some conditions it can be significant or may be underestimated, particularly in relation to indirect effects on protists that in turn affect bacterial communities. In an extreme case, where planktivorous fish predation on cladocerans was essentially absent, the cladoceran *Daphnia* dominated the zooplankton community with heavy predation on protists. Under these circumstances, the percentage bacterivory by cladocerans can become a significant part of total bacterivory (e.g., Jürgens *et al.*, 1994a,b, 1997). Similarly, naupliar stages of copepods can graze heavily on protozoan microplankton, picoplankton, and bacteria (Roff *et al.*, 1995; Merrell and Stoecker, 1998). Again, although the naupliar feeding rates are individually small, the collective large numbers of immature copepods can impose both direct and indirect effects on bacterial communities and growth.

Examination of bacterial populations in lakes often demonstrates relatively stable biomass and production distributions. Yet, a number of experimental studies indicate that when predation of larger zooplankton on phagotrophic protists and protozoans occurs, this release of the bacteria from protistan grazing pressure can induce marked alterations of morphology, densities, and community structure of bacterioplankton (cf. reviews of Güde, 1989; Jürgens and Güde, 1994; and Jürgens *et al.*, 1994a,b, 1996, 1997). A major portion of bacterial production can be consumed by nanoflagellates, and moderate densities of copepods and small cladocerans have relatively small effects on the flagellate growth rates and population development (Fig. 16-5). Oligotrichous ciliates are efficient feeders on nanoflagellates, whereas differences among the filter-feeding rotifers, calanoid copepods, and cladocerans were relatively slight. Cyclopoid copepods tend to be relatively inefficient grazers on nanoflagellates. When ciliates or large cladocerans, such as *Daphnia*, are present in dense populations, however, nanoflagellate protists can be markedly suppressed.

Many bacteria can be consumed both by the nanoflagellates or by the metazoans. Depending upon the predators that dominate, the type of predator grazing can induce marked changes in bacterial morphology, usually within 24 h. Under nanoflagellate-dominated bacterivory, a shift to protistan-resistant bacteria in large aggregates and long filaments occurred. When bacteria were exposed to little protistan predation or to metazoan bacterivory, freely dispersed, single-celled, small rod and cocci morphology predominated that are less efficiently grazed by the metazoans. As depicted from laboratory experiments in Figure 16-6, these changes suggest very rapid compensatory responses in bacterial production and formation of size refuges from grazing at both the lower and upper ends of the bacterial size range as potential mechanisms buffering bacterioplankton from large seasonal fluctuations in abundance.

F. Mortality in Perspective

Clearly, *in situ* bacterivory by protistans can be high. For example, the calculated total grazing mortality ranged from 11 to 159% of bacterial cell production in the example just cited. However, theoretical values that protistan grazing could balance bacterial production (Capriulo *et al.*, 1991) are unlikely and require further study. Other sources of mortality are not only poorly understood in nature but rarely measured or even estimated. To assume that all or most mortality of organisms occurs by bacterivory, herbivory, or carnivory in natural ecosystems, as has been commonly done until very recently, is unsound scientifically and grossly misleading (cf. Wetzel, 1995).

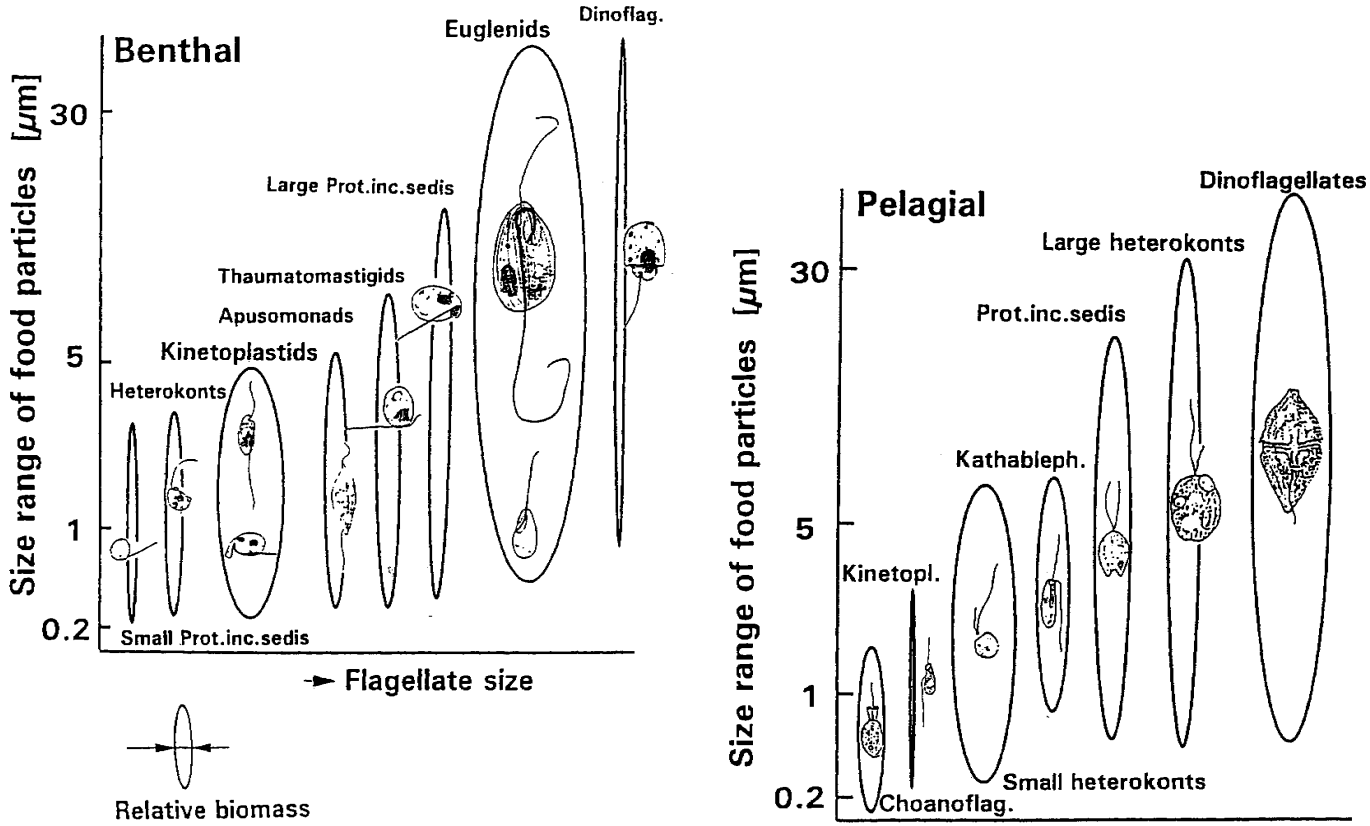

FIGURE 16-5 Comparative food size spectra of important pelagic and benthic flagellate taxa in relation to their mean body size. The relative importance of their biomass contribution is indicated by the width of the elliptical symbols. Prot. inc. sedis = Protista *incertae sedis*. (Slightly modified from Arndt *et al.*, 1999.)

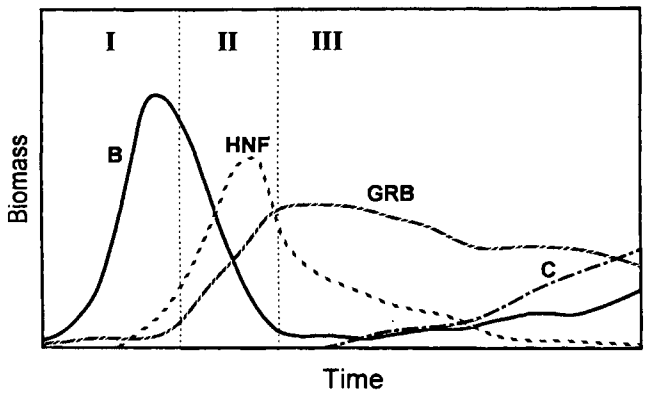

FIGURE 16-6 Model of common microbial succession under conditions of adequate sources of organic substrates for bacteria and with low populations of large zooplankton. *B* = highly edible bacteria; *HNF* = heterotrophic nanoflagellates; *GRB* = grazing-resistant bacteria as aggregates, filaments, and similar forms; *C* = ciliates. (Modified from Jürgens and Güde, 1994.)

Mortality often results simply by termination of biochemical cycles caused by genetic limits of longevity. The common approximate synchronous death of adults of metazoans after reproduction is an example. In addition to losses by simple physiological death, viral lysis can be a major means of bacterial mortality. These statements assume, however, that measures of bacterial productivity are accurate in comparative analyses. Methodological variance is high in sampling, techniques, and metabolic interpretations, and a large number of quantitatively unsubstantiated and likely most erroneous statements of mortality causes and significance litter the scientific literature.

In reservoir ecosystems, rivers can import considerable bacterial biomass from allochthonous sources. Evidence indicates that heterotrophic nanoflagellates consume much of the bacterial production (50–100%) over an annual cycle (Šimek *et al.*, 1999). With increasing trophy of the reservoir ecosystems, however, ciliates (small oligotrichs, vorticellids, and scuticociliates) become as important bacterivores as the nanoflagellates (chrysomonads, bodonids, and choanoflagellates). The bacteria of reservoirs are variably augmented by microbes that are imported from allochthonous terrestrial and wetland sources. It should be noted, however, that apparent genetic variations exist in bacteria from allochthonous versus autochthonous sources (e.g., Iriberri *et al.*, 1994) and that these differences could also lead to variations in consumption by bacterivores.

The nature and quantity of available food have been implicated as major controlling factors in the population dynamics of ciliates. For example, in a shallow pond in Pennsylvania, three population surges of ciliates occurred and were correlated with different nutritional habits (Bamforth, 1958). The small prostomatid *Urotricha* developed rapidly under ice and fed actively on a dense population of chrysomonads. Oxytrichid ciliates appeared as the *Chlamydomonas* algal populations were declining rapidly in spring. Ciliate populations, mainly of the genus *Holophyra*, appeared following spring maxima of phytoplankton and persisted during the summer, coincident with euglenoid algal blooms. Selectivity of algae ingested by ciliates is common (e.g., Takamura and Yasuno, 1983). Food selection is largely a function of the size and shape of the algae, rather than species.

Assimilation of ingested food is of course far from efficient. Little is known of the assimilation efficiencies of consumed prey of protists. Under optimal growth conditions in cultures, the assimilation efficiencies of the protozoan *Amoeba proteus* ranged from 22 to 59% regardless of temperature (Rogerson, 1981). Under ideal growth conditions, assimilation efficiencies as high as 75% have been observed for some protists (Sleigh, 1989). Assimilation efficiencies in nature are likely much lower than this range.

Fecal aggregates are released from protists during feeding. The quantitative variations in such fecal releases certainly varies with prey resource availability. Some particulate egestion values for ciliates are in the range of 20–25% of the volume of algae consumed (Stoecker, 1984). Release of excretory dissolved organic matter by protists is very poorly understood, even though such organic recycling could be highly significant to ecosystem carbon fluxes. General figures cited (Sleigh, 1989) estimate that 30% of food consumed by an actively growing protist is used in respiration, 30% is egested or excreted, and approximately 40% contributes to growth.

Grazing by protists on phytoplankton has been intensively studied, particularly in marine habitats (Capriulo *et al.*, 1991). Phagotrophic ciliate and dinoflagellate ingestion of phytoplankton often equals that of other microzooplankton (copepod nauplii and rotifers). Frequently grazing impacts 20–60% of production of the algal picoplankton (<2 μm in size).

III. TROPHIC RELATIONSHIPS OF PROTISTS IN PELAGIC FOOD WEBS

The functional roles of microbiota in pelagic food webs has received extraordinary study in the past decade. This emphasis is important because clearly a major portion of the pelagic metabolism is occurring within a microbial food web. Before the importance of these microorganisms is evaluated as a support component of the metazoan food web, it is essential to

examine the primary characteristics of these pelagic microbial communities.

A. Microbial Food Web

The microbial food web concept was developed in marine studies long ago with the position that heterotrophic and phototrophic microbial metabolism constituted a significant portion of the total metabolism of the ocean (Vernadskii, 1926). With many data from detailed studies of a lake ecosystem, Wetzel *et al.* (1972) developed a general paradigm which stated that bacteria metabolize a significant fraction of total photosynthetic production in natural waters. In particular, that work demonstrated that most of the microbial utilization of primary production occurred in littoral and benthic regions and that only a small portion of the ecosystem primary production entered the metazoan trophic levels (see full discussion in Chap. 23). That same paradigm was developed for pelagic marine waters in a seminal paper by Pomeroy (1974). Many subsequent studies provided data to reinforce the importance of microbes; these were synthesized in the concept of the "microbial loop" (Azam *et al.*, 1983; Sherr and Sherr, 1988).

The ***microbial loop*** is simply a model of the pathways of carbon and nutrient cycling through microbial components of pelagic aquatic communities. In addition to bacterial uptake of nonliving organic matter, many direct links exist among algae, bacteria, and other heterotrophic microbes (Fig. 16-7). By these numerous pathways, fixed organic carbon can be recovered, often into larger-sized microorganisms that may be more available for consumption by larger organisms (Sherr and Sherr, 1988). Metazoans would utilize organisms of the microbial food web by grazing phytoplankton, colorless flagellates, and ciliates >5 μm. In oligotrophic waters that may be dominated by phytoplankton too small (ca. <5 μm) to be effectively

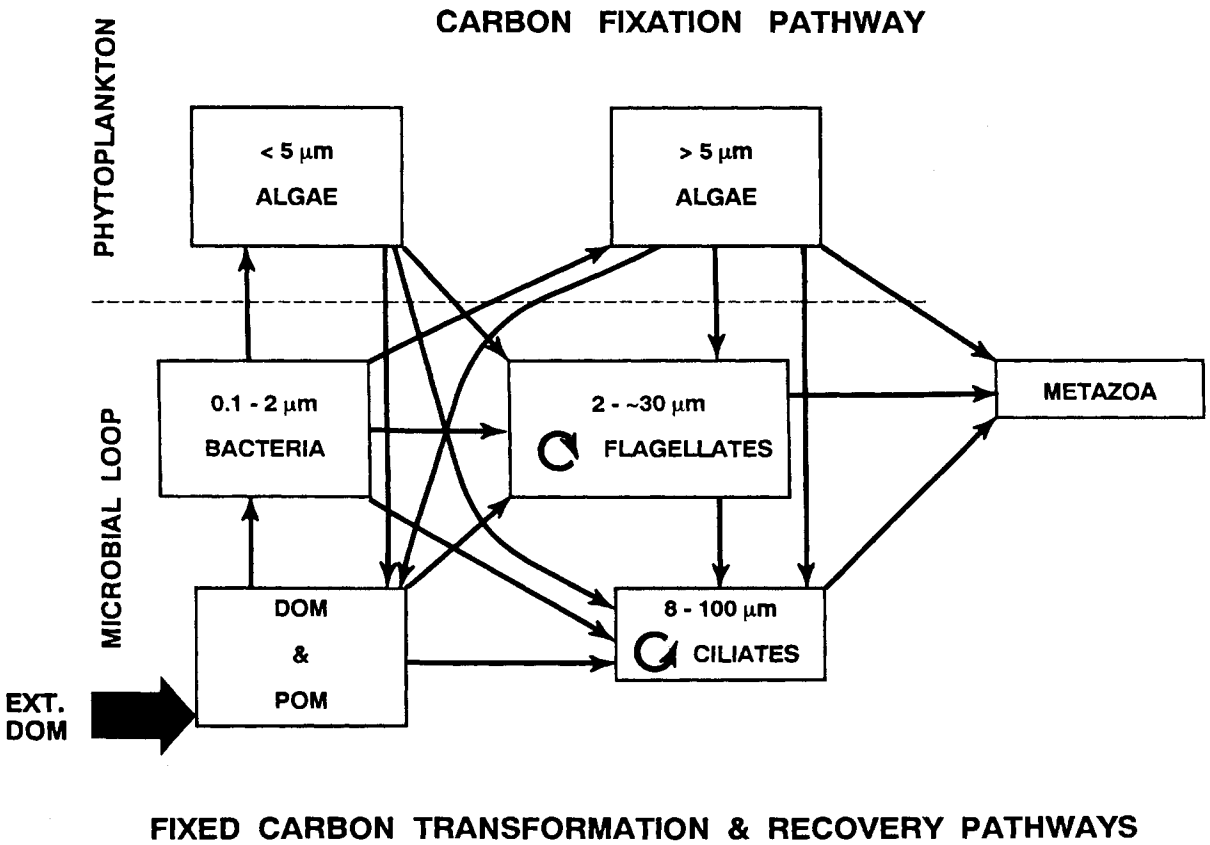

FIGURE 16-7 Trophic interactions within the microbial food web, which is separated here into phytoplankton and "microbial loop" (bacterial and protistan) components. Note the many direct links among heterotrophic and autotrophic microbes, as well as ingestion of phytoplankton by flagellates and ciliates and ingestion of bacteria by mixotrophic algae. The curved arrows in the flagellate and ciliate compartments indicate further predator–prey interactions within these broad classes of organisms. In this model, production of the <5-μm algae is accessible to metazoa only after being transformed into larger protozoan cells. A large portion of the dissolved organic matter (DOM) enters the pelagic from littoral and allochthonous sources in most lakes and rivers. (Modified from Sherr and Sherr, 1988.)

consumed by many zooplankton, the phagotrophic flagellates and ciliates could function as a primary trophic link within the ecosystem.

Under most prevailing conditions, significant fractions, at least 50%, of the dissolved organic matter and nonliving particulate organic materials are metabolized to gases, soluble nutrients, and living bacterial biomass (Fig. 16-7). This bacterial biomass may be living, dormant, senescing and utilized by other bacteria and viruses or may be consumed by bacterivores. The predominant bacterivores are protists, often microflagellates and protozoan ciliates. For example, pelagic bacterivory in eutrophic Lake Oglethorpe, Georgia, was dominated at all times by heterotrophic flagellates, which accounted for 49–81% of grazing on an areal basis and up to 98% of grazing at some depths at certain times of the year (Sanders *et al.*, 1989). Mixotrophic flagellates were major grazers during winter and spring and contributed up to a maximum of 45% of community grazing on an areal basis and to 79% at depths of maximum abundance. In late spring and early summer, ciliate bacterivory constituted as much as 30% at some depths but averaged ca. 11% over the year. Bacterivory by pelagic cladoceran crustaceans was generally <1% of the total and was not detected among copepods.

The bacterivores can also function as decomposers and efficient nutrient remineralizers (Fig. 16-8A) or transfer some of the fixed carbon and nutrients to higher organisms (Fig. 16-8B). In the prevailing conditions (Fig. 16-8A), most of the carbon and nutrients in

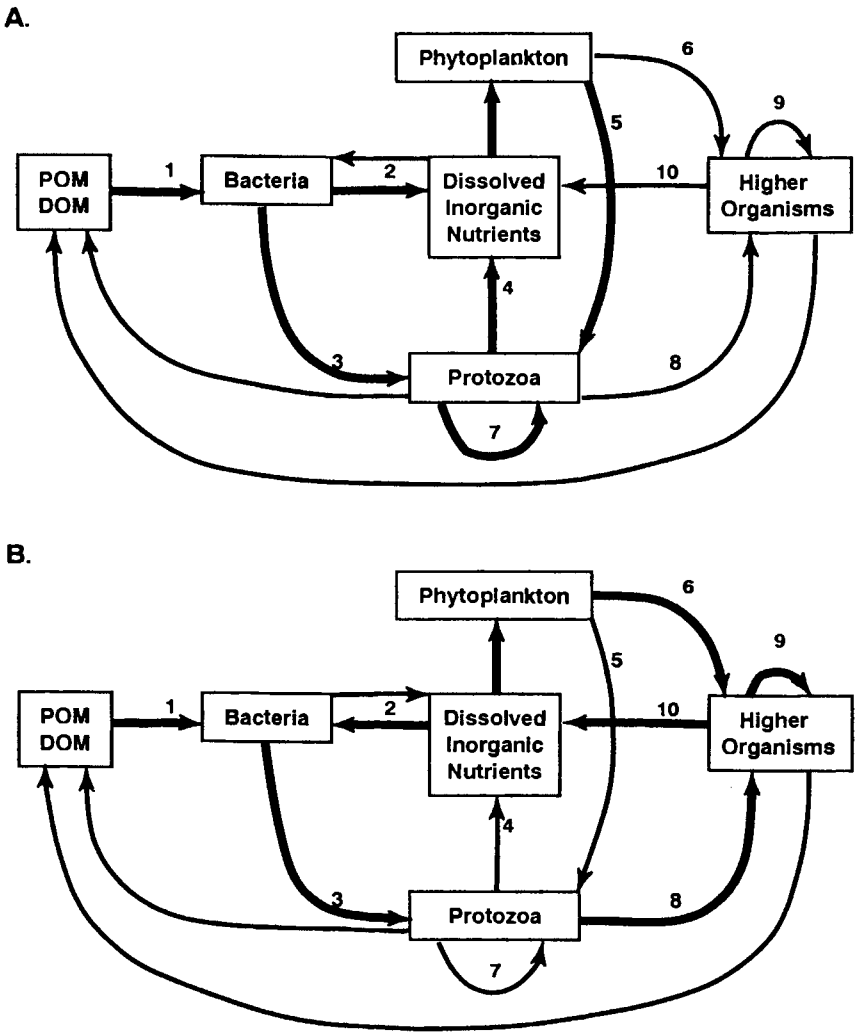

FIGURE 16-8 Idealized models for nutrient cycling through the "microbial loop" of pelagic communities. The thickness of the arrows indicates the hypothesized relative importance of the pathway for nutrient flow. (A) A microbial loop characterized by a high efficiency of nutrient remineralization. (B) A microbial loop characterized by a high efficiency of transfer of nutrients to higher organisms. (Modified from Caron, 1991.)

bacterial substrates are remineralized directly by bacteria (arrow 2) or their protistan consumers (arrow 4) (Caron, 1991). In this case, which is likely often the case, little carbon and nutrients are available to higher organisms as living biomass; hence, the microbial loop functions as both a carbon and a nutrient "sink," that is, the carbon is not directly available to higher animals. As is emphasized later (Chap. 23), however, the carbon and nutrients are not usually lost from the ecosystem but are rather displaced spatially and temporally and recycled later. The size structure, species composition, and possibly the rate of production of the phytoplankton may determine the amount of the composite assemblage that is grazed by the larger zooplankton (arrow 6) or the protozoa/protists (arrow 5). Much complexity within the protistan assemblage (arrow 7) would decrease the quantitative transfer of carbon and nutrients to higher organisms.

In a stronger "link" to the metazoan hypothesis (Fig. 16-8B), carbon and nutrients in organic substrates are utilized by bacteria (arrows 1 and 2) and incorporated into their consumers (arrow 3). As these organisms are utilized by higher organisms (arrow 8), the pathway represents a direct trophic coupling ("link") between dissolved and particulate detrital matter and higher organisms. The large zooplankton then would dominate carbon and nutrient remineralization (arrow 10) and remineralization by the animal microbial loop components would be less (arrow 4). This predation by large zooplankton can impose major regulation of carbon and nutrient fluxes to higher trophic levels. Predation by larger zooplankton is discussed in each of the subsequent sections on the major zooplankton types.

When larger zooplankton are present in abundance, mortality rates on ciliates can be high (Table 16-6), which would allow an appreciable transfer of carbon and energy from the microbial loop to higher trophic levels. Large differences in rates of ingestion of protists have been observed, and these rates are not necessarily proportional to the size of the prey or predator (Wickham, 1995). Although feeding clearance rates of copepods (ml copepod^{-1} day^{-1}) and other large zooplankton do increase in proportion to body length, under natural conditions many types of prey may be available. Predation on ciliates, for example, was appreciably less when copepods had alternative prey species available (Wickham, 1995a). The growth of the ciliate *Stobilidium velox* (43 μm) could be halted in summer by predation of copepods at modest densities (1.6 adult *Epischura* liter^{-1} or 16 *Diaptomus* liter^{-1}) (Burns and Gilbert, 1993). Experimental studies both in the laboratory and in the field demonstrated marked increases in the mortality per day with increases in the size of different species of the cladoceran *Daphnia* (μg per species) (Wickham and Gilbert, 1993; Pace and Vaque, 1994). Heterotrophic nanoflagellates were impacted more severely than ciliates, and the mortality of oligotrich ciliates was more severe than the impact on rotifers. Growth rates of both the flagellates and especially the ciliates were severely suppressed by the large (35 μg) *Daphnia*. Despite this mortality of ciliates, it is well known (e.g., DeBiase *et al.*, 1990) that ciliates alone are insufficient as a food source to support *Daphnia* population growth. The nutritional value of ciliates is variable and represents in part the highly dynamic nutritional values of their prey in relation to season and nutrient availability in the lakes.

B. Organic Carbon Release during Feeding by Protists and Larger Zooplankton

During such feeding and predation, nutrients and dissolved organic compounds are released, either directly during the ingestion and mastication processes, in excretion as dissolved organic matter, and in fecal particles that can leach subsequently into the surrounding water. Nutrients released during protistan and other zooplanktonic feeding are discussed in separate sections (see Chaps. 12 and 13). Practically nothing is known of the release of dissolved organic carbon from

TABLE 16-6 Mortality Rates of Small (< 30 μm) Ciliate Protists by Zooplankton Predators

	Predator density (*ind liter*$^{-1}$)	°C	*Mortality rate* (*d day*$^{-1}$)	*Ingestion rates* (*cells ind*$^{-1}$ *h*$^{-1}$)	*Source*

protistan feeding processes in the microbial food web (cf. review of Nagata and Kirchman, 1997). Clearly, bacterial uptake of dissolved organic substrates is high. As bacteria and pico- (<2 μm) and ultraphytoplankton (<20 μm) are consumed, digested, and remineralized by microflagellates, some of the organic carbon is released. For example, among marine environments, microalgal and bacterial biomass was incorporated into herbivorous/bacterivorous microflagellates with equal efficiency (44%) during exponential growth (Caron *et al.*, 1985). Only 10% of the ingested particulate organic carbon (POC) was released as dissolved organic carbon, while 10% was released as egested POC. Some 70–80% of the organic matter ingested was respired by the microflagellates. Although ammonium regeneration rates of flagellates have been observed to be closely related to the ingested bacterial nitrogen content (e.g., Caron *et al.*, 1988), phosphate regeneration rates depended on bacterial C:P ratios (Nakano, 1994c). P release from grazing by phagotrophic flagellates was most efficient when bacteria were C-limited, a condition that led to the regeneration of 50–90% of the bacterial P (Jürgens and Güde, 1990). When bacteria were P-limited rather than C-limited, regeneration efficiency was variable and often reduced to <20%. These relationships are important because when P availability is low in lakes, regeneration rates are markedly impeded. Conversely, when loading of P increases availability and incorporation into prey, regeneration rates can be accelerated by protistan feeding activities.

Among larger zooplankton, such as *Daphnia*, a significant portion (>15%) of algal carbon ingested is released, largely as feces (Olsen *et al.*, 1986). Of the carbon released, a portion, in the range of 20%, is released as dissolved organic compounds. These compounds are generally relatively small molecules (<10,000 D), some of which consist of nitrogenous compounds and simple amino acids (Riemann *et al.*, 1986; Park *et al.*, 1997; Ferrier-Pagès *et al.*, 1998). The more labile substrates are readily utilized by bacteria. A number of more recalcitrant organic substrates are released as well during zooplankton feeding. These substances are very slowly metabolized but can be photolysed to simple substrates, such as fatty acids, by exposure to natural incident ultraviolet irradiance (e.g., Wetzel *et al.*, 1995).

IV. GENERAL CHARACTERISTICS OF ROTIFERS, CLADOCERA, AND COPEPODS

A. Rotifers

The Rotifera (Rotatoria) is a large class of the pseudocoelomate phylum Aschelminthes, clearly originating in fresh water; only two significant genera and a few species are marine. About three-quarters of the rotifers are sessile and associated with littoral substrates. Approximately 100 species are completely planktonic, and these rotifers form a significant component of the zooplankton. Rotifers form an important group of soft-bodied invertebrates of the plankton. The general characteristics of the group have been treated in some detail by Pennak (1978), Hyman (1951), Hutchinson (1967), Ruttner-Kolisko (1972), Dumont and Green (1980); and Wallace and Snell (1991).

The rotifers exhibit a very wide range of morphological variations and adaptations. In most, the body shape tends to be elongated, and regions of the head, trunk, and foot usually are distinguishable (Fig. 16-9). The cuticle is generally thin and flexible, but in some rotifers it is thickened and more rigid and is termed a *lorica*; the lorica is of taxonomic importance in some groups. The anterior end or corona of rotifers is ciliated; in some species the periphery is ciliated as well. The movement of the cilia functions both in locomotion, especially among planktonic forms, and in movement of food particles toward the mouth. The mouth, although variously located, is generally anterior. The digestive system contains a complex muscular pharynx, termed the *mastax*, and a set of jaws or *trophi* unique to the rotifers that functions to seize and disrupt food particles. Most rotifers, both sessile and planktonic, are nonpredatory. Omnivorous feeding occurs by means of ciliary movement of living and detrital particulate organic matter into the mouth cavity. Predatory species, such as the common *Asplanchna*, are usually large and prey upon protozoa, other rotifers, and other micrometazoa of appropriate size.

Most rotifers are not planktonic, but are sessile and associated with littoral substrata. Population numbers are highest in association with submersed macrophytes, especially plants with finely divided leaves; densities commonly reach 25,000 per liter (Edmondson, 1944, 1945, 1946). Even greater densities are found in the interstitial water of beach sand at or slightly above the waterline (Pennak, 1940). With reduced sites for attachment and presumably less protection from predation, planktonic rotifer populations are much less dense. Densities of planktonic rotifers of 200 to 300 liter^{-1} are common and occasionally reach 1000 liter^{-1}; densities rarely exceed 5000 liter^{-1} under natural conditions.

Several changes characterize the transition from the predominantly sessile to the planktonic life forms (Fig. 16-10). Weight reduction is common as a result of diminution of the lorica and enlargement of body volume with gelatinous materials. Planktonic species tend to have suspension processes and swimming organs in the form of immovable spines or movable setae. A reduction of attachment organs as a result of diminution or total loss of the foot structures also takes place. Adaptations that reduce the sinking rates of reproductive products also occur; for example, attachment of

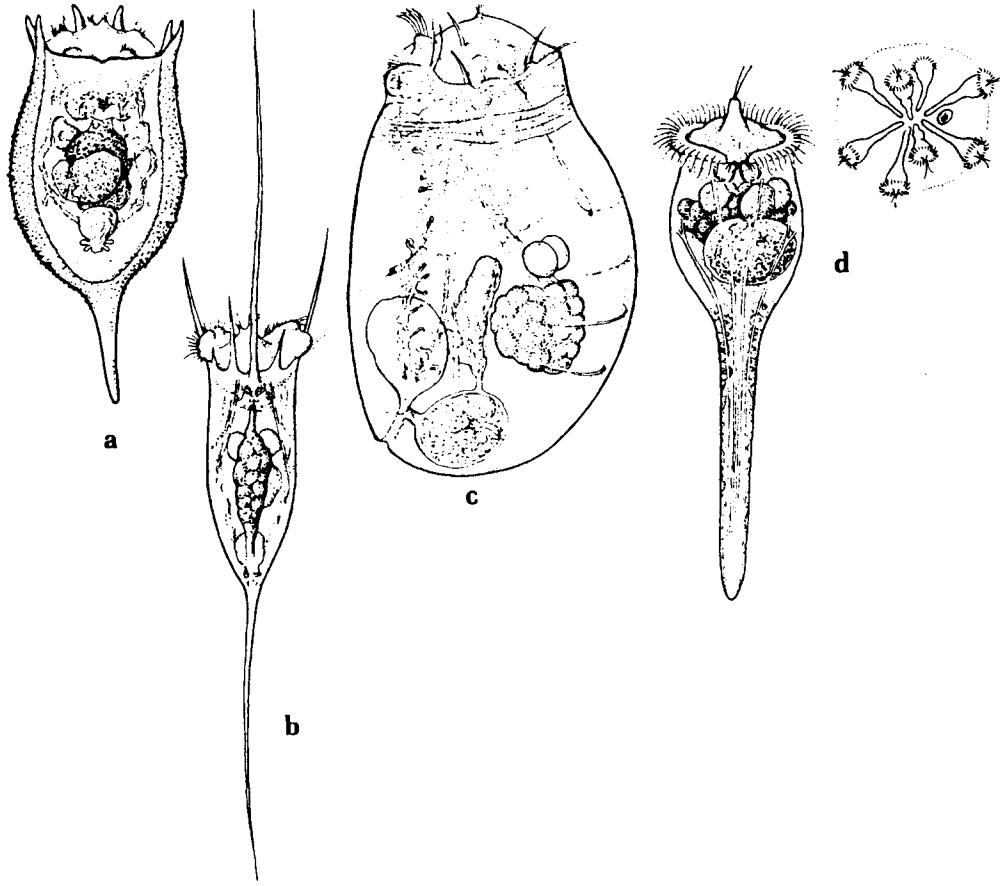

FIGURE 16-9 Exemplary planktonic rotifers: (a) *Keratella cochlearis*; (b) *Kellicottia longispina*; (c) *Asplanchna girodi*; (d) *Conochilus unicornis* singly and in a colony. eggs to the adult, production of lipid-rich eggs that may be extensively ornamented, and vivipary.

B. Crustacean Zooplankton

The crustacean arthropods are almost entirely aquatic; most are marine. Respiration is accomplished through the body surface or gills. The body generally is separated into three distinct regions, but the tendency is toward fusion of abdominal and thoracic segments until, in the Cladocera and Ostracoda, apparent body segmentation has been lost. In many crustaceans, the body bears paired, usually biramous, jointed appendages, and is covered wholly or in part by a carapace.

(From Dodson and Frey, 1991, with permission.)

In fresh water, the truly planktonic Crustacea are dominated almost completely by the cladocerans and Copepoda, to which most of the ensuing discussion is devoted. Only a few insects are planktonic in immature stages; the larvae of *Chaoborus* (Diptera) is a notable example of major importance in the zooplankton that demands special consideration. Most of the Ostracoda are benthic (cf. Chap. 22). A few species of *Cypria* are apparently partly planktonic, but very little is known of their ecology.

The freshwater Branchiopoda (fairy and clam shrimps) are common inhabitants of shallow lakes, particularly of temporary, saline inland waters. All members of this primitive group are distinctly segmented and bear many pairs of swimming and respiratory appendages. The tadpole shrimps (Notostraca) are essentially benthic and most often restricted to shallow, temporary lakes of arid regions. The fairy shrimps (Anostraca), lacking a carapace, and the clam shrimps (Conchostraca), compressed laterally with a bivalved flexible carapace, are common in the plankton in shallow playa lakes and vernal ponds of semiarid regions. The members of the latter groups are bisexual, although parthenogenesis is known to occur in brine shrimp *Artemia* under some conditions. Resistant eggs can be subjected to long periods of desiccation and hatch when wetted again, probably as a result of a reduction in osmotic pressure at the egg surface (Hutchinson, 1967). In semipermanent lakes of more humid regions, hatching and reproductive rates are related strongly to temperature.

1. Cladocera

The suborder Cladocera (Branchiopoda; order Phyllopoda) includes mainly microzooplankton (Dobson and Frey, 1991). With the exception of two species, nearly all the cladocerans range in size from 0.2 to 3.0 mm (Fig. 16-11). All have a distinct head, and the body is covered by a bivalve cuticular carapace. Light-sensitive organs usually consist of a large, compound eye and a smaller ocellus. The second antennae are large swimming appendages and constitute the primary organs of locomotion. The mouthparts consist of (1) large, chitinized mandibles that grind food particles, (2) a pair of small maxillules used to push food between the mandibles, and (3) a median labrum that covers the other mouth parts.

2. Copepoda

The free-living copepods of this order of the class Crustacea are separable into three distinct groups: the suborders Calanoida, Cyclopoida, and Harpacticoida. Although accurate identification is based largely on morphological details of appendages, several general characteristics delineate the major groups (Williamson, 1991). The body consists of the anterior metasome (cephalothorax), which is divided into the head region, bearing five pairs of appendages representing antennae and mouth parts, and the thorax, with six pairs of mainly swimming legs. The posterior urosome consists of abdominal segments, the first of which is modified in females as the genital segment, and terminal caudal rami bearing setae.

The three suborders of free-living copepods can be distinguished by the general structure of the first antennae, urosome, and fifth leg (Fig. 16-12 and Table 16-7). The harpacticoid copepods are almost exclusively littoral, habitating macrovegetation, mosses in particular, and the littoral sediments. Certain species have life histories with a diapause similar to that discussed further on for the cyclopoid copepods. Although the cyclopoid copepods are primarily littoral benthic species, those few members that are predominantly planktonic form major components of the copepod zooplankton,

TABLE 16-7 Some Characteristics of the Three Suborders of Free-Living Freshwater Copepoda[a]

Calanoida	*Cyclopoida*	*Harpacticoida*
Anterior part of body much broader than posterior	Anterior part of body much broader than posterior	Anterior part of body a little broader than posterior
Marked constriction between somite of fifth leg and genital segment	Marked constriction between somites of fourth and fifth legs	Slight or no constriction between somites of fourth and fifth legs
One egg sac, carried medially	Two egg sacs, carried laterally	Usually one egg sac, carried medially
First antennae long, extend from end of metasome to near end of caudal setae, 23–25 segments in female	First antennae short, extend from proximal third of head segment to near end of metasome, 6–17 segments in female	First antennae very short, extend from proximal fifth to end of head segment, 5–9 segments in female
Fifth leg similar to other legs	Fifth leg vestigial	Fifth leg vestigial
Planktonic, rarely littoral	Littoral, a few species planktonic	Exclusively littoral, on macrovegetation and sediments

[a] Modified from the summary of Wilson and Yeatman (1959).

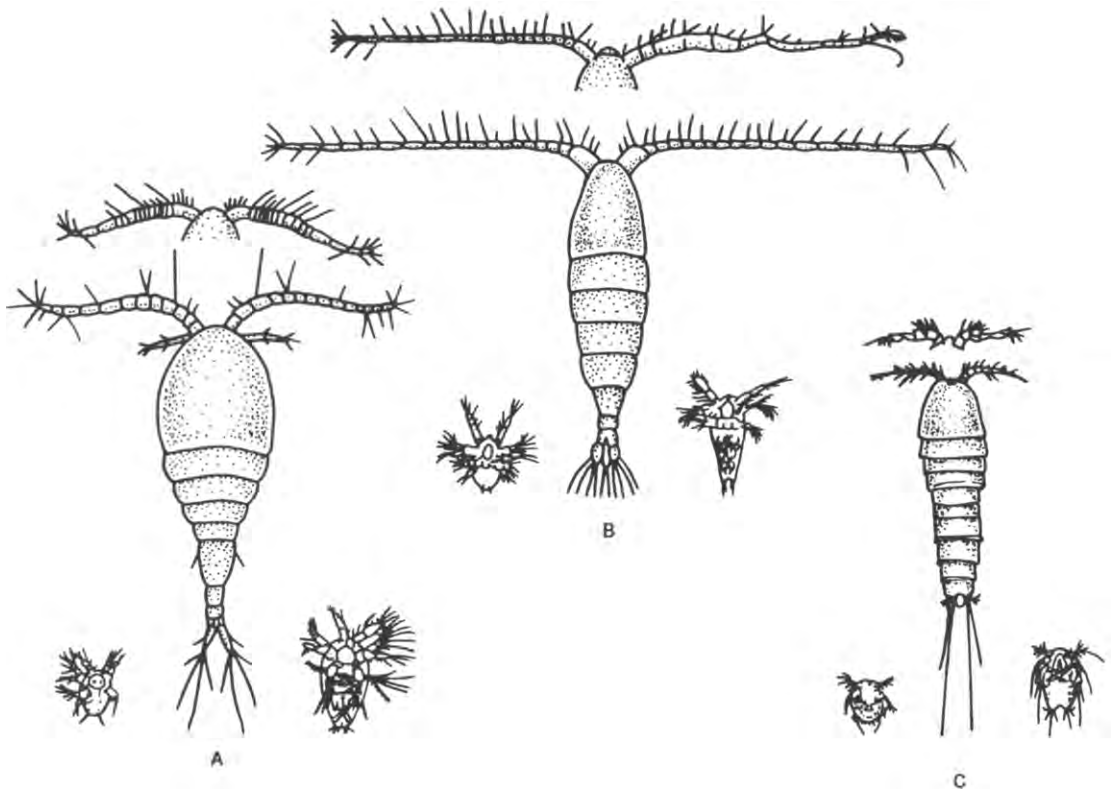

FIGURE 16-12 Diagrams of the three major types of free-living freshwater copepods. Adult females are shown in full, while the adult male first antennae and early- and late-stage nauplii are shown for each group. (A) Cyclopoid; (B) Calanoid; and (C) Harpacticoid. (From Williamson, 1991, with permission.)

especially in small, shallow lakes. The calanoid copepods are almost exclusively planktonic.

V. FOOD, FEEDING, AND FOOD SELECTIVITY

A. Rotifers

The planktonic rotifers feed largely by sedimenting seston particles into the mouth orifice by means of the pulsating action of the coronal cilia (reviewed at length by Pourriot, 1965, and Hutchinson, 1967). The size of the food consumed is quite variable. Most food particles taken are small, less than about 12 μm in diameter, although larger cells, up to approximately 50 μm, are sometimes seized, ruptured, and their particulate parts ingested. Feeding behavior of suspension-feeding rotifers is related to the type of particles, the food size and shape, and food density. Food selectivity clearly occurs in some rotifers and is governed by several rejection mechanisms, either by screening particles or by rejection of particles once they have been ingested (Starkweather, 1980a,b).

Detailed analyses of the feeding behavior of *Brachionus calyciflorus* on varying quantities and mixtures of different types of foods (bacteria, yeast, and algae) demonstrated complex relationships between ingestion rates, food density, and selectivity. Several mechanisms regulate the ingestion of suspended particles (Gilbert and Starkweather, 1977): (a) Cirri of the pseudotrochus may be extended, allowing particles to enter the funnel-shaped buccal field, or they may be bent over to form a screen that prevents even some very small particles (e.g., yeast) from entering the buccal field; (b) Particles in the buccal field may be rejected by ciliary movements before entering the oral canal; and (c) Particles in the oral canal can be rejected by the jaws and pushed back into the buccal field.

Different food types induce different ingestion rates in *Brachionus* (Starkweather and Gilbert, 1977a,b, 1978; Gilbert and Starkweather, 1978). When feeding on yeast, ingestion increased continuously with increasing food-cell densities without the use of pseudotrochal screening. When feeding on certain bacteria and algae, however, ingestion rates were constant over a considerable range of particle densities. The use of pseudotrochal screening increased with larger-sized particles and with increasing particle densities. Screening was also influenced by past feeding history.

Animals selected food of the type they had grown on if exposed to a mixed type of food, and previously starved rotifers used screening less than well-fed animals. The time required for ingested food to pass entirely through the alimentary canal is from 3 to 20 min; this time varies greatly among species and with external conditions.

Some rotifers are raptorial, seizing and ingesting whole prey organisms or drawing in the cell contents after the cell or body wall has been punctured. The largest rotifer, *Asplanchna*, which is predatory on algae, rotifers, and small planktonic crustaceans, has the ability to shift size in response to changes in food size and prey densities, as discussed later (cf. Gilbert, 1980c). Although a large range in size of food particles is consumed by any given rotifer species, in many cases, there is a reasonable separation of rotifer species along a food-particle-size gradient. This separation is congruent with the observed co-occurrence of several species within the pelagial zone of lakes (e.g., Makarowicz and Likens, 1975). It is probable that fairly discrete niches have evolved within the zooplankton, corresponding to specialized utilization of part of the range of available particulate matter. These specializations are adequate to permit co-occurrence without severe competitive interactions.

Food limitations to growth of rotifers vary widely. Threshold food concentrations for rotifers are high in relation to their small size in comparison to other zooplankton (Duncan, 1989). In particular, large rotifer species have high threshold food concentrations that restrict them ecologically to nonpelagic particle-rich environments.

B. Cladocera

Cladocerans usually have five pairs of legs attached to the ventral part of the thorax. The legs are flattened and bear numerous hairs and long setae. Complex movements of these setose legs create a current of water through the valves. This current oxygenates the body surface and forces a stream of food particles anteriorly. The food particles, filtered by the setae, collect in a ventral food groove between the bases of the legs and are impelled forward toward the mouth to be mixed there with oral secretions. The importance of size of food particles in relation to morphological limitations of the filtering apparatus and food selectivity will be discussed later.

The primarily littoral chydorid cladocerans have modified legs that are somewhat prehensile in scraping up larger pieces of detrital material. Feeding by filtration occurs as well. Two other common cladocerans, *Polyphemus* and *Leptodora*, contain members that are predaceous and feed mainly by seizing relatively large particles, such as protozoa, rotifers, and small crustaceans, with their prehensile legs.

C. Copepods

The mouth parts of harpacticoids are adapted for seizing and scraping particles from the sediments and macrovegetation. The food and feeding behavior of the cyclopoid copepods have been studied in detail in two masterful works by Fryer (1957a,b). No filtration mechanisms occur in the free-living Cyclopoida. Feeding is raptorial; plant or animal food particles are seized by mouth parts and brought to the mouth. The maxillules hold and pierce the prey and force particles between the mandibles; intermittent oscillating movements macerate some of the food. Some particles are swallowed intact and are differentially digested. Diatoms tend to be digested, while some green algae, if they are not ruptured, pass through the gut undigested.

Many species of the major cyclopoid genera *Macrocyclops*, *Acanthocyclops*, *Cyclops*, and *Mesocyclops* are carnivorous. The food of these carnivores includes microcrustaceans, dipteran larvae, and oligochaetes, many of which are larger than the copepod that preys on them. Herbivorous cyclopoids include many species of *Eucyclops*, some *Acanthocyclops*, and *Microcyclops*, which feed on a variety of algae ranging from unicellular diatoms to long strands of filamentous species. Carnivorous cyclopoid species tend to be larger than herbivorous species. Random encounter appears to be the dominant mode of finding food in both carnivorous and herbivorous species, which search by discontinuous, irregular movements in the water or over the substratum. Herbivorous species apparently employ gustatory chemoreceptor organs, which may help in food seeking if only to facilitate discrimination between inorganic and organic particles encountered by chance. The filtering rate of *Diaptomus tyrrelli* is reduced in the presence of a predacious copepod *Epischura* (Folt and Goldman, 1981). The alteration in feeding rate is in response to a chemical released into the water by the predator. Presumably, the decreased movement functions as an evasive action taken by *Diaptomus* to reduce predatory success of *Epischura*.

While locomotion in most copepods is in the form of short, jerky swimming movements, the animals being propelled by rapid movement of most appendages simultaneously, swimming is more continuous in the Calanoida copepods. Their gliding movement results from rotary motion of the antennae and mouth appendages. The movements set up small vortical currents that carry particles to the maxillae, which are modified to remove the water. High-speed motion

pictures have revealed that calanoid copepods do not strain particles out of the water, but instead propel water past the body by flapping four pairs of feeding appendages (Koehl and Strickler, 1981). The second maxillae actively capture "parcels" of that water containing food particles. Particles are then pushed into the mouth by the first maxillae. Selective feeding also exists among the calanoid copepods. For example, two closely related calanoids, *Diaptomus laticeps* and *D. gracilis*,[3] were found to coexist in the plankton of Lake Windermere, England (Fryer, 1954; cf. Maly and Maly, 1974). The species were separated by size differences, which were correlated with differences in food consumed. The larger *D. laticeps* fed chiefly on *Melosira*, and the smaller *D. gracilis* consumed mainly minute spherical green algae and particulate detritus. Neither species fed upon the then-abundant diatom *Asterionella*. Competition for food by these two calanoid species was virtually nonexistent. Such small differences in feeding habits, based on morphological and behavioral variations, are common in the calanoids and may be sufficient to separate species into different food niches, even though they occupy the same volume of water.

Similar results were found for *Diaptomus* feeding on natural phytoplanktonic populations (McQueen, 1970). Filtration rates were low for cells smaller than 100 μm^3, increased to a maximum of 12.9 ml per animal per day for cells ranging from 102 to 333 μm^3, and remained constant with increased cell volume and decreased cell concentrations.

D. Filtration and Food Selectivity

The entire subject of feeding in Cladocera and in copepods is an area currently under intensive investigation. Recent results indicate not only a number of physical and biotic factors that affect rates of ingestion but also that some organisms possess at least minimal abilities to select food for consumption. The implications of these studies are major not only from the standpoint of effectiveness of food ingestion and differential assimilation by the animals but also because they point out the effects of the consumption on the food populations. This latter subject is most complex. However, it is apparent that at times zooplankton, as a result of direct cropping, can have appreciable effects on phytoplanktonic populations and, through selective grazing, can influence the seasonal succession of the phytoplankton. This area of research has great potential for demonstrating subtle but major community interactions of significant impact on the overall productivity of lake systems.

Filtration of water to remove particulate organic matter is the dominant mode by which most cladocerans collect and ingest food. The ***filtration rate*** of a zooplankter refers to volume per unit time and is defined as the volume of water containing food particles that is filtered by the animal in a given time (cf. Rigler, 1971). This term does not imply that the volume of water passed over the filtering appendages is known, that all particles of any given type have been removed from the water, or that all particles retained by the filtration apparatus have been consumed. The terms *filtration rate*, *grazing rate*, and *filtration capacity* have been used synonymously with *filtering rate*. In contrast, ***feeding rate*** is a measure of the quantity of food ingested by an animal in a given time (Rigler, 1971), measured in terms of number of cells, volume, dry weight, carbon, nitrogen, or some other relevant aspect of the food that is ingested.

E. Suspension Feeding

The size of particles that can be cleared from the water is a function of (a) the morphology of the setae of the moving appendages, (b) physical characteristics of the sieving surfaces and particle movements, and (c) entrapment and concentrations as locomotion of the animal brings particle-laden water to the setae. The morphological characteristics and dimensions of the filter structures and apertures have been examined among many cladocera in particular (e.g., Crittenden, 1981; Geller and Müller, 1981; Brendelberger and Geller, 1985; Ganf and Shiel, 1985; Gophen and Geller, 1985; Hessen, 1985a; Brendelberger, 1991). There is a general direct correlation between the morphology and intersetular spacing of the filtering setae and the ability to retain particles of different sizes. Greater amounts of food particles at low particle concentrations can be collected by increasing filtering rates either by enlarging the area of the filter screens or by increasing appendage beat rate (Lampert and Brendelberger, 1996). Alternatively, over longer periods of time, phenotypic reductions in intersetular distances would reduce mesh sizes.

Discrepancies between sizes of particles retained and morphological apertures and the size selection of particles retained, however, indicated that capture is not a simple mechanical process. In herbivorous copepods, the appendages function more like paddles than filters and move particles along the surfaces for concentration (Brendelberger *et al.*, 1986; Gerritsen *et al.*, 1988). In cladocerans, some flows also occur along the appendages toward the oral groove. Because the intersetular spaces and the resulting Reynolds numbers

[3] Hutchinson (1967) differentiates these species into *Arctodiaptomus laticeps* and *Eudiaptomus gracilis*, respectively.

($\approx 10^{-3}$) are very small, some pressure difference would be needed to force water through the mesh. In cladocerans, a closed filtering chamber allows water to be forced through the apparatus with minimal expenditure of energy (ca. 5% of the total metabolic requirements of the animal) (Brendelberger *et al.*, 1986). Surface charge chemistry likely assists in concentration of particles and the filter apparatus (Gerritsen and Porter, 1982).

Measurements of particle removal are made by observing changes in the number of particles in different size classes caused by grazing over time (cf. Harbison and McAlister, 1980). Caution is needed in extrapolation of laboratory measurements of filtration and ingestion rates among herbivorous zooplankton to grazing rates in natural planktonic environments. Laboratory measurements commonly overestimate *in situ* grazing rates by at least 30–50% because of spatial heterogeneity in natural plankton distributions (Wirick, 1989). The rate of removal of radioactively labeled food particles has also been used to measure zooplankton feeding rates (see review of Rigler, 1971). The latter approach has been extended effectively to natural populations by use of an *in situ* grazing chamber (Haney, 1971) that permits estimates of feeding rates over short periods of time (<10 min) so that ingested food is not excreted during the incubation period of measurement. These methods measure food actually taken into the gut after losses, either through active rejection of food or losses of food particles during the maceration process. Ingestion rates give little insight into assimilation rates of incorporated food, which can be highly variable with food types and diet concentrations.

A number of studies indicate that the rate of feeding stabilizes or decreases as the concentration of food particles increases. For example, in *Daphnia magna*, feeding rate is proportional to concentration of food particles below a critical level (McMahon and Rigler, 1963, 1965). Feeding rate is constant above the incipient limiting concentration of food particles. At concentrations of food above this limiting level, rates of movement of the thoracic appendages that collect the food decrease, movements of mandibles and swallowing of food remain about the same or decrease slightly, and the rate of rejection of food increases (Burns, 1968b, personal communication). For adult *D. rosea* feeding on yeast, the critical concentration for feeding was between 0.75×10^5 and 1.0×10^5 cells ml^{-1} (Burns and Rigler, 1967). Incipient limiting concentrations (cells ml^{-1}) for feeding rate appear to increase with decreasing particle size, although other factors may be involved as well.

Within a given range of food concentrations, filtering efficiency was found to be independent of size of food particles ($0.9-1.8 \times 10^4$ μm^3 for *D. magna*) (McMahon and Rigler, 1963, 1965; see also Kersting and Holterman, 1973; Geller, 1975). At concentrations of yeast cells above 0.25×10^5 cells ml^{-1}, filtering rates of *D. rosea* decreased. The filtering rate of *Ceriodaphnia reticulata* decreased linearly with increasing concentrations of phytoplankton within a size range of 3–24 μm from low to high densities (10^4–10^6 ml^{-1}) (O'Brien and deNoyelles, 1974). This relationship was not evident in cultures of *Ceriodaphnia* exposed to low densities (10^4–10^5 ml^{-1}) of algae (Czeczuga and Bobiatynska-Ksok, 1970), although the latter methods (very high zooplanktonic densities in a small volume with long incubation periods) do not permit comparison.

Filtering rates have been found commonly to increase with increasing body length (e.g., Peters and Downing, 1984) and with increasing temperatures (Fig. 16-13). Temperatures above a given point result in a decrease in the filtration rate. The temperature of maximum filtration rates differs among species; for *D. rosea*, the maximum was found to be about 20°C (Fig. 16-13), for *D. magna* 28°C, and for *D. galeata mendotae* and *D. pulex* 25°C or above (McMahon, 1965; Burns and Rigler, 1967; Burns, 1969b; Geller, 1975). Brooks and Dodson (1965) have emphasized that the filtering rate should be proportional to the square of the body length in filter-feeding Cladocera. The increase in filtration rate relative to body length, however, varies among species, for example, about to the square in *D. magna* and to the cube of the length in smaller *D. rosea* (Burns, 1969b). Although the area of the filtering setae of these two *Daphnia* species increases approximately as the square of the body length, the filtering area and the filtering rates of *D. rosea* become proportionately greater than those of *D. magna* as the body length increases (Egloff and Palmer, 1971). The difference in the calculated rate of flow of water through the filtering setae, however, remains nearly constant at all body lengths.

The relationship between body size and the maximum size of particles that could be ingested was studied in six species of *Daphnia* and the smaller *Bosmina longirostris* using spherical beads within a size range from <1 to 80 μm in diameter (Burns, 1968a, 1969a). A positive correlation between increasing body size and increasing size of the largest particle ingested was evident for the species assayed (Fig. 16-14). Zooplankton body length, however, may influence the maximal particle size a species can ingest, but it has little influence on the ingestion of smaller particles (Bogdan and Gilbert, 1984; Knoechel and Holtby, 1986). Much selectivity and individual specialization exists, and it is likely unrealistic to predict the diet of a zooplankton species by its size or taxonomic group.

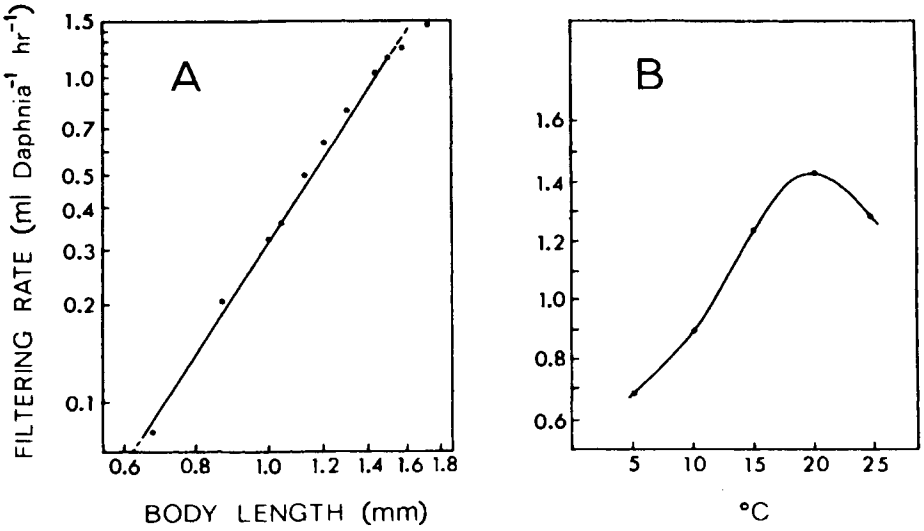

FIGURE 16-13 Relationship between filtering rate and (a) body length at a constant food supply at 20°C, and (b) water temperature (body length 1.65–1.85 mm) of *Daphnia rosea*. (Modified from Burns and Rigler, 1967.)

Extension of these and other results from laboratory feeding studies to natural populations by observations of *in situ* grazing rates has demonstrated some striking relationships. In analyses from small, eutrophic Heart Lake in southern Ontario, seasonal grazing patterns (Fig. 16-15) were found to be similar over a 2-year period (Haney, 1973). At certain depths during periods of the summer, grazing rates exceeded 100% of the water volume per day, but during much of the year, values were less than complete filtration per day and became <10% day^{-1} during the winter (Fig. 16-15; Table 16-8). The lower vertical boundary of zooplanktonic filter feeding was found to be closely defined by the 1 mg liter^{-1} ispoleth of dissolved oxygen concentration, below which filtering rates declined precipitously. There were seasonal patterns in the rates of grazing on different food items. Smaller, bacteria-sized particles apparently were ingested most rapidly in summer, whereas in the autumn the larger-sized algal particles were eaten most rapidly.

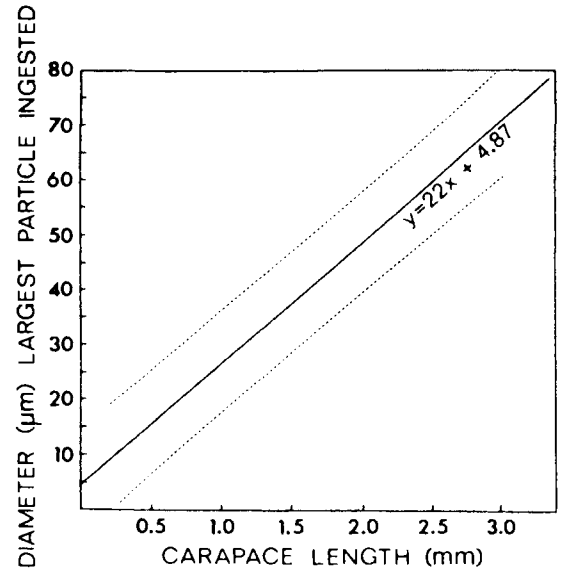

FIGURE 16-14 Relationship between body size and the diameter of the largest particle ingested by seven species of Cladocera. Broken lines equal 95% confidence limits. (Modified from Burns, 1968a.)

Since, as indicated earlier, the grazing rates of cladoceran zooplankton vary greatly with body size, food, and temperature, the *in situ* rates of filtration vary considerably seasonally. The average rates given in Table 16-9, however, show the general relationship to body size. Returning to the example from Heart Lake, the grazing contribution of each species can be estimated by multiplying filtering rates of each species at a given time by its population density at that time. In Heart Lake, *Daphnia rosea* and *D. galeata* were the most important grazers and together accounted for about 80% of the total annual grazing activity by the larger zooplankton (Haney, 1973). Cladocerans (several *Daphnia* species) were also the dominant grazers in moderately productive Lawrence Lake, Michigan (Crumpton and Wetzel, 1982). Grazing of the phytoplankton in this lake became significant only during late summer (Table 16-8; cf. Figure 15-13). Zooplankton filtered <5% of the volume of the epilimnion per day throughout most of the year and had a minor

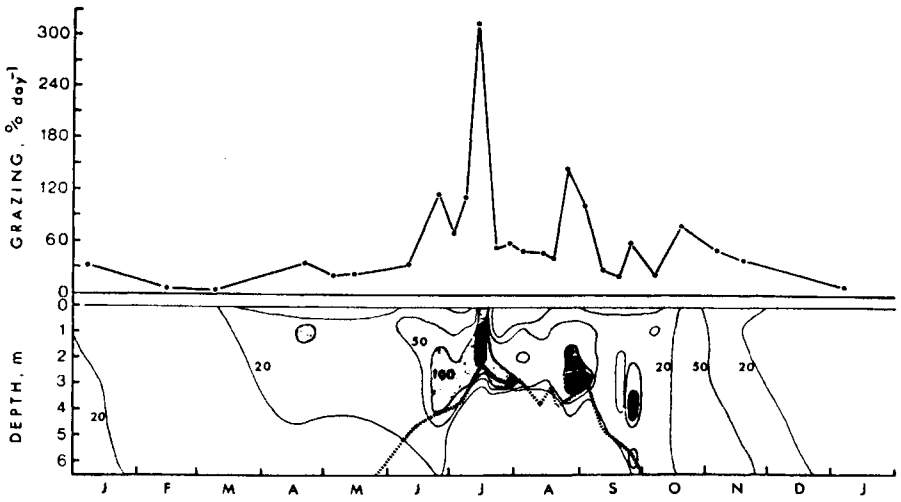

FIGURE 16-15 Seasonal and vertical changes in grazing by the zooplankton community in Heart Lake, Ontario, 1969. Mean grazing rates of the upper figure calculated for the aerobic stratum. Isopleths of grazing rates (lower figure) are at 20, 50, 100, and 200% per day. The broken line is the 1 mg liter^{-1} dissolved oxygen isopleth. (After Haney, J. F.: An in situ examination of the grazing activities of natural zooplankton communities. *Arch. Hydrobiol.* 72:87–132, 1973.)

impact on phytoplankton mortality. In August and September of 1979, however, grazing had a significant effect on both algal productivity and species succession (cf. Chap. 15). During the night, when many cladocerans and copepods migrate to the epilimnetic waters, grazing rates are about five times greater than during daylight hours (Table 16-8; cf. Hart, 1977; Mourelatos *et al.*, 1989). Often, zooplankton encounter strata of reduced oxygen concentrations as they migrate to deep, poorly illuminated water during daylight hours.

[a] Type of food = *in situ* phytoplankton, in most cases.
[b] Estimated from culture analyses.

Filtering and respiration rates decrease rapidly at oxygen concentrations below 3 mg liter^{-1} (Kring and O'Brien, 1976; Heisey and Porter, 1977).

Filtering rates of the major zooplankton were also studied, although less intensively, in two much less productive lakes in southern Ontario: Halls Lake, a deep oligotrophic lake, and Drowned Bog Lake, a typical *Sphagnum* acidic bog lake (cf. Chap. 25) with high concentrations of dissolved humic matter. The filtration rates of the two dominant zooplankters, *Bosmina* and *Holopedium*, were very different, but the small *Bosmina* formed a dominant percentage of the total grazing in the autumn because of its very large population densities (Table 16-10). In contrast to the bog lake and to eutrophic Heart Lake, in which intense grazing occurred in the upper 3 m, the grazing rates in oligotrophic Halls Lake were extremely low and distributed uniformly throughout the water column. The dominant zooplankter of this oligotrophic lake was the copepod *Diaptomus*, and in general, nonpredatory copepods have much lower grazing rates than the Cladocera (Tables 16-9 and 16-11).

	Rhodoturula (yeast)	—	0.1 (<5°C)	
Heterocope				
H. appendiculata	Natural phytoplankton	—	0.2–16	Persson (1985)

In studies in which species of widely different algae were fed to cladoceran and copepod zooplankton at concentrations above critical limitations to feeding, filtering rates decreased markedly with increases in the food concentration (Fig. 16-16). Ingestion rates were calculated as the product of the filtration rate (ml animal^{-1} day^{-1}) and the food concentration (cells ml^{-1}) (Infante, 1973). These results, when coupled with measurements of radioactively labeled carbon from the algae that were incorporated into the animals as an estimate of assimilation, showed marked differences with algal species. The diatom *Asterionella* was ingested and assimilated more readily than *Nitzschia*. Algae with heavy cell walls, such as *Scenedesmus* and *Stichococcus*, were ingested rapidly (Fig. 16-16) but were not utilized well. The Cladocera digested some of the protoplasm of such cells without visible changes in the cell walls, whereas the copepods assayed (*Eudiaptomus* and *Cyclops*) were unable to digest them, and the algae that left the gut were essentially intact. *Staurastrum* and *Cryptomonas* were poorly utilized. Differences also occurred among zooplanktonic species. *Daphnia longispina*, for example, incorporated nearly twice the number of *Nitzschia* that

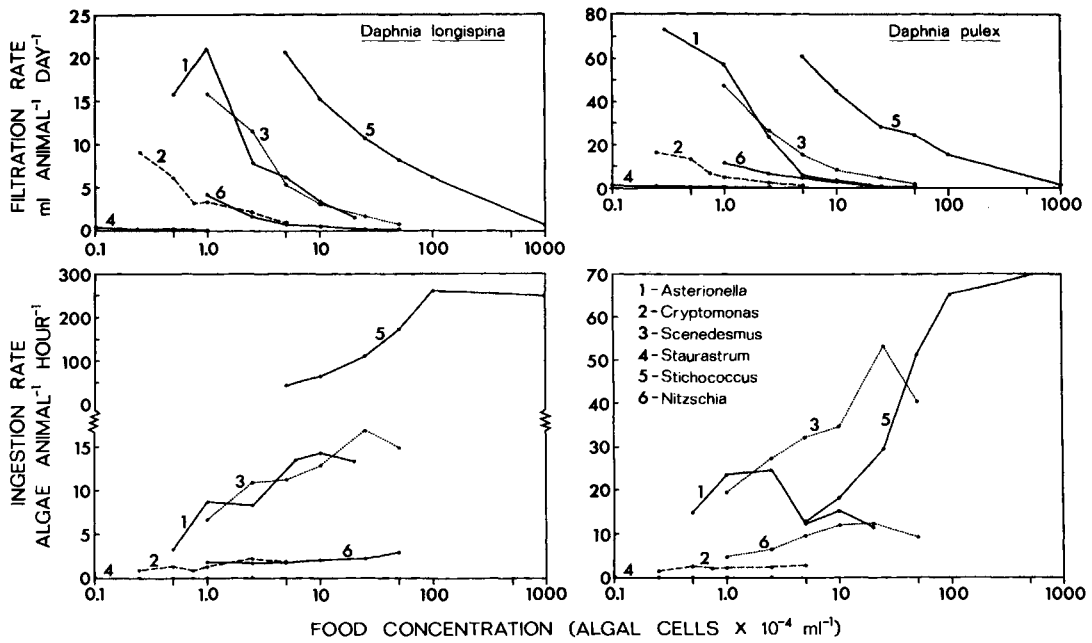

FIGURE 16-16 *Upper:* Filtration rates (in ml animal^{-1} day^{-1}); *lower:* ingestion rates (in cells animal^{-1} h^{-1} as the filtration rate times food concentration in cells ml^{-1}), in *Daphnia longispina* and *D. pulex* exposed to different algal species. The ingestion rate of *Stichococcus* (5) for *D. pulex* is drawn × 0.1 of that found. (Drawn from data of Infante, 1973.)

D. pulex did but only one-half the amount of *Scenedesmus*.

Certain zooplankton feed on a wide variety of algae of different sizes and shapes, with or without sheaths, without any significant selectivity (Gliwicz, 1980; McNaught *et al.*, 1980; Porter and Orcutt, 1980; Kasprzak *et al.*, 1986; Fulton, 1988; Burns and Xu, 1990). Other zooplankton are quite selective in the algal types ingested. Cellular forms are ingested more readily than filamentous or spinuosus forms, and zooplanktonic filtration rates, growth, and survivorship are greater when feeding on cellular forms. Some of the restricted feeding on large or filamentous algae is simply physical reduction of ingestion. For example, the width distance between the margins of carapace valves in filter-feeding cladocerans was significantly smaller when they were exposed to high concentrations of large filamentous algae (Gliwicz and Siedlar, 1980). This reduction in gape width resulted in less ingestion of the large algae in relation to smaller prey.

Evidence also suggests that algae releasing toxic organic compounds are selected against by zooplankton, regardless of suitability of food size and shape, which implies chemoreception (taste). Other zooplankton, often species-specific, feed somewhat selectively on particles impregnated with organic compounds specific to certain algae (DeMott, 1989). Certain cyanobacteria produce and actively release dissolved organic products into the water that reduce thoracic appendage beat rate and filtering rates of cladocera by 50% or more, as well as ingestion rates (Lampert, 1982; Chow-Fraser and Sprules, 1986; Jungmann *et al.*, 1991; Haney *et al.*, 1994, 1995). Such selectivity has been found in certain species of rotifers, copepods, and cladocerans and almost certainly allows for selection of different species of algae of different food quality.

Similarly, when the numbers of grazing Cladocera and copepods were increased experimentally among natural phytoplanktonic populations, small algae such as cryptomonads, certain diatoms, and other nanoplankton decreased, gelatinous green algae such as *Sphaerocystis* increased, and large or unpalatable species such as the cyanobacterium *Anabaena* remained unchanged (Porter, 1973). Although the size of particles grazed is limited by the morphological structure of the setae (Monakov and Sorokin, 1961), large or unpalatable algae result in reduced filtering rates. For example, the ingestion, assimilation, survivorship, and reproduction rates of *Daphnia* that were fed cyanobacteria were lower than those fed green algae (Arnold, 1971). Therefore, even though food species of a usable size may be present, they may be too rare or may be selectively rejected by the grazer at high algal densities. This selection is apparently at least partly related to the relative abundance of particles of different biomass. Selectivity by *Daphnia* increases with increasing particle

concentrations until particle consumption is maximized when particles of one size dominate in mixed food (Berman and Richman, 1974; Gliwicz and Lampert, 1990). When concentrations of all particles were approximately equal, selection favored small, abundant particles (e.g., Holm *et al.*, 1983; Hartmann, 1985). Thus, both mechanical and chemical interference in algal selection and ingestion can lead to differential success of algae in lakes of different trophy.

Ingestion of algae does not necessarily result in their utilization and assimilation by the grazers. In some grazer species, algae with durable cell walls, gelatinous sheaths, or masses of colonial cells can pass through the gut intact and remain viable (Porter, 1975, 1976). Other species can utilize broken colonies or partially decayed cells of colonies by breaking them into smaller pieces, while intact colonies pass through relatively unaffected. Increases in the growth rates of certain algae after ingestion and passage through grazers may be the result of several interrelated mechanisms. Nutrients may be obtained from the degradation and digestion of other algae; phosphorus, in particular, is probably a major nutrient that is made more available during this process.

Selective grazing and utilization can remove species or reduce population size in the algal community, which can alter competition for the given resource base. Alternatively, grazer utilization of an algal species can result in enhancement of primary productivity of that species by increased selection for faster-growing genotypes and by increased nutrient supply (Crumpton and Wetzel, 1982).

F. Importance of Food Quality

A number of studies have demonstrated the effects of food quality as well as quantity on assimilation efficiencies. Analyses of *Daphnia pulex* (Richman, 1958) have shown assimilation efficiency to decrease markedly with increasing food concentrations (Table 16-12). Respiratory rates increase considerably with increasing concentrations of algae until a maximum rate is achieved at an algal concentration corresponding to the incipient limiting level for feeding, beyond which filtering rate decreases with increasing food concentrations (Lampert, 1986). Growth as average length, number of young per brood, and total young increased with increasing food concentrations at the levels used. The energy used for growth was nearly constant at all food levels in preadults, because the energy of egestion increased and assimilation efficiency declined as food consumption increased. In adults, however, the major portion of stored energy went into the production of young.

Similar results have been found for a number of other cladocerans (cf. especially Lampert, 1977a,b). A population food threshold is the amount of food necessary for reproduction to offset mortality; a zero change in population size results. As one examines the allocation of food resources into growth and reproduction, slightly more is allocated to reproduction than to body growth among cladocerans (Duncan, 1989). Similarly among rotifers, most food resources were allocated to growth under scarce food resources but shifted largely to increasing egg production under optimal food resource availability.

The individual food threshold is the amount of food necessary for assimilation to balance metabolic losses, which results in a zero change in mass of the individual animal. Maintenance metabolism requires mainly energy, while body growth requires other essential substances, including essential minerals and growth substances in the diet (Sterner and Robinson, 1994; Sterner and Hessen, 1994). For example, algae with a low growth rate resulting from a low availability of phosphorus will contain less phosphorus and be an inferior food for cladoceran growth. Because the carbon content per unit biovolume is similar among both low- and high-growth-rate algal food, both foods are satisfactory as an energy source for maintenance metabolism. Body growth, however, requires essential nutrients, such as phosphorus in this example, which is not uniformly available in food (see stoichiometry discussion in Chap. 15). Therefore, herbivores with high nutrient demands, exemplified by *Daphnia* and phosphorus, appear frequently to be limited not by the food quantity or energy available to them but by the quantity of minerals in their food. Much phosphorus can be associated with bacteria, and as a result, bacteria can be an important source of phosphorus to bacterivorous zooplankton (Hessen and Andersen, 1990).

In addition to the increase in assimilation rates with increasing temperature, several studies show that the assimilation efficiency increases with higher energy content of the food (Schindler, 1968; Pechen-Finenko, 1971). Foods of low caloric value, such as detritus of plant origin in the range of 2–4 cal mg^{-1} dry weight, are assimilated more slowly than algae and bacteria in a caloric range of 5–6 cal mg^{-1}. Although the assimilation efficiency of detritus is low, that of algae and bacteria by zooplankton is variable. The few studies on the subject show that in general algae are assimilated more efficiently (15–90%) than bacteria (3–50%) (Monakov and Sorokin, 1961; Saunders, 1969; Winberg *et al.*, 1973; Hart and Jarvis, 1993; Ojala *et al.*, 1995). The percentage of assimilation varies seasonally with shifts in algal composition and is generally at the lower portion of the range cited. In contrast, when given

[a] After data of Richman (1958).

mixed diets of green algae and a photosynthetic bacterium, *Ceriodaphnia* assimilated less of the algae than when fed on algae alone (Gophen *et al.*, 1974). In a related study, live filaments of a cyanobacterium, *Oscillatoria limnetica*, were of lower food quality than detrital particles derived from the cyanobacterium (Repka *et al.*, 1999). Detritus supported growth and reproduction of *Daphnia* at rates comparable to those on a diet of the green alga *Scenedesmus*. Utilization of bacteria was relatively unchanged when the algae were also included in the diet.

G. Utilization of Bacteria by Crustacean Zooplankton

Clearly cladocerans and copepods are capable of ingesting bacteria both in aggregates as well as freely in the water (Horn, 1985; Knoechel and Holtby, 1986; Bern, 1987). Grazing on bacteria by crustacean zooplankton can remove significant (e.g., 25–50%) portions of bacterial production. Removal of the larger zooplankton, such as by planktivorous fish predation, can result in an intensified utilization of bacterioplankton by protistan grazers and rotifers (Riemann, 1985; Geertz-Hansen *et al.*, 1987; Jürgens, 1994b). Regulation of bacterial productivity is much more effective by protistan grazing than metazooplankton (Berninger *et al.*, 1991; Jürgens 1994a).

Many comparative analyses of feeding on natural bacterioplankton and phytoplankton indicate that even at maximal filtration rates bacterioplankton can only be a minor constituent of the diet and are inadequate to support growth and reproduction (e.g., Pedrós-Alio and Brock, 1983; Børsheim and Olsen, 1984; Forsyth and James, 1984; Kankaala, 1988; Sanders *et al.*, 1989; Wylie and Currie, 1991; Urabe and Watanabe, 1991). The ingestion ratios between algae and bacteria, however, exhibit considerable differences in relation to seasonal availability and relative abundances. Bacterial abundance and production, as discussed in detail in Chapter 17, are regulated by nutrient availability. When bacterial abundance and productivity are at low-to-moderate levels, protistan grazing dominates (e.g., Jürgens *et al.*, 1994b; Pace and Cole, 1996). Under highly eutrophic conditions where bacterial abundance is high, rotifer and crustacean zooplankton bacterivory can increase. Bacterial feeding by large cladocerans can be in large part incidental to the process of algal feeding. It should again be noted, as discussed earlier with the algae, that ingestion of bacteria does not necessarily result in mortality. Some bacterioplankton clearly can survive digestion in the guts of zooplankton and gain nutritionally (King *et al.*, 1991).

There are several indications that algae alone do not meet the nutritional requirements of cladocerans (see, e.g., Taub and Dollar, 1968; Sanders *et al.*, 1996). In spite of the moderate assimilation rates by zooplankton of algae, bacteria, and heterotrophic flagellates and ciliates and low assimilation rates of detritus, it is unusual for bacteria and other microheterotrophs to dominate the energy income of zooplankton. Clearly, some nutritional component of algae is needed by cladoceran, copepods, and other zooplankton that is critical to growth and reproduction (see following section on lipids). Moreover, in the few cases in which it has been analyzed in some detail (cf. Chap. 22), detritus can form a major energy resource over much of the year. For macrozooplankton, however, detrital material is of limited value in nutrition. Combined with bacteria, detritus may enable macrozooplankton to survive during periods of algal shortage.

H. Lipids in Zooplankton and Fish

In zooplankton, lipids are dominant energy storage compounds and can constitute a significant portion (to 60–70%) of their dry mass (Arts, 1999b). *De novo* synthesis is very small (Goulden and Place, 1990, 1993); lipids in zooplankton and fish are primarily dietary in origin. As a result, the type and amount of lipid contained within zooplankton tissues are correlated directly with recent feeding activities and food selectivity. The correlation between food type ingestion and body lipid content can be modified by temperature (Arts *et al.*, 1993) and reproduction (Vanderploeg *et al.*, 1992) and result collectively in distinct temporal patterns of lipid content in the zooplankton.

Storage lipids are composed primarily of nonessential lipids and constitute major energy reserves. Some polyunsaturated fatty acids (PUFA) and sterols are essential but are required in trace quantities (Goulden *et al.*, 1999; Olsen, 1999). Essential fatty acids (EFA) include linoleic (18:2ω6), linolenic (18:3ω3), and likely eicosapentaenoic (20:5ω3) acids. The phospholipids, which are abundant in cellular membranes, contain a high percentage of essential PUFA. The absolute amount of phospholipids in tissue of zooplankton and fish is partly under genetic control and relatively constant. In contrast, the triacylglyceride and wax ester contents are highly variable and composition dependent on diet.

Zooplankton are often food-limited during the summer months (Lampert, 1977; Threlkeld, 1979; Tessier, 1986). When food availability is low, lipid reserves are essential to the survival of cladoceran embryos, neonates, and adults (Lampert and Bohrer, 1984; Goulden and Henry, 1985; Goulden *et al.*, 1999). It is important to distinguish the effects of food limitation simply on the basis of reduced total food

quantity during summer from limitations in the availability of essential fatty acids (EFA) in the algal food. For example, the low lipid content of the cyanobacterium *Aphanizomenon* provides a totally inadequate food source for normal growth and survival of *Daphnia* and other crustacean zooplankton (Holm and Shapiro, 1984; Arts *et al.*, 1992).

Lipid content of zooplankton has been found to decrease from spring to early summer and to increase again in late summer and autumn (Wainman and Lean, 1990; Goulden *et al.*, 1990; Arts *et al.*, 1992, 1993; Brett and Müller-Navarra, 1997). A number of correlational analyses suggest strongly that the nutritional quality of phytoplankton communities and their essential fatty acid content can be an important factor regulating species and seasonal succession in zooplankton (Ahlgren *et al.*, 1990, 1996; Ahlgren, 1993). For example, in two eutrophic lakes, the total fatty acid content of phytoplankton content varied fivefold during the active growing season, with the lowest values during the summer when cyanobacteria dominated. Highest values occurred during spring and late autumn when diatoms dominated. Essential fatty acids were much more abundant in phytoplankton of the spring and late autumn than during the summer. Specific growth rates of several species of cladocerans were much greater when consuming algae that contained high percentages of essential polyunsaturated fatty acids.

Highly polyunsaturated fatty acids (PUFA) are critical for maintaining high growth, survival, and reproductive rates of zooplankton and fish. High-food-quality algae are rich in such PUFA content, and, conversely, low-food-quality algae are poor in PUFA content (Brett and Müller-Navarra, 1997; DeMott and Müller-Navarra, 1997; Sundbom and Vrede, 1997; Weers and Gulati, 1997). Growth rates of *Daphnia*, for example, can be limited directly by the availability of eicosapentaenoic acid (20:5ω3) within seston used as food (Müller-Navarra, 1995). If fed cryptophyceans or green algae with high PUFA content or if emulsions of PUFAs are added to algal cultures of poor food quality, growth and reproduction rates of zooplankton feeding on these algae can be increased markedly. Fish modify fatty acids such as linolenic (18:3ω3) and linoleic (18:3ω6) acids by elongation and desaturation to form long-chain PUFA such as docosahexaenoic acid (DHA; 22:6ω3) and arachidonic acid (AA; 20:4ω6), respectively. In fish, essential fatty acids, including eicosapentaenoic acid (20:5ω3), DHA, and probably AA, are required to maintain proper growth and development (Bell *et al.*, 1994). For example, deficits in essential fatty acids, in particular DHA, have been shown to affect the number of rods in the photoreceptor population of the eyes of herring (Bell and Dick, 1993) and to hamper the feeding of herring under low light intensities (Bell *et al.*, 1995).

VI. REPRODUCTION AND LIFE HISTORIES

A number of similarities exist among the common life histories and reproductive processes of rotifers and cladocerans. For many successive generations during the main growing season, males are absent and reproduction occurs via parthenogenesis of diploid females. Under certain conditions of environmental stress (e.g., crowding), males develop, meiosis occurs, and sexual (mictic) reproduction occurs, leading to the formation of mictic haploid eggs (Fig. 16-17). If fertilized, the now-diploid eggs ("resting eggs") develop a heavy cell wall and become resistant to environmental extremes.

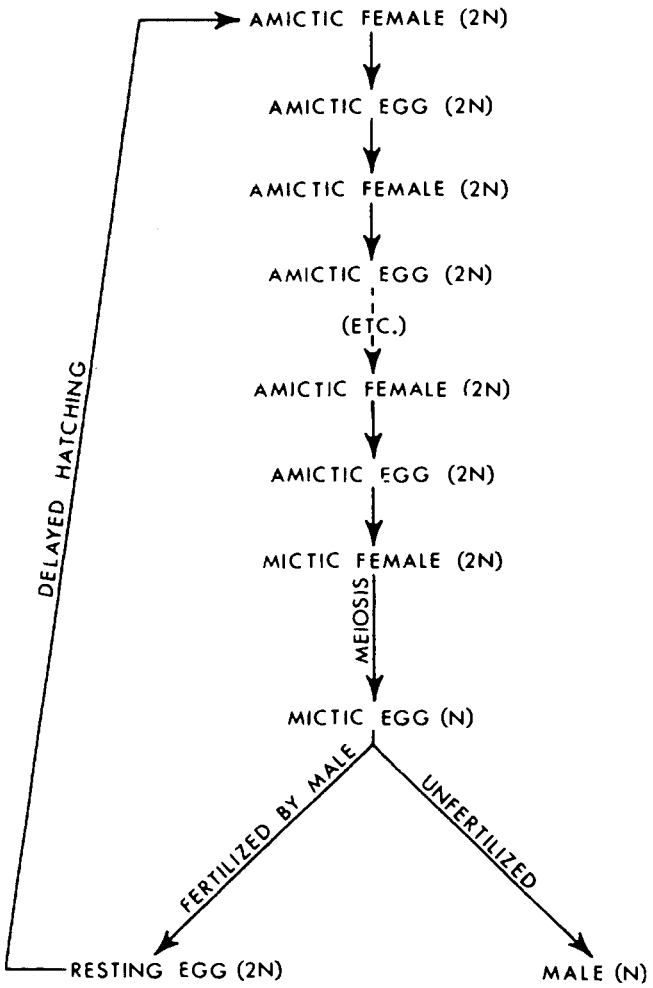

FIGURE 16-17 Diagrammatic sequence of the reproductive life history characteristic of most planktonic and many benthic rotifers. (Redrawn from Pennak, 1953.)

The resting eggs commonly enter diapause, with hatching delayed for long periods, and, upon return of favorable conditions, will develop into amictic diploid females. In contrast, freshwater copepods are bisexual and have a much longer life cycle than do rotifers and cladocerans.

A. Rotifers

The reproductive life history of typical planktonic rotifers, all in the subclass Monogononta, is characterized by a large number of generations in which reproduction is parthenogenetic. These amictic females are all diploid and produce amictic eggs that develop into amictic females (Fig. 16-17). There may be as many as 20–40 of such amictic generations. With an egg-development time of about one day under warm, optimal conditions, and without the need to encounter males for fertilization, a population of amictic females can develop rapidly in 2–5 days.

This nonmeiotic egg production is intermittently broken, often only once or twice per year, by the development of morphologically indistinguishable mictic females. The eggs of the mictic females are produced by normal double meiotic division and are thus haploid (Fig. 16-17). If eggs of these mictic females are fertilized, they develop into thick-walled encysted embryos called resting eggs. The resting eggs undergo prolonged diapause and are highly resistant to adverse environmental conditions. If the mictic eggs are not fertilized, however, they develop rapidly into males. The males are greatly reduced in size and complexity (Gilbert, 1993). The males are short-lived and extremely active and are capable of copulation within an hour of hatching. The hatching of resting eggs can be induced by biochemical factors, but induction under natural conditions is poorly understood. The diapause extends over a period of several weeks or months. Resting eggs accumulate in the sediments and hatch when their environment changes, generally from cold, dark, and anaerobic to relatively warm, light, and aerobic (Gilbert, 1995). The resting eggs always result in parthenogenetic amictic females.

The mechanisms underlying the production of mictic females are unclear, although a number of environmental conditions have been proposed (reviewed by Hutchinson, 1967, and Ruttner-Kolisko, 1972). Although the stimuli are quite species-specific, significant factors include crowding of amictic females in relation to food and accumulation of substances such as pheromones, which are produced by the females. In clones of *Brachionus* reproducing amictically at 20°C, brief exposure to a shock temperature of 6°C resulted in nearly 50% of the clones becoming mictic in <2 days (Ruttner-Kolisko, 1964; Gilbert, 1977).

Asplanchna, the large predatory rotifer, is certainly among the best-studied examples in this regard. Gilbert and co-workers, in a series of superb papers (1967a, 1968, 1972, 1973, 1975, 1976; Gilbert and Thompson, 1968; Gilbert and Birky, 1971; Riggs and Gilbert, 1972; Gilbert and Litton, 1975; reviewed by Gilbert, 1980a), have demonstrated the subtle reproductive controls in this species that have far-reaching implications among the zooplankton. When fed the protozoan *Paramecium*, *Asplanchna* produced only amictic females. Increasing the population densities of the rotifer to extraordinary levels of crowding produced no mictic females, whereas adding low populations of the algae *Chlamydomonas* or *Euglena* to the dense paramecia resulted in the production of a significant number of mictic females. It was also shown that the algal cells had to be eaten to induce the reproductive change in *Asplanchna*; extracellular algal products would not induce the change. It was shown subsequently that the important dietary component from the plants was *d*-α-tocopherol (vitamin E), which induced the transition from parthenogenetic to sexual reproduction and is essential for spermatogenesis or male fertility. The mictic female offspring were also larger and changed in morphology, exhibiting four partially retractile outgrowths of the body wall. These "humps" were elicited by *d*-α-tocopherol within a range of 5×10^{-13} mol (0.2 ng) in a linear fashion to a maximum of 5×10^{-11} mol (20 ng) per female. Tocopherol, as well as cannibalism, also induced a third polymorph, a very large campanulate type.

The adaptive significance of control of sexual reproduction and nongenetic female polymorphisms is complex (reviewed by Gilbert, 1980a). The initial response to tocopherol is a general increase in growth that permits the carnivorous *Asplanchna* to more easily ingest larger, possibly more nutritious, herbivorous prey. Tocopherol can act as an adaptive cue for this growth, for it is synthesized only by photosynthetic organisms and is readily assimilated by herbivores. Upon ingestion of rotifer and crustacean prey, tocopherol is readily assimilated by *Asplanchna* and is transmitted to its embryos without degradation. Tocopherol can promote differential polymorphism in some species of *Asplanchna* through cell enlargement and increased cell division. Population densities of *Asplanchna* increase when herbivorous zooplankton are more abundant; the resulting increase in contacts between males and mictic females facilitates production of resting eggs.

Body-wall outgrowths, which reduce cannibalism by the large individuals, likely evolved with the growth response to tocopherol (Gilbert, 1980a). Two tocopherol-dependent, female morphotypes evolved in some species. The larger, campanulate morphotype is adapted for ingestion of very large prey and, in one

species of *Asplanchna*, for parthenogenetic reproduction only. The well-protected cruciform morphotype, with prominent body-wall outgrowths, is adapted for ensuring sexual reproduction and avoiding capture by cannibalistic conspecific *Asplanchna*. Growth responses to tocopherol evolved only in those species that (1) do not depend on the direct utilization of relatively small tocopherol-rich algae and (2) can ingest the copious quantities of zooplankton prey needed for sustaining populations of large individuals.

Other rotifers, such as the sessile bdelloids, none of which are planktonic, reproduce exclusively by parthenogenesis. Resting eggs are unknown, but these adults can survive drying.

The survival and reproductives rate of rotifers are related strongly to the quality and abundance of food as well as to temperature (Edmondson, 1946, 1965; King, 1967; Halbach and Halbach-Keup, 1974; Baker, 1979; Sterzynski, 1979). It is clear that these factors are of major importance in determining seasonal fluctuations in the populations resulting from changes in the balance between increases by reproduction and declines from mortality.

In addition to effects on the rate of development of eggs, temperature obviously influences the rates of biochemical reactions, feeding, movement, longevity, and fecundity. For example, increased temperature reduces survivorship with an age-specific compression of fecundity (Fig. 16-18). Intrinsic rates of increase (r_m) were 0.34 offspring per female at 15°C, 0.48 at 20°C, and 0.82 at 25°C. A number of other factors affect natural populations, but temperature is clearly a major factor affecting birth rate. It is also apparent that species are variable in their responses and habitat restrictions; some are very restricted stenotherms, while others are eurythermal.

A number of studies under both natural and laboratory conditions have shown that food type and quality exert a major influence on the population dynamics of rotifers. For example, in investigations of the dynamics and reproduction of two clones of *Euchlanis dilatata* fed different algal species at various concentrations, King (1967) found several relationships that also have been shown to varying degrees by others. Two genetically identical clones of *Euchlanis* were grown from a single parent by parthenogenesis, so that in succeeding generations, the individuals of one clone, the young orthoclone, were always derived from young parents and those of the other orthoclone from old parents. The clones were fed different concentrations of three algal species, *Chlamydomonas reinhardi, Euglena gracilis*, and *E. geniculata*. Growth rates of individual animals were found to depend on food concentration and not on animal age or algal species. The rate of population increase was related directly to the density of food for concentrations up to 16.4 μg ml^{-1}, beyond which no further changes were observed. In *Brachionus*, filtration rate decreased at high algal densities; this was related to clogging of the filtration apparatus, reduced digestion, or inactivation of the corona by algal toxicants (Halbach and Halbach-Keup, 1974). Within the population, however, growth rates were related to both food species and food concentration (Fig. 16-19). *Euchlanis* fed on *Chlamydomonas* had higher rates of population increase than when feeding upon *Euglena gracilis*. *E. gracilis*, on the other hand, led to higher

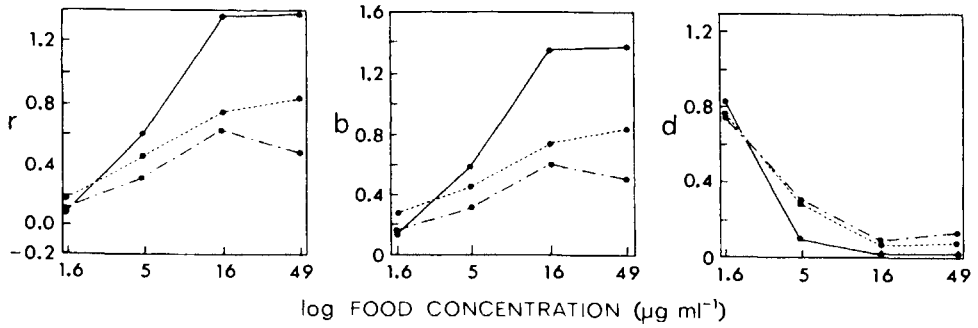

FIGURE 16-19 The instantaneous rate of increase (r), birth rate (b), and death rate (d) of young orthoclones of the rotifer *Euchlanis dilatata* as a function of food level and food species. _____ = *Chlamydomonas reinhardi*; - - - - - - = *Euglena gracilis*; – . – . – . = *Euglena geniculata*. (Drawn from data of King, 1967.)

rates of population increase than *E. geniculata*. Individuals of the young orthoclone exhibited greater rates of population increase than those of the old orthoclone. The different rates of increase resulted more from corresponding differences in net reproduction (the number of eggs laid by the average female in her lifetime) than from the frequency of egg laying or survivorship. The results, confirmed by others (e.g., Snell, 1980), imply differences in assimilation, differences in the chemical quality of the food, or both.

B. Cladocera

Somewhat analogous to that of the rotifers, reproduction in the cladocerans is parthenogenetic during a greater part of the year. Until interrupted by sexual reproduction, females produce eggs that develop into more parthenogenetic females. The number of eggs produced per clutch varies from two or more in the Chydoridae to as many as 40 in the larger Daphnidae. The eggs are deposited into a brood chamber, or pouch, a cavity dorsal to the body bounded by the valves of the carapace. The eggs develop in the brood pouch and hatch as a small form of the parent. As a result, in contrast to the copepods, there are, with the exception of *Leptodora*, no free-living larval forms among the Cladocera. One clutch of eggs is normally released into the brood pouch during each adult instar.

The number of molts is variable. Four preadult instars are common within a range of 2 to about 8 in some *Daphnia*. Longevity, from the time of egg release into the brood pouch until death of the adult, varies widely with species and environmental conditions (Threlkeld, 1987). Longevity and time between molts are approximately inversely related to temperature. For example, longevity in *Daphnia magna* averaged 108, 88, 42, and 26 days at 8, 10, 18, and 28°C, respectively (MacArthur and Baille, 1929). Longevity also is affected by food availability and commonly increases with a decrease in food consumption, short of starvation, which results in rapid death. Lipid reserves in the Cladocera accumulate in the body coelom when food is abundant and can be used as an energy reserve when food is scarce (Goulden and Hornig, 1980). The quantity of lipid that can be stored by individuals in a species is related to recent feeding activities and food selectivity (see Lipids in Zooplankton and Fish, p. 427). The importance of temperature, however, can be seen in studies of *Daphnia galeata mendotae* (Table 16-13) that were fed differing concentrations of

TABLE 16-13 Instantaneous Rates of Population Increase per Day (r) ± S.E. of *Daphnia galeata mendotae* at Different Temperatures and Levels of Food Supply[a]

	Temperature		
Relative food levels	*11°C*	*20°C*	*25°C*

mixed green algae at different temperatures (see Hall, 1964).

In adult cladocerans, the number of molts is more variable than in juveniles and can range from a few to well over 20 instars. Each instar ends with the release of young from the brood pouch, molting, rapid increase in size, and deposition of a new clutch of eggs into the pouch, all of which occurs in a matter of minutes. Therefore, an individual can produce several hundred progeny in a lifespan under favorable growing conditions.

Increases in temperature result in an immediate effect by increasing the rate of molting and brood production, whereas increases in food supply, within limits, affect the rate of development of the population by increasing survivorship and fecundity (i.e., the number of eggs per brood). The latter process is not immediate and this time lag can contribute to population oscillations. When the growth of the population exceeds available food supply, reproduction decreases, with reduced replacement of adults. Reduction of the population below the environmental carrying capacity set by available food results in an increase in the population after a lag period. The extent of population oscillations depends greatly on the duration of the time lag. These relationships have been demonstrated in detailed studies under culture conditions (Frank, 1952, 1957; Slobodkin, 1954), and will be discussed in greater detail later on. When several zooplankton species are competing for limited food resources, the decline of some or all of the populations is responsive to the interactions of food quality and supply, feeding capabilities, and the effect of temperature on reproductive responses of each zooplankton species. Degeneration and abortion of parthenogenic eggs is well known but difficult to quantify (Threlkeld, 1979, 1985). Causes for egg abortion are unclear; egg abortion was found to be inversely correlated with cyanobacterial development. Decline of a population does not necessarily eliminate that species, which may shift to an inactive state by the formation of resting stages.

Parthenogenesis continues until unfavorable conditions arise, whether they are physical, such as temperature reductions, drying, or short day-length photoperiod (cf. Shan, 1974; Pourriot and Clement, 1975; Bunner and Halcrow, 1977; Carvalho and Hughes, 1983), or biotic, that is, induced through crowding by competition for low food supply or a decrease in quality–size of food organisms. As the production of parthenogenetic eggs declines, some of the eggs develop into males. Some females then produce sexual (haploid) eggs, as in the rotifers. Though morphologically similar to parthenogenetic females, sexual females usually produce only one or a few resting eggs. Following copulation and fertilization, the carapace surrounding the brood pouch thickens and encloses the egg(s), forming a semielliptical, saddle-shaped *ephippium* (Zaffagnini, 1987). During the subsequent molt, the ephippium either is shed, as in the daphnids, or remains attached, as in the chydorids. If females carrying resting eggs are not fertilized, the resting eggs are resorbed. One species, the arctic *Daphnia middendorffiana*, is known to be able to produce ephippial eggs parthenogenetically.

The ephippia either sink or float, and can withstand severe conditions such as freezing or drying. It is not unusual to find large accumulations of ephippia along windward shore lines. It is easy to envision entanglement and transport of ephippia by birds to other water bodies. A large percentage of the ephippia hatch under favorable but poorly understood conditions, always into parthenogenetic females. In a laboratory-cultured strain of *Daphnia pulex*, light was required for termination of diapause regardless of temperature or duration of ephippial storage (Stross, 1966). In naturally occurring ephippia of a lake population of the same species, diapause also was broken by light, but prolonged storage in darkness eliminated the need for light. The time required was 5–6 months at 3.5°C and only 3–6 weeks at 22°C. Increases in temperature thus increase the rate of hatching (e.g., Herzig, 1985; Yurista, 1997). Hatching is often irregular over a long period of time, in part related to ample genetic variability as determined from maternal inheritance (Meester and de Jager, 1993).

Males are smaller and only slightly modified in morphology from females (larger antennules and clasping modifications of the first leg for copulation). Mechanisms underlying the periodic induction of males and ephippial females are unclear, although evidence indicates that the stimuli are different (reviewed by Hutchinson, 1967). Male production is correlated with crowding and a rapid reduction of food supply, whereas a constant low food supply simply inhibits reproduction (Slobodkin, 1954). Short-day photoperiods (12 h light and 12 h dark) increased the production of ephippia markedly in *Daphnia pulex*, in contrast to longer light photoperiods, which would be characteristic of midsummer in temperate latitudes (Fig. 16-20). If universal, this photoperiodic response must vary among species.

C. Copepods

Reproduction in free-living copepods is similar in spite of widely varying species differences in sexual behavior and periodicity of breeding. Some species reproduce throughout the year, others only briefly at specific

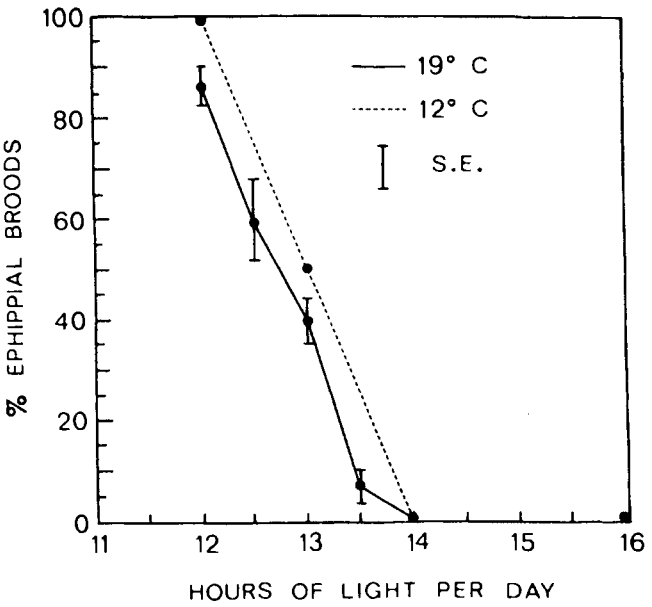

FIGURE 16-20 Influence of photoperiod on the production of ephippial egg broods in *Daphnia pulex* at high population densities. (Modified from Stross and Hill, 1965.)

times of the year. Copepod copulation occurs by a male briefly clasping the female with transfer of spermatophores to the ventral side of the female genital segment. Fertilization may take place immediately or several months after copulation. Fertilized eggs are carried by the female in 1 or 2 egg sacs. The number of eggs in cyclopoid copepods, carried in two lateral egg sacs, is variable; differences observed between populations in different lakes and between seasons, have not been associated clearly with changing environmental conditions. Egg number, up to 72, is generally low in summer and increases in the autumn.

In the calanoid copepods, eggs are carried in a single egg sac and are variable in number (from about 1 to 30). Eggs are differentiated into subitaneous and resting eggs, both being fertilized in many species. Resting eggs usually are dropped to the sediments, where they undergo a period of diapause. Clutch size varies greatly in calanoids; often it is maximal in the spring and the fall, and these two peaks may be separated by a summer minimum. Larger clutch size is correlated with lakes of greater primary productivity and to spring conditions that favor more abundant food supplies. As in the Cladocera, food availability directly influences the clutch size, while temperature determines the rate of egg production and egg development times in copepods (Elster, 1954; Comita and Anderson, 1959; Burgis, 1970; Ceiling and Campbell, 1972; Elmore, 1983; Watras, 1983; Maier, 1989, 1990). The reproductive cycle is apparently not affected by variations in the photoperiod. In this way, a small number of females carrying a few eggs for a short period at high temperatures can produce more young than many females with large egg clutches that are exposed to long periods at low temperatures.

Copepod eggs hatch into small, free-swimming larvae, termed *nauplii*, and then develop by molting through a number of subsequent larval stages. The initial nauplius has three pairs of reduced appendages (first and second antennae, mandibles). The successive naupliar stages, six in all, feed, grow, molt, and acquire further appendages. After six naupliar molts, the next molt results in an enlarged and more elongated form, the first copepodite instar. There are five copepodite stages, during which additional appendages and body segments develop. The sixth and final copepodite stage is the adult. The time required to complete the juvenile stages and period of diapause is highly variable among species and depends upon seasonal conditions (see following discussions).

VII. SEASONAL POPULATION DYNAMICS

A. General Considerations

More useful information on zooplankton population dynamics can be obtained if the stages in the life history of species are analyzed separately than if only the total population is measured.[4] Analyses of egg production and instar dynamics yield information on growth rates and mortality, as well as the duration of each stage and the interval between generations. Instar analyses are easier with copepods than with cladocerans because the naupliar and immature and adult copepodite stages can be distinguished morphologically (cf. Wetzel and Likens, 2000). Among the cladocerans, and to some extent the rotifers, instars can sometimes be evaluated on the basis of size.

Analyses of the population dynamics of zooplankton require sound sampling methods with known statistics on sampling variance and on population heterogeneity within the aquatic system. This subject is outside the purview of the present work and, moreover, has been treated excellently in methods manuals edited by Edmondson and Winberg (1971), Winberg (1971), and Downing and Rigler (1984), and in the reviews by Bottrell *et al.* (1976), Waters (1977), and Benke (1993). Once representative samples of the animal population are obtained, a number of methods have been employed to evaluate population size and fluctuations. Enumeration can be adequate to address certain

[4]The generous counsel of W. T. Edmondson on the population analyses of zooplankton is gratefully acknowledged.

questions concerning population dynamics and interactions, but in order to evaluate secondary productivity, precise knowledge of changes in biomass throughout all stages of the organisms' life cycles is mandatory. Development times must be known and, although they are variable among organisms and environmental conditions, time between samplings must be less than the shortest developmental period. Assuming stable egg distribution, the number of eggs present in a sample of a zooplankton population at some instant in time represents the increment that would have been added to the population over a period of time equal to the duration of development of the eggs (time from laying to hatching). The population would increase by the number hatched during the time period if no deaths occurred.

The population dynamics of rotifers are somewhat simplified because of the very short time between hatching and attainment of reproductive capacity. Analyses of birth and death rates may be estimated from reproductive rates and rates of population change. The reproductive rate can be determined indirectly from the ratio of eggs per female (Edmondson, 1960, 1965, 1968, 1974). The ratio of eggs per female (E) observable in a sample at any given moment can be used to calculate a finite population birth rate (B) as eggs per female per day, by

$$B = \frac{E}{D} \tag{16-1}$$

when D is the duration of development of the eggs, or the mean time an individual spends in the egg stage. This relationship assumes that eggs present at a given time will be added to the population during the next period of time, D. If the age distribution of the eggs is stable, the fraction of eggs hatched during a day is $1/D$. If the population is changing size, the value of B is exact only if $D = 1$; the bias introduced by longer durations can be estimated (Edmondson, 1968).

From the reproductive rate B, the instantaneous growth rate of the population, r, can be calculated based on the conventional exponential growth model (cf. Chap. 8), in which positive or negative growth over a short time interval is

$$N_t = N_0 e^{rt} \quad \text{and} \quad r = b - d \tag{16-2}$$

in which

N_0 = the size of the initial population at time zero
N_t = the population size at a later time t
r = the growth rate coefficient or intrinsic rate of growth
d = the instantaneous rate of mortality and
b = the instantaneous birth rate (calculated from B)

The effective rate of population increase is the difference between the natural logarithms divided by the time increment $(t - 0)$:

$$r = \frac{\ln N_t - \ln N_0}{t} \tag{16-3}$$

which is in essence the difference between natality (b) and mortality (d) over the time interval (t).

Alternatively, birth rate, estimated by the egg-ratio method, gives the daily increment to the population. For a population growing by the amount E/D in one day with no deaths, its growth rate would be

$$b = \ln(B + 1) \tag{16-4}$$

Here B is estimated at the beginning of the time interval with the assumption that for each female in the population there will be $(E/D) + 1 = B + 1$ females one day later. Assuming no mortality, the population would grow in one day at a rate of

$$\ln(B + 1) - \ln(1) = \ln(B + 1) \tag{16-5}$$

Thus by Equation (16-4), a finite per capita birth rate, B, can be used to estimate the instantaneous rate, b. The calculations assume that B is small; under such circumstances both B and the E/D are approximately equal to the instantaneous birth rate b.

As pointed out by Edmondson (1968) and rederived by Paloheimo (1974), for moderately large values of r and bD, the finite per capita birth rate and the egg-ratio/D can diverge considerably (see Lynch, 1982). Further, the relationships are most applicable to planktonic animals that carry their eggs until hatching, at which time free-swimming progeny are liberated, that is, the eggs are subjected to the same mortality as the adults. Paloheimo (1974; Gabriel *et al.*, 1987) has shown that

$$E/D = (e^{bD} - 1)/D \tag{16-6}$$

when D is the development time of the eggs, which is algebraically equivalent to

$$b = \ln[(C_t/N_t) + 1]/D \tag{16-7}$$

when C_t is the total number of eggs counted at time t, which estimates the instantaneous birth rate b from egg counts C, where C_t/N_t is the egg ratio. This formula assumes that steady-state conditions prevail, which is not usually the case. Development time is temperature dependent, and in analyses of natural populations this primary factor must be estimated from good experimentally determined changes with temperature. Examples of estimates of instantaneous birth rates are given in Table 16-14, in which the C_t/N_t ratio has been held at 1. The egg-ratio method has been used in several detailed population analyses of planktonic rotifers

(especially by Edmondson, 1960, 1968; Gabriel *et al.*, 1987), from which the following examples are drawn, as well as for cladoceran and copepod zooplanktonic populations to be discussed later.

B. Development Time

The rate of development of eggs, which is required to determine the reproductive rate B, has been shown to be a function of temperature among a large number of rotifers and planktonic crustaceans. Examples of this relationship for a number of rotifer species are seen in Figure 16-21. The development time is quite independent of the type and quantitative nutrition of the adult female carrying the eggs (see, e.g., King, 1967; Meier, 1989a, 1990b). The age in cladocerans can be calculated from body size once the relationship of length of juvenile development is known as a function of temperature (Geller, 1987). Embryonic development time for a species of *Diacyclops*, for example, was between 14 days at 2°C and 2 days at 25°C.

The instantaneous growth rate, r, is the effective rate of population increase per unit time. A measure of death rate, d, is calculated by difference and varies with the abundance of predators.[5] The procedure assumes continuity of birth and death rates during the sampling interval (cf. Keen and Nassar, 1981; Taylor and Slatkin, 1981; Gabriel *et al.*, 1987). The method demands that the sampling interval be short in relation to the life cycle and immaturity time of the animals. Although natural populations do not strictly conform to these assumptions, the discrepancies introduced are usually rather small (see Caswell, 1972; Edmondson, 1974; Paloheimo, 1974; Threlkeld, 1979; Polishchuk and Ghilarov, 1981; Lynch, 1982; Berberovic *et al.*, 1990,

[5] In the calanoid copepod *Diaptomus clavipes*, egg size can differ, and larger eggs give rise to larger nauplii, each of which presumably has a greater likelihood of survival compared with smaller nauplii (Cooney and Gehrs, 1980). In some species of cladocerans, lipid reserves deposited in the eggs by the adult depend upon the nutritional status of the adult; neonates with lower lipid reserves (see p. 427) may not survive as well as neonates with extensive lipid reserves (Goulden and Henry, 1982). The extent to which differential survival of newly hatched or neonate zooplankton is influenced by nutritional history of the parent animal is not fully understood and may alter our view of zooplankton life strategies as more data become available.

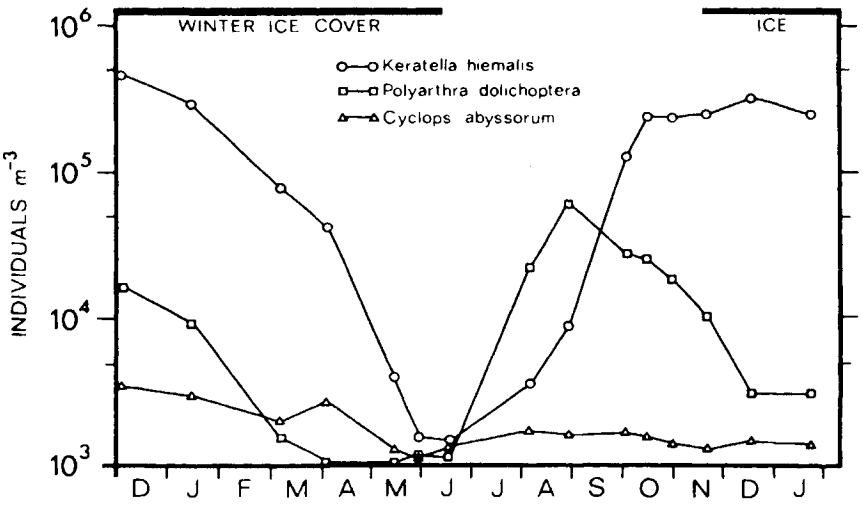

FIGURE 16-22 Seasonal variations in the population densities of three dominating zooplankton species (>99% of the total) of Vorderer Finstertaler See, Central Alps of Austria, 1969. (Modified from Pechlaner *et al.*, 1970.)

for a rigorous discussion of these assumptions). The method is very useful for analyzing factors that control birth and death rates in natural populations of zooplankton.

VIII. ROTIFER POPULATION DYNAMICS

Changes in the seasonal distribution of planktonic rotifer populations are complex and generalizations are difficult to make. A number of perennial species occur that commonly exhibit maximal densities in early summer in temperate regions. Even though most rotifers have wide ranges of temperature tolerances (Berzinš and Pejler, 1989), species are distinctly seasonal and of two general types: (a) cold stenotherms that develop greatest populations in winter and early spring and (b) species that develop maxima in summer, often with two or more maxima, especially in late summer in conjunction with the development of certain cyanobacteria populations. Some of the variations in seasonal succession can be seen in certain well-studied examples from several lakes. Additional examples from several older works are discussed critically in Hutchinson (1967).

The zooplanktonic community of Vorderer Finstertaler See, a deep, alpine drainage lake above the timber line in the Central Alps of Austria, was extremely simple.[6] Two rotifers (*Keratella hiemalis* and *Polyarthra dolichoptera*) and a single copepod (*Cyclops abyssorum*) constituted over 99% of the zooplankton. The species of *Keratella*, known as a ***hypolimnetic cold stenotherm***, developed maximal population densities in midwinter, decreasing conspicuously during spring and early summer (Fig. 16-22). The species of *Polyarthra* is also a coldwater form that tolerates reduced oxygen concentrations and is commonly found in hypolimnia. The *Polyarthra* maximum was seen in midsummer in this lake.

A number of other species of rotifers are similarly cold stenotherms with varying tolerances to reduced oxygen concentrations (Ruttner-Kolisko, 1975, 1980; Elliott, 1977; Herzig, 1980; May, 1980; Laxhuber, 1987). These capabilities permit the rotifers to occupy niches both spatially (metalimnion and hypolimnion) and seasonally (winter throughout much of the water column; spring period) that are unsuitable for other rotifers. Often, bacteria are more abundant in these regions than in the epilimnion and apparently serve as significant food sources. Other rotifers, such as *Notholca*, can feed on the cell contents of large diatoms (e.g., *Asterionella*) and may increase in abundance during the spring diatom bloom.

Studies of the rotifer populations in two small lakes in southern Ontario showed that the seasonal distribution varies considerably among lakes and is synchronous among lakes only in a general way (George and Fernando, 1969). Paradise Lake, for example, is a small (7 ha), shallow (6 m), dimictic lake that exhibits reduced oxygen concentrations in the hypolimnion in late summer but does not become anaerobic. Summer stratification extended from early June through September in the year of the investigation. Of the four

[6] The lake has since been modified drastically by a large hydroelectric project.

species[7] of *Keratella* found in this lake, *K. canadensis* is a cold stenotherm found in the upper strata in early winter. *K. quadrata*, also a cold form, occurred from early winter in the upper layers and moved to the cooler hypolimnion in midsummer before declining. *K. cochlearis* is also a cold stenotherm and exhibited two maxima in this lake, one in winter and another in late spring, but the seasonal distribution of this species varies greatly among different lakes. *K. hiemalis*, known as a winter and early spring species, was common during colder periods but was reduced abruptly as temperatures reached approximately 15°C.

Polyarthra vulgaris, P. euryptera, Conochilus unicornia, Gastropus stylifer, and *Keratella crassa* are largely summer and autumn species, although a considerable displacement and spatial separation of the populations occurred seasonally with depth. The predatory species of *Asplanchna* generally was a minor component of the rotifer community and was relatively uniformly distributed in winter and early summer. The two species of *Kellicottia*, both perennial, were distributed uniformly with depth throughout much of the year; *K. bostoniensis*, however, was restricted to cooler areas during much of the summer. Both species exhibited summer population maxima.

The rotifer community of Lake Constance of southern Germany was examined repeatedly over >50 yr, a period during which the lake experienced gradual eutrophication from oligotrophic to mesotrophic conditions (Walz *et al.*, 1987). A continual quantitative increase in the rotifer populations was observed over this interval, particularly among the epilimnetic populations. Approximately in the middle of this time period, a large *Daphnia hyalina* and a carnivorous species of copepod, *Cyclops*, increased markedly and overwhelmed other cladocerans. Predation by the *Cyclops vicinus* effectively controlled both the *Daphnia* and the large predatory rotifer *Asplanchna*. As predation pressure relaxed in May as the *Cyclops* entered diapause, *Asplanchna* and other rotifers developed rapidly before *Daphnia* populations could recover. Predation on some rotifer species was effective by both *Cyclops* and *Asplanchna*; other species of rotifers were impacted only by *Cyclops*. Similar relationships of *Cyclops* predation on rotifers were found in Lake Michigan zooplankton communities (Stemberger and Evans, 1984).

In a eutrophic reservoir in Georgia, USA, an inverse correlation between the abundance of rotifers and crustaceans was found (Orcutt and Pace, 1984). Rotifers dominated in abundance during the summer months (June–September) and crustacean zooplankton dominated during the remainder of the year.

These examples serve to illustrate some of the variations found in seasonal succession. Variations are very common, and in warm temperate regions very little is known about seasonal succession among rotifers. Interactions among species of rotifers are poorly understood; a notable exception is the predation of *Asplanchna* on *Brachionus*, discussed earlier. Clearly, temperature and food quality and quantity are dominant factors in the regulation of rotifer reproductive rates and population succession.

A. Exploitative Competition for Shared Food Resources

The food concentrations for which population growth is zero (i.e., the threshold food level) varies greatly among planktonic rotifer species (Stemberger and Gilbert, 1985). The threshold food concentration was positively correlated to both rotifer body mass and to population growth rates. Thus, the smallest species require less food to attain maximum growth rates; they are better adapted to living in food-poor environments than large species that attain maximum growth in food-rich environments. Under very low food conditions, starvation can occur. Resistance to starvation, that is the ability of a species to persist when energy intake is less than energy expenditure, varies among rotifers and their life stages (Kirk, 1997). Juveniles that allocated little energy to reproduction had greater resistance to starvation than did adults.

Increasing food concentration promotes increasing body growth of adult rotifers, and this direct relationship continues into the reproductive stages until about the laying of the third egg (Walz and Rothbucher, 1991). Relative egg size, volume, and egg–female ratio (fecundity) increase with greater food concentrations and size of adults among many, but not all, rotifer species (Hillbricht-Ilkowska, 1983). High food concentrations enhance growth, shorten juvenile stages, and accelerate reproduction, some of which is seen in increased fecundity. Egg ratios were related to growth rates, however, and were not influenced by the type of algal food available to the rotifers (Rothhaupt, 1990).

Analyses of interactions *in situ* under natural conditions are rare. A detailed regression analysis of the seasonal dynamics of reproductive rates of planktonic rotifers of four lakes in the English Lake District in relation to food abundance verified the results of culture analyses (Edmondson, 1965). The abundance of food at a given time is an imperfect measure of food supply to the feeding organisms; the food consumed during a period of time depends upon the grazers' capabilities,

[7] *Keratella canadensis*, which may not be a valid species, is very similar to *K. quadrata*.

as well as the predators' reproductive rate, which is under the influence of still other environmental variables. Among the three dominant rotifer populations analyzed by Edmondson, reproductive rates were strongly related to temperature, especially in the case of *Keratella*. A small flagellate, *Chrysochromulina*, was of major importance in the success of both *Keratella* and *Kellicottia*. Limited data on bacterial densities showed no significant correlations with reproductive rates of the rotifers. The reproductive rate of *Polyarthra* was directly correlated with the abundance of the small alga *Cryptomonas*.

The significance of food organisms to the rotifers was found to be partly but not wholly related to size. Some food organisms within an acceptable size range were of little significance. The green alga *Chlorella* was consistently not utilized as a food organism. Similarly, *Eudorina* was not eaten and may exert an inhibitory effect. Some rotifer species do not discriminate between feeding upon living and dead algal cells (Bogdan *et al.*, 1980; Starkweather and Bogdan, 1980). *Keratella cochlearis* was found to feed selectively on detritus when given both dead and live algae but, as with several other rotifers, would ingest bacteria, yeast, and algae in mixed diets, although at different rates. Other rotifers (e.g., *Polyarthra*) ingested only algal cells.

Food availability was found to be instrumental in the population dynamics of *Keratella cochlearis* in a eutrophic Danish Lake (Bosselmann, 1979a,b). A small, nonreproducing population occurred in the open water during late autumn and in winter; mortality was low. The existing population started to reproduce and the population was augmented by the hatching of resting eggs. With low mortality in the spring, the population grew exponentially (Fig. 16-23); reproduction was limited only by low water temperatures. During May, the turnover rate of biomass of this rotifer species was 7.7 days. In early summer, the population was large but constant and had a moderate mortality and a low birth rate because of low food availability. Food availability improved in late summer and, along with high water temperatures, resulted in more rapid biomass turnover rates (5.0 days). Mortality was higher in late summer and the population numbers fluctuated widely. In the autumn, reproduction decreased because of declining temperatures and food availability. Similar direct correlations, with some experimental support, were found between rotifer abundance and food availability in summer in a Wisconsin lake (González and Frost, 1992). In natural rotifer communities of a small lake in Vermont, poor food conditions seasonally induced diapausing amictic eggs in *Synchaeta* that resulted in an obligatory dormant period before resuming development (Gilbert and Schreiber, 1995). Diapausing amictic eggs differ markedly from fertilized resting eggs produced following bisexual reproduction during favorable conditions of food availability (Pourriot and Snell, 1983; Gilbert, 1995). Diapausing eggs are induced immediately after a brief starvation period at relatively little energetic cost. However, a population producing a high proportion of diapausing eggs has a greatly reduced reproductive potential because of lower hatching success subsequently.

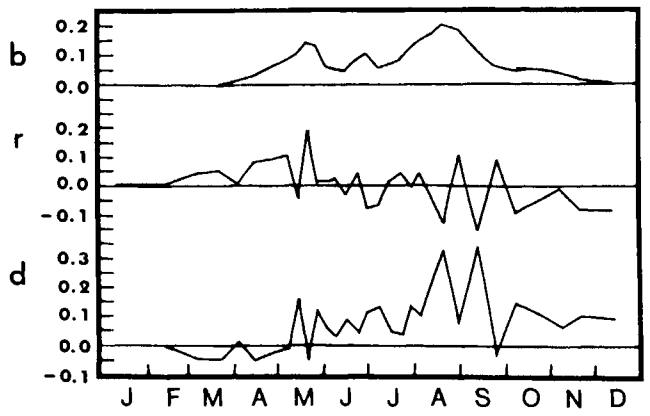

FIGURE 16-23 Estimates of the birth rate (*b*), rate of growth (*r*), and the rate of mortality (*d*) of *Keratella cochlearis* in Lake Esrom, Denmark, 1973. (Modified from Bosselmann, 1979a.)

A detailed analysis of the zooplanktonic population dynamics and productivity of Mirror Lake, New Hampshire, also demonstrates the spatial and temporal separation of the individual populations (Makarewicz and Likens, 1975, 1979; cf. also Hofmann, 1982). As illustrated in the depth–time productivity data of Figure 16-44, the rotifers were major components of the zooplankton community in this lake. Although copepods constituted 55% of the total zooplankton biomass, they represented only 19% of the zooplankton productivity because of their slow growth over an entire year. In contrast, despite lower biomass, the rotifers accounted for 40% of the annual zooplankton production primarily because of faster growth rates and generation times of 8–10 days (at 17°C). As discussed later (p. 480), the niche hyperspace of the limnetic zooplankton community was subdivided by dispersion of the populations of rotifers, cladocerans, and copepods along gradients of food size, depth, and time. Differences in the life histories in the timing of development of different populations, feeding behavior and food size and types utilized, tolerances of vertical and seasonal variations in temperature and oxygen, and vertical migratory behavior all contributed to minimizing niche overlap and permitting coexistence of species within the annual zooplankton community.

B. Mechanical Interference Competition

Rotifers generally cannot become abundant members of freshwater zooplankton communities in the presence of large (≥1.2 mm) *Daphnia* and copepods even when shared food resources are abundant (Neill, 1984; Gilbert and Stemberger, 1985; Gilbert, 1988; Lair, 1990; MacIsaac and Gilbert, 1991). Commonly, rotifers appear early in the seasonal succession of zooplankton communities and are succeeded by *Daphnia*. As large *Daphnia* populations decline seasonally or are suppressed by planktivorous fish or altered water quality such as lake acidity (Siegfried, 1991), rotifers rapidly dominate. Rotifers are suppressed by large *Daphnia* both through exploitative competition for shared, limiting food resources. Additionally, mechanical interference can occur as rotifers are swept into the brachial chamber of *Daphnia*, where they are immediately killed, mortally wounded, or lose attached eggs before being rejected. In some cases, the rotifers are ingested along with algae. Large rotifers are little damaged by cladocerans but must compete with them for food and are often suppressed by exploitative competition when food is limited. Small cladocerans generally do not mechanically interfere with rotifers.

The larval dipteran midge *Chaoborus* can be a voracious predator on algae and small zooplankton such as rotifers, naupli, and small cladocerans. Impacts on small cladocerans can be significant and can shift the community structure to larger species (e.g., Lynch, 1979; Vanni, 1988). Detailed studies of *Chaoborus* predation on rotifers in several lakes did not, however, demonstrate appreciable selective predation on rotifers, and reproductive output of new individuals could easily exceed predatory losses (Havens, 1990; Rodusky and Havens, 1996).

The predatory rotifer *Asplanchna* releases a soluble organic compound that induces eggs of other rotifers, such as *Keratella*, to develop into larger individuals with longer posterior spines (Gilbert and Stemberger, 1984). This induced polymorphism renders the *Keratella* much less likely to be captured and ingested by the *Asplanchna* and is most effective in reducing predation.

IX. CLADOCERAN POPULATION DYNAMICS

The seasonal succession of the Cladocera is quite variable, both among species and within a species living in different lake conditions. Some species are perennial and overwinter in low population densities as adults (parthenogenetic females) rather than as resting eggs. These species may exhibit one, two, or more irregular maxima. Some perennial species exhibit maxima in surface layers only during colder periods in the spring and in the cooler hypolimnetic and metalimnetic strata during summer stratification. The aestival species that have a distinct diapause in a resting egg stage commonly develop population maxima in the spring and summer when the water is relatively warm. Although one population maximum is general, a second population peak often occurs in the autumn.

Much of the seasonality within cladoceran life histories depends upon the environmental conditions. A comparison of the life history data of an arctic species, *Daphnia middendorffiana*, and a temperate species, *D. pulex*, is instructive. Even though much variation exists among different populations, locations, and seasons, two distinct patterns emerge (Schwartz, 1984). The temperate *D. pulex* matures sooner, at a smaller size, and gives birth to more, smaller progeny in many more adult instars than does the arctic *D. middendorffiana* (Table 16-15). The temperate species also tended to live longer than did its arctic relative that requires more time to mature and produces many fewer broods of large neonates.

Another example of a typical case of temperate pelagic cladoceran population dynamics can be seen in the well-studied zooplankton of Base Line Lake,

TABLE 16-15 Life History Characteristics of Two Species of *Daphnia* from Arctic and Temperate Surface Waters[a]

Characteristic	*Arctic* D. middendorffiana	*Temperate* D. pulex
Time to maturity	10–12 days	5–9 days
Average brood size	4.8–14	3–29.5
Maximum brood size	6–10	70
Number of broods	5	15–30
Size of neonates	0.98 mm	0.69 mm
Longevity	50 days	50–145 days
Maximum size at first reproduction	2.10 mm	1.00 mm
Maximum size	5.90 mm	3.50 mm

[a] Compiled from data in Schwartz (1984) after many sources.

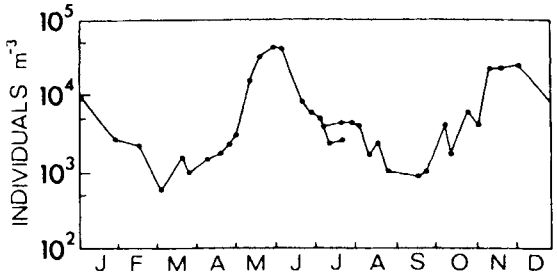

FIGURE 16-24 Population density of *Daphnia galeata mendotae* in Base Line Lake, Michigan, 1960–1961. (Redrawn from Hall, 1964.)

Michigan (Hall, 1964), consisting mainly of *Daphnia*. Two maxima occurred in the population of *Daphnia galeata mendotae*, one in the spring and a second in late autumn (Fig. 16-24). Although a few ephippia were produced, this species, in contrast to *D. pulex* in the same lake, overwintered in the free-swimming stage with little or no reproduction. The initial spring maximum in May–June and that in the fall were preceded by a maximum in brood size (ratio of eggs to mature *Daphnia*) (Fig. 16-25). Degenerate eggs were observed frequently in the brood pouches of *Daphnia* and had no apparent relationship to normal brood size.

Employing the instantaneous rate of increase of the population discussed earlier, the population dynamics of *D. galeata mendotae* were evaluated in Base Line Lake. The instantaneous birth rate (b) was estimated from the finite birth rate of newborn occurring over a time interval in relation to the existing population size. The development time of eggs was determined experimentally in relation to temperature. The instantaneous

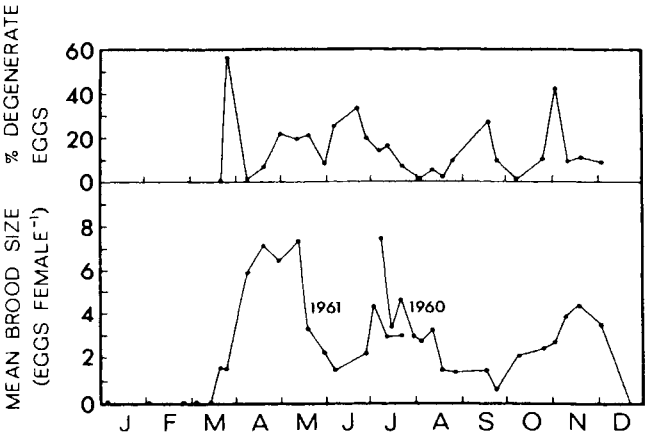

FIGURE 16-25 *Upper*: Percentage of degenerate eggs in the population, *lower*: mean brood size (mean number of eggs per adult) of *Daphnia galeata mendotae*, Base Line Lake, Michigan, 1960–1961. (Redrawn from Hall, 1964.)

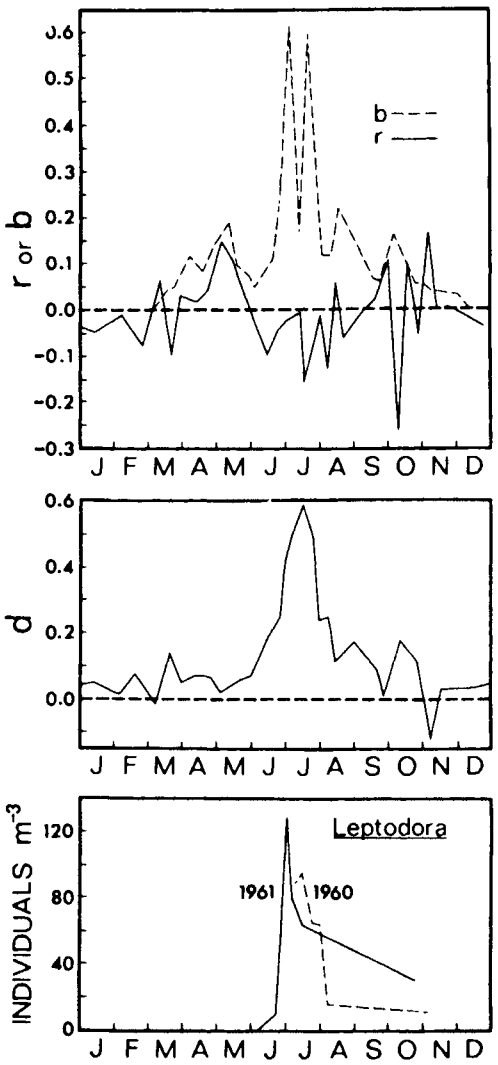

FIGURE 16-26 *Upper*: Instantaneous birth rate (natality), b, and rate of population change (increase or decrease), r, of *Daphnia galeata mendotae*; *middle*: instantaneous death rate, d (b minus r), of *Daphnia galeata mendotae*; *lower*: population density of the predatory *Leptodora*, Base Line Lake, Michigan, 1960–1961. (Redrawn from Hall, 1964.)

rate of population increase, r (see Eq. 16-2), and birth rate were both positive and nearly equal during the spring and fall months (Fig. 16-26). Maximum values of b occurred in the summer months, but r was negative during this period of population decrease because of the increased death rate, d. During the winter, b was zero as reproduction ceased and r was negative as a slow death rate, d, gradually reduced the population until March.

The summer minimum, with a loss rate of 28% per day, apparently was associated with predation on the juvenile stages of *Daphnia galeata* by the large

cladoceran *Leptodora*, which reached its maximum in summer (Fig. 16-26). *D. retrocurva* reached its maximum density, greatly exceeding *D. galeata*, in late summer, well after water temperatures exceeded 20°C. Its successful competition for available food in fall was most likely contributory to the reduced birth rate of *D. galeata* at that time. Analyses of fish consumption showed that fish fed extensively on the large *D. pulex* in spring but not significantly on the smaller *D. galeata*. *Daphnia catawba*, which like *D. retrocurva* exhibits one late summer maximum and overwinters with resting eggs, is also known to coexist with *D. galeata* in late summer (Tappa, 1965). The presence of *D. catawba* and its competition for the same food base appeared to be instrumental in delaying the autumnal maximum of *D. galeata*.

In a detailed study of the zooplanktonic populations of shallow ($\bar{z}$ = approx. 1 m), extremely productive Sanctuary Lake in northwestern Pennsylvania, three species of *Daphnia* occurred and exhibited a large spring maximum and a small autumn peak (Cummins et al., 1969), similar to that discussed in the Base Line Lake example. *D. galeata mendotae* dominated these populations and *D. retrocurva* became a codominant in late summer. With the decline of the spring maximum, a massive development of the predacious cladoceran *Leptodora kindtii* occurred and reached a biomass maxima in June in 1 yr and in June, July, and August the following year. Only the large *Leptodora* of from 6 to 12 mm are predaceous and ingest the fluids of their prey. The population dynamics of *Leptodora* were correlated with loss rates of prey; *Leptodora* apparently shifted seasonally to preying on *Daphnia, Ceriodaphnia, Bosmina,* and *Chydorus* and the copepods *Cyclops* and *Diaptomus*. Similar predatory regulation of both small and large cladocerans and copepods nauplii and adults by predation of *Leptodora* has been observed in very different lake environments (e.g., Lunte and Luecke, 1990; Branstrator and Lehman, 1991; Hellsten and Stensen, 1995). Seasonal polymorphism with increased spine length in *Bosmina* often coincides with the heightened predation by *Leptodora* as presumably a defensive mechanism for reduction of predatory success (see discussion on cyclomorphosis, p. 456).

A few cladocerans are distinctly coldwater species and inhabit shallow lakes of northern regions. These species develop large populations only in the early spring and in cooler meta- and hypolimnetic strata in more temperate lakes. These species generally are perennial and tend to tolerate lower oxygen concentrations than the more common warmwater species.

Among cladoceran zooplanktonic populations in general, low populations in winter among perennial species and a near absence in winter among aestival species are common. With increasing food supply from algae, detritus, and bacteria with rising temperatures in spring, cladoceran populations increase from overwintering adults or resting eggs. Temperature increases the rate of molting and brood production, while rising food supply results in increases in the number of eggs per brood. The herbivorous populations can increase exponentially to the point where the community filtration rates crop the phytoplankton at rates that exceed the reproductive rates of the phytoplankton community. As a result of this intensive grazing, phytoplankton biomass can decrease to low levels, with a marked increase in the optical transparency of the water. The "clearwater phase" can persist until less edible algal species populations develop. The herbivorous zooplankton species become food-limited, which results in a precipitous decline in their body weight per unit length and fecundity, both of which quickly translate into declining population densities and biomasses in the summer. Predation by other zooplankton and fish accelerates this decline to very low summer levels.

A shift toward smaller average body size among the surviving crustacean zooplankton is often seen in the summer period of high predation. The larger species of crustacean herbivores are replaced by smaller species and by rotifers. These small species are less vulnerable to fish predation (discussed at length on p. 462ff) and are less affected by interference with their food-collecting apparatus, which can be caused by some forms of inedible algae (Sommer *et al.*, 1986; Christoffersen *et al.*, 1993; Telesh, 1993). As a result, the population mortality of the smaller zooplankton is lower and their fecundity is higher than that of the larger zooplankton species. High predation of both cladocerans and copepods can result also from the mysid malacostracean crustaceans (see Chap. 22). Although differences in life history sequences preclude severe competitive exclusion of cladocerans and copepods under usual natural conditions, when they are introduced to lakes, as has commonly been done for fish management purposes, exploitation of the zooplankton can lead to nearly total suppression of cladocerans and many copepods (e.g., Murtaugh, 1983; Langeland, 1988). Rotifers often proliferate following this release from cladoceran and copepod predation pressures.

Many factors can influence the onset of sexual reproduction in cladocerans (day length, low temperature, flow food availability, and chemical induction from crowding), and distinct species differences are known in response to these factors or a combination of them. In addition, chemical compounds, termed *kairomones*, released by fish induced production of diapausing ephippial eggs in parthenogenetic females of *Daphnia magna* and reduced brood size (Slusarczyk,

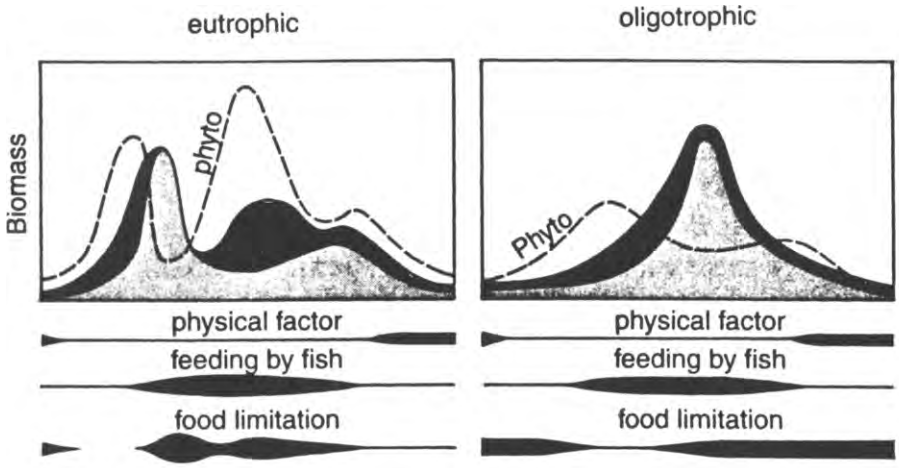

FIGURE 16-27 General model of seasonal succession of zooplankton in typical thermally stratified eutrophic (*left*) and oligotrophic (*right*) lakes of the temperate region. Phytoplankton: dashed line. Zooplankton: small species, dark shading; large species, lighter shading. Black lower bars indicate relative intensity seasonally of factors noted. (Modified from Sommer *et al.*, 1986.)

1995; Pijanowska and Stolpe, 1996). Under heavy predation by fish and low survival probability of parthenogenetic females, ephippia formation in summer can be adaptive by achieving higher fitness by survival than potential immediate reproductive gain via parthenogenesis. Fish kairomones can also alter swimming and population aggregation behavior (Jensen *et al.*, 1998) that may alter vulnerability to predation.

Food availability also influences the size structure of zooplankton communities by age-specific differential mortality. Under conditions of starvation, respiration increases and body weight decreases before death (Threlkeld, 1976). Survival time (t) is greater in larger zooplankton and is a function of body weight (w, in μg dry weight): $t = 2.95w^{0.25}$. Older individuals, however, survive for shorter periods of time than younger zooplankton under nonstarvation conditions. Juveniles tend to be more vulnerable to food limitations than adults (Neill, 1975). The impact of periods of size-related starvation on community size structure may be augmented or reversed by the timing of the onset of food limitation on its members (Threlkeld, 1976) and by the extent to which starvation influences prey utilization by the zooplankton (Williamson, 1980).

Loss of thermal stratification in lakes in autumn and increased nutrient regeneration from deeper strata usually coincides with reduction of light. Large unicellular or filamentous algae, and particularly diatoms, are common in the autumn. Fish predation is generally reduced under declining light conditions and colder temperatures. Zooplankton populations, particularly of certain larger forms, can increase for a brief period. Herbivore biomass rapidly declines because of reduced fecundity from both declining temperatures and food availability. Many cladoceran zooplankton enter diapause stages at this time. These relationships have been set forth in a model, primarily for large cladoceran zooplankton in stratified lakes of the temperate region (Fig. 16-27). Among eutrophic lakes, a spring maximum of small phytoplankton algae is followed by a dominant persisting summer maximum of large, grazing-resistant algae and cyanobacteria. These common phytoplankton maxima of eutrophic lakes are often separated by the "clearwater phase," a very short-lived period when large zooplankton graze phytoplankton rapidly to conditions of acute food limitation and are rapidly replaced by smaller zooplankton species. The phytoplankton "clearwater phase" may persist somewhat longer into the summer, depending on the effectiveness of the grazing of the smaller zooplankton species and nutrient loading, particularly of phosphorus. The collective primary productivity of phytoplankton, however, particularly with smaller species of higher reproductive rates and less biogenic "turbidity" generally is very high during the summer period (cf. Chap. 15). In oligotrophic lakes, the phytoplankton–zooplankton successional process is similar, although highly muted and slower (Fig. 16-27).

X. COPEPOD POPULATION DYNAMICS

A number of cyclopoid copepods are known to enter various periods of diapause, either at the egg stage or in the copepodite stages with or without encystment,

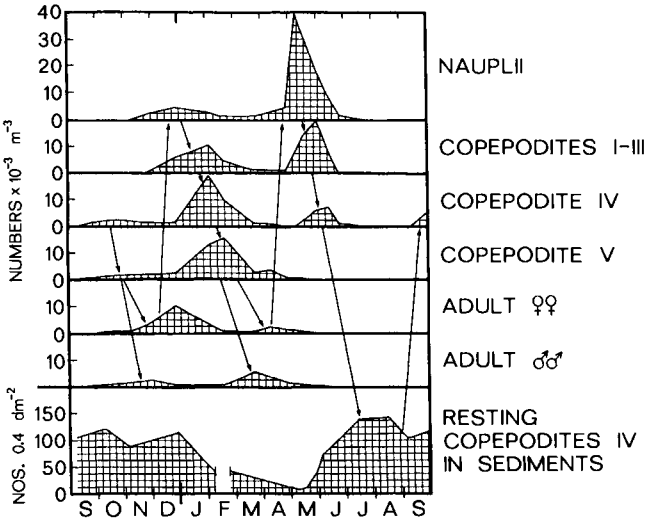

FIGURE 16-28 Development and resting stages of *Cyclops strenuus* in Bergstjern, Norway. Midsummer diapause is indicated by aestivation of copepodites IV in the sediments. (Drawn from data of Elgmork, 1959.)

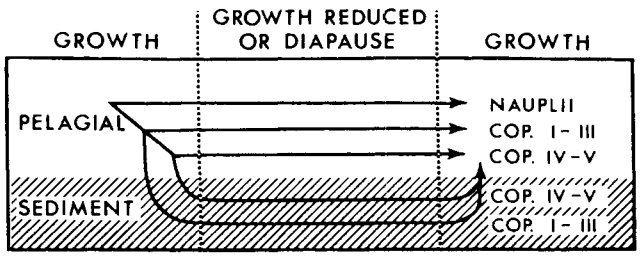

FIGURE 16-29 Generalized life-cycle patterns of limnetic cyclopoid copepods. COP = copepodid instar stages as indicated. (Adapted from Nilssen, 1978.)

upon the sediments (see, e.g., Wierzbicka, 1966; Maier, 1994). Consequently, for reasons discussed later, the annual cycle of the copepod populations may be interrupted by a diapause that persists from one to several months. For example, the resting stage may occur in midwinter, as in *Cyclops bicolor*, or in summer, as is seen in *Cyclops strenuus strenuus* (Fig. 16-28). Nauplii develop from egg-bearing females in this species in a bimodal population during winter and spring. Then, in summer, the larger population of copepodite stage IV aestivates in the sediments for about two months in midsummer before becoming pelagic again in the autumn and developing into adults. In contrast, *Cyclops strenuus abyssorum* exhibits only one effective generation in each year in several lakes in the English Lake District (Smyly, 1973). In the deepest of the four lakes studied in great detail, individuals of this generation hatched from eggs laid in the spring and reached the adult stage in early winter. The adults passed the winter in the plankton and started laying eggs early in the following year. In the three other lakes, most individuals of the spring generation reached the fifth copepodite stage by midsummer and spent the next eight months aestivating in the profundal zone. The copepods left this zone in February or March to return to the pelagic zone, where they became adults and started breeding. Water temperature, oxygen concentrations, light intensity, and day length were believed to be associated with the initiation and termination of this diapause (Smyly, 1973). Co-occurring species of cyclopoid copepods are known to have their maxima and diapause periods at different times. This alternation presumably minimizes competitive interactions for the same food resources.

Although the general pattern of diapause is similar among the cyclopoid copepods, marked variations in the timing of instar stages and their distribution in the water and the sediments have been observed (e.g., Elgmork, 1959; Smyly, 1973; George, 1976; Nilssen and Elgmork, 1977; Vijverberg, 1977; Boers and Carter, 1978; Elgmork *et al.*, 1978; Elgmork and Langeland, 1980; Hansen and Jeppesen, 1992). The basic life-cycle pattern in limnetic cyclopoid copepods can be divided into two parts (Nilssen, 1978; Elgmork and Nilssen, 1978): (a) a period of growth, followed by (b) a period of retarded growth or diapause, the latter resulting from adverse environmental conditions (Fig. 16-29). The intensity of the lines and pathways shown in Figure 16-30 differ in different lake ecosystems. Examples include:

1. In arctic and alpine lakes, diapause as copepodites in the sediments is less common. Adult stages frequently predominate in pelagic waters just above the sediments, perhaps to avoid fish predation. The adults feed heavily on rotifers and their own nauplii during winter.
2. Large differences in life cycles of limnetic cyclopoid copepods occur in temperate environments. In the temperate region, a period of diapause as copepodites IV and V is the rule. In less predictable environments (eutrophic lakes and temporary ponds), many cyclopoid copepods persist during periods of reduced growth in naupliar or advanced copepodid stages in the winter; a relatively small proportion of the population enters copepodid IV–V diapause in the sediments. In more predictable and less productive lakes, during colder periods of reduced or arrested growth the tendency is for most of the population to diapause in naupliar stages or resting stages in the sediments. This response is

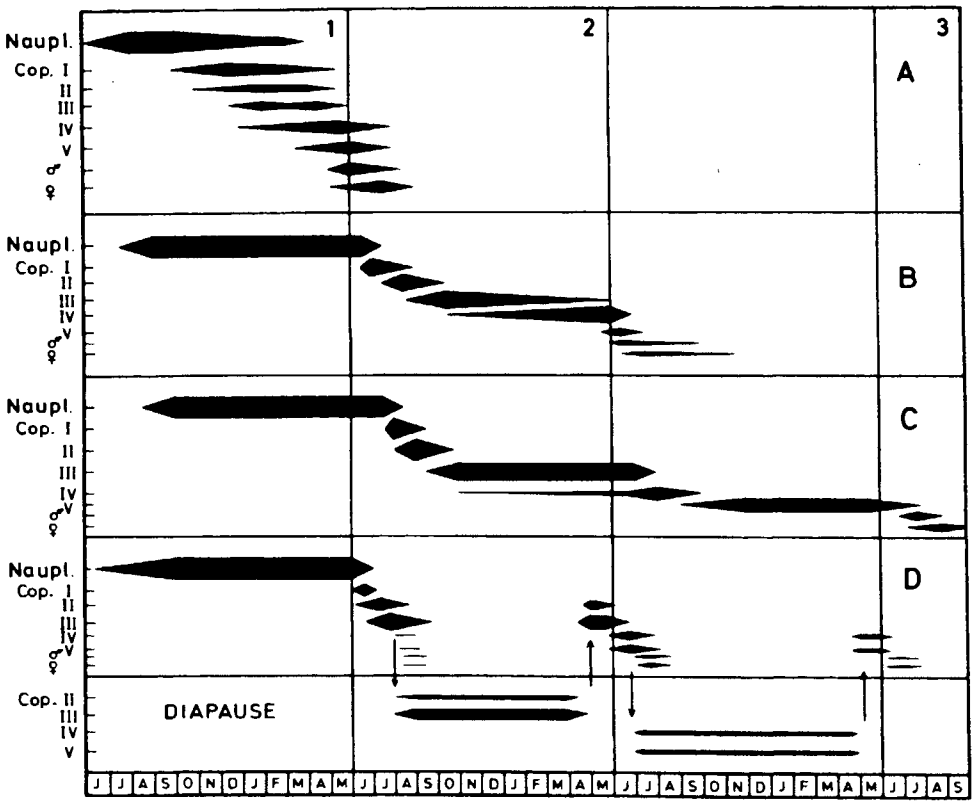

FIGURE 16-30 Variations in the life cycles in the planktonic *Cyclops scutifer*. (A) 1-yr cycle without diapause from a small humic lake; (B) 2-yr cycle without diapause in an oligotrophic lake; (C) 3-yr cycle without diapause in a subpolar lake of Norway; and (D) combined 1-2-3-yr cycle with two periods of diapause in an oligotrophic lake. (From Elgmork, 1985.)

believed to result largely as an adaptation to avoid predation by fish and predatory copepods during periods of slow growth when the population is most vulnerable (Strickler and Twomby, 1975; Nilssen, 1978; Hairston and Munns, 1984).

3. In tropical lakes showing no great seasonal changes in environmental parameters, resting stages have not been observed.

However, adaptability is large and the same species can vary greatly in its life history among different environments. For example, the reproductive period of the planktonic copepod *Cyclops scutifer* can be delayed by retarded development, particularly among the nauplii (Elgmork, 1985). Differences in life cycles ranged from 1 yr to many years (Fig. 16-30). Primary causal factors are focused on differences in temperature and the prolongation was inversely related to food availability. Conversely, when temperatures are high, predation pressures low, and food availability is very high as in shallow hypereutrophic lakes, naupliar stages can be very short and the cyclopoid copepods have several (3–6) generations per year (Hansen and Jeppesen, 1992). This deviation from the normal life cycle has been observed in other eutrophic lakes and can be interpreted as a strategy to optimize the reproductive output (Maier, 1996).

A. Dormancy among Copepoda

Copepod dormancy occurs in various ontogenetic stages as resting eggs, arrested larval development, juvenile and adult encystment, or arrested development of free-swimming nonencysted copepodids or adults (Dahms, 1995). Much study has been devoted to the study of copepod dormancy as resting eggs. Diapause eggs commonly have a thick chorion that serves as protection against digestion by predators (Hairston and Olds, 1984; Marcus and Schmidt-Gegenbach, 1986), desiccation, and bacterial degrada-

tion. Species with prolonged diapause tend to be small and tend to be found in inland waters (Hairston and Cáceres, 1996). Although diapause is widespread among the crustaceans, it is particularly prevalent among the copepods.

Diapausing eggs can remain viable in aquatic sediments for decades or longer and have a mortality of ca. 1% per year (Hairston and Olds, 1984; Hairston *et al.*, 1995; Hairston, 1996). Diapausing eggs can serve as a major genetic reservoir for repopulating copepod communities following severe environmental disturbances. Under these conditions, years of good reproductive success can be stored in diapausing eggs in the sediments and allow species to persist during years when reproductive success is poor. The interactions between environmental variations and generation overlap produced by prolonged diapause results in the maintenance of species diversity and genetic variation.

Nonencysted dormant copepodids do not feed and they survive on stored lipids while drifting with the plankton during periods of poor environmental conditions (Fryer and Smyly, 1954; Elgmork, 1980). Encysted copepodids are also common, particularly among the Cyclopoida and Harpacticoida. Dispersal of all of these forms likely occurs only occasionally during major circulation events and is not a viable adaptive strategy (Hairston and Munns, 1984).

Dormancy functions as an energy-saving mechanism that allows individuals to survive transitional periods of harsh, unfavorable environmental conditions (Hairston, 1987; De Stasio, 1989; Hairston *et al.*, 1990; Dahms, 1993; Fryer, 1996). Adverse conditions that have been shown to induce or alter diapause include

a. Reduced temperatures. Production of diapausing eggs has been found to begin earlier in small lakes that cool more rapidly than in large lakes (Hairston and van Brunt, 1994). Rates of emergence from diapause are strongly temperature-dependent (Maier, 1990d).
b. Reduced dissolved oxygen.
c. Photoperiod, particularly long-day lengths.
d. Desiccation, particularly in sediments of reservoirs experiencing fluctuating water levels or of temporary ponds, particularly during the summer periods (e.g., Taylor *et al.*, 1990).
e. Reductions in food availability. There is some evidence supporting the putative adaptive strategy that fourth-instar copepodites entering the sediment during summer would relieve grazing pressures on available food for herbivorous juvenile naupliar stages caused by the grazing of competing cladocerans (Santer and Lampert, 1995). High concentrations of flagellates are required of naupliar development among some cyclopoids. Among lakes that are more productive and have higher food availability, some copepod species do not enter summer diapause.
f. Increased carnivorous predation by invertebrates or fish. Summer diapause in freshwater copepods is often regarded as an adaptation to avoid fish predation.

B. Copepod Community Dynamics

The life cycles of the calanoid copepods are generally somewhat longer than those of the cyclopoids. In the temperate region, most species exhibit prolonged reproductive periods with several generations per year that are indistinguishable from one another. An example of these seasonal dynamics is seen in the populations of *Diaptomus* in a small, shallow beaver pond of southern Ontario (Fig. 16-31). The *Diaptomus* hatched from resting eggs in early May and produced four complete generations, the last maturing in late autumn (Carter, 1974). During spring and summer, generation times were about 4 weeks, while the time was about 6 weeks in autumn generations. Population characteristics were similar over a 3-yr period. In one year, water levels were low, which resulted in increased mean heat content per unit volume; during this year, development time of the generation was reduced and population production increased significantly. Similar annual sequences of the generations were found among the population dynamics of a species, *Eudiaptomus*, in a shallow lake of southern Germany (Maier, 1990b).

A number of studies have demonstrated that most adult cyclopoid copepods are carnivorous and that their predatory activities can play a significant role in the population dynamics of other copepod species. For example, *Mesocyclops* was found to be selectively predacious on copepodites of *Diaptomus* rather than on cladocerans (Confer, 1971). Similarly, adult *Cyclops* preys heavily on nauplii of *Diaptomus* and its own species (McQueen, 1969; Bosch and Santer, 1993). Some 30% of the naupliar recruitment has been observed to be lost by copepod predation and by cannibalism. Juvenile mortality often is very high and is density dependent and can increase conspicuously at high population levels (Elster, 1954).

The coexistence of several congeneric species of copepods in the same volume of water has been a subject of much interest. It is assumed that when coexistence does occur, the species have slightly differ-

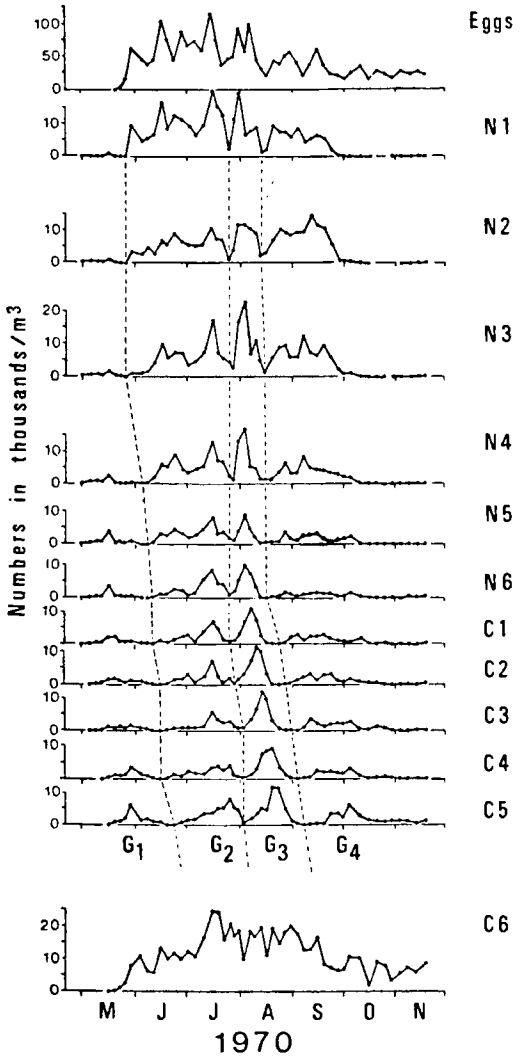

FIGURE 16-31 Seasonal cycles of *Diaptomus reighardi* in Black Pond, Ontario. Broken lines separate the estimated limits of successive generations, G. (From Carter, J. C. H.: Life cycles of three limnetic copepods in a beaver pond. *J. Fish. Res. Bd. Canada 31*: 421–434, 1974. Reprinted by permission of the Journal of the Fisheries Research Board of Canada.)

ing tolerances and optima to existing environmental conditions. Mechanisms promoting coexistence include (a) seasonal separation, discussed earlier; (b) vertical separation in relation to stratification and the distribution of food resources; and (c) size differences in relation to available food particles utilized. All of these mechanisms were implicated as factors permitting the coexistence of three species of *Diaptomus* in an Ontario lake (Sandercock, 1967; see also Hammer and Sawchyn, 1968). *D. minutus* was separated vertically from *D. sanguineus*, and the latter is distinctly smaller than the former species. *D. minutus* and *D. oregonensis* also were separated to some degree by size differences and exhibited different seasonal maxima. *D. sanguineus* and *D. oregonensis* were separated vertically and had different seasonal maxima. Therefore, in this lake, differences in two of the three factors provided the mutual separation among these three congeneric species that is believed necessary to coexistence.

Two common species of predatory cyclopoid copepods, *Acanthocyclops* and *Mesocyclops*, of similar size were found to coexist in similar water strata and have similar seasonal population sequences (Maier, 1990c). Small but significant differences in embryonic and juvenile development rates, feeding rates, and selective predation by fish allowed coexistence. Considerable evidence, reviewed by Hart (1990), exists that stresses the importance of variations in embryonic and juvenile development among copepods. In the generally high predation environment of fresh waters, acceleration of naupliar development potentially reduces the vulnerability of these smaller stages to size-selective tactile predation, while larger copepodid instars are able to reduce the opposing size-selective predation by visual planktivores by virtue of their ability to move quickly and escape fish ingestion.

XI. PARASITISM AND ZOOPLANKTON POPULATION DYNAMICS

The incidence of parasitism among zooplankton is poorly documented, but evidence suggests that population dynamics, species diversity, and productivity can be markedly affected by even moderate parasitic infection. For example, fungal parasitism can induce a high percentage of mortality of copepod eggs and female adults (Redfield and Vincent, 1979; Hoenicke, 1984; Burns, 1985). Subsequent depressions of birth rates can alter population dynamics and function as a predator to increase zooplankton species diversity. A digenetic trematode can infect cladoceran zooplankton and reduce egg production and survival (Schwartz and Cameron, 1993).

XII. ZOOPLANKTON DISTRIBUTION IN RESERVOIRS AND IN FLOODPLAIN LAKES

In contrast to the general distribution in temperate lakes, cladoceran and copepod abundance in reservoirs is markedly influenced by hydrodynamics. The commonly observed distribution of macrozooplankton is (a) low abundance in the riverine portions, (b) maximal abundance and biomass in the transitional zone (cf.

Fig. 15-12), and (c) reduced but somewhat more stable distribution in the lacustrine zone where water residence times are somewhat longer than in the other zones (e.g., Siegfried and Kopache, 1984; Marzolf, 1990). In the transitional zone, deposition of particulate materials and the concentrations of imported silts and clays increases as the load-carrying capacities decrease among reduced currents.

Filter-feeding zooplankton respond to changing quantity and quality of food resources in the shift from imported detrital particles to improved quality of algal and bacterial particles. For example, recruitment, longevity, and fecundity of some species of cladocerans can be reduced during flooding events when abundant silt particles overwhelm algal particles in the water column (Threlkeld, 1986; Kirk, 1992). Other cladocerans are able to grow well in silt-laden water. Although dissolved organic compounds adsorbed onto clay particles can serve as food supplements to particulate microbiota when ingested by cladoceran zooplankton, these sources are likely poor food substitutes for effective long-term reproductive success (Arruda *et al.*, 1983).

Clay and silt turbidity, so common in reservoirs, commonly suppresses zooplankton growth and productivity by direct interference mechanisms and by suppressing food availability from primary productivity as a result of greatly reduced light by shading. Nutrient enrichment to enhance phytoplankton development is usually insufficient to overcome the negative effects of turbidity on higher zooplankton development and productivity. Examples are many. Suspended clay particles suppressed the growth and reproductive rates of some algivorous and bacterivorous ciliates but had minimal effects on others (Hart, 1986; Jack and Gilbert, 1993b). In cladocera, mechanical interference of suspended clay reduces the feeding rate by as much as 70% and severely restricts growth and reproduction (Kirk, 1992). Zooplankton feeding on clay particles may assist in sedimentation and improve water clarity (Gliwicz, 1986c), although the positive correlation observed may simply result from improved algal growth. In contrast, rotifers are more selective in feeding on algae than inorganic particles and are not affected by high concentrations of suspended clay particles, and in turbid reservoirs rotifers are favored over cladocerans (Kirk and Gilbert, 1990; Kirk, 1991; Cuker and Hudson, 1992).

Similarly to irregular and large variations found in reservoirs, physical and biological cycles within floodplain lakes fluctuate widely, particularly in response to the annual rise and fall of the adjacent main river. The productivity of floodplain lakes tends to be very high, particularly in tropical regions, during low water periods. Planktonic crustaceans are commonly abundant during those periods but commonly experience severe declines during high water periods of inundation by the main river when inorganic suspended particles are high and phytoplankton production low (e.g., Twombly and Lewis, 1989; Lansactôha *et al.*, 1993; Junk and Robertson, 1997). Rapid increases in population sizes can result both from high birth rates associated with decreasing turbidity for some period following inundation and from the hatching of resting eggs. Although natality and productivity can be very high for extended periods, high mortality from intense predation by fish and by dipteran *Chaoborus* larvae can be more important in controlling cladoceran abundance than resource limitation in these ephemeral lakes (Twombly and Lewis, 1989).

XIII. ZOOPLANKTON DISTRIBUTION IN TROPICAL FRESH WATERS

Zooplankton of tropical fresh waters do not exhibit greater biodiversity than in more temperate waters. It is believed that tropical zooplankton are mostly opportunists recruited from river backwaters and temporary habitats (Fernando, 1994). Even in ancient lakes, such as Lake Tanganyika, the low biodiversity has likely been regulated by effective year-round continuous fish predation, particularly by young herbivorous Cichlidae (tilapias). Smaller zooplankton, particularly rotifers and protists, predominate (Green, 1993, 1994; Fernando, 1994). Within these large groups, species associations of the tropics are governed largely by temperature and salinity gradients. Large Cladocera are often virtually absent. In tropical lakes and flood plains, the littoral macrophytes offer a partial refuge for many zooplankton. The salinity of the water is restrictive to zooplankton biodiversity. Species richness generally decreases with increasing salinity, particularly above 7 g liter^{-1}, both in tropical and temperate saline waters (Green, 1993; Hammer, 1993; Evans *et al.*, 1996). Those few adapted species, however, can be very effective herbivores in these environments of reduced interspecific competition.

Detailed analyses of zooplankton population dynamics and productivity in Lake Lanao of the Philippines indicate that invertebrate predation by *Chaoborus* is of major importance in the regulation of cladoceran and copepod productivity (Lewis, 1979). At no time do the macrozooplankton approach resource limitations. Similar relationships emerged from analyses of the zooplankton community dynamics and their control mechanisms in a large, warm, monomictic,

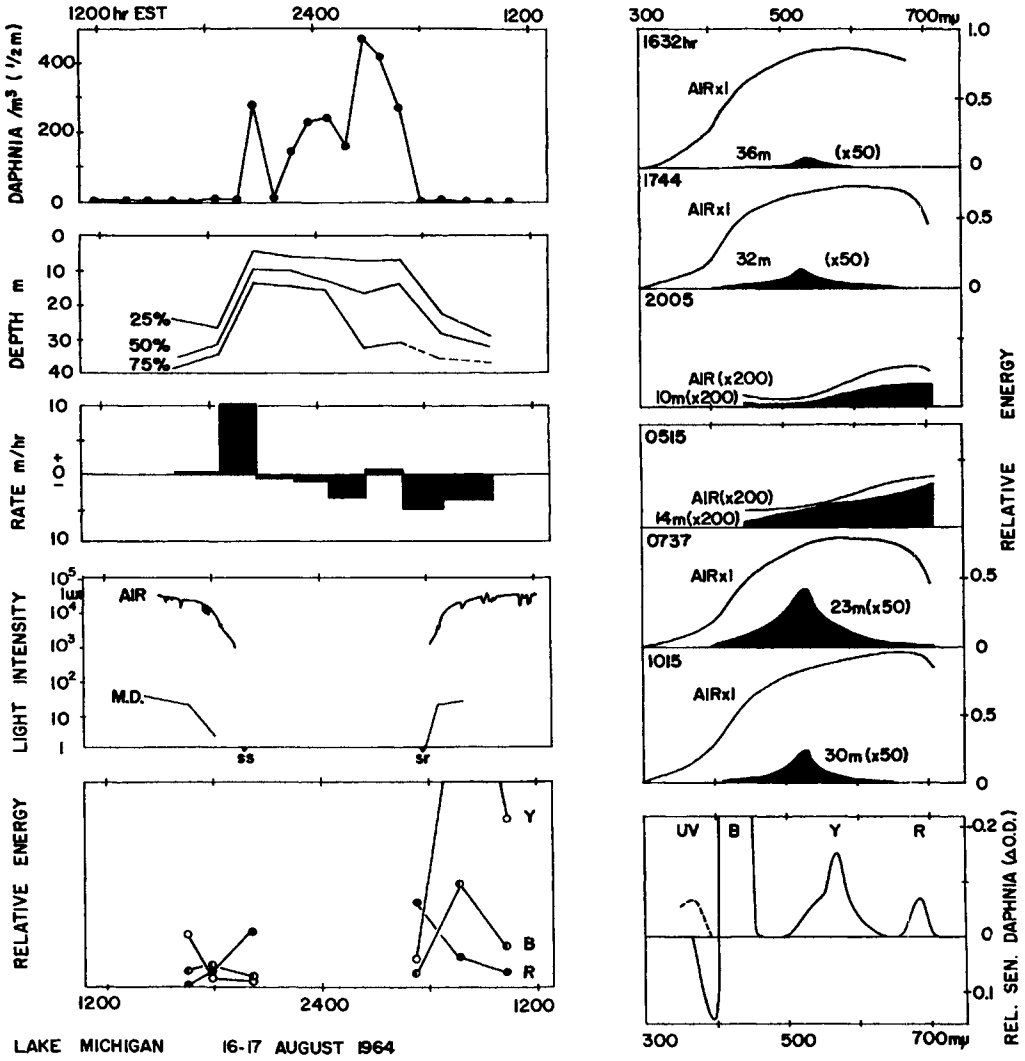
eutrophic lake of Venezuela (Saunders and Lewis, 1988). Although algal food quality only occasionally suppressed herbivorous zooplankton, carnivorous predation, particularly by the dipteran *Chaoborus* larvae, was a major regulator of mortality. Herbivores coexisted with their predators by several mechanisms: (a) some rotifer species could match predation losses by reproductive increases; (b) copepods under intense predation as adults were able to sustain high losses in the adult stages by recruitment from earlier, less vulnerable developmental stages; and (c) some rotifers and the cladocerans increased in population size only during periods when predator abundance was minimal during the mixing season when the lake was circulating completely.

XIV. ZOOPLANKTON DISTRIBUTION IN FLOWING WATERS

The zooplankton community structure within rivers is generally similar to that of lakes but is commonly dominated by small forms, such as protists, rotifers, bosminids, and juvenile copepods, throughout the year (e.g., Pace *et al.*, 1992; Pourriot *et al.*, 1997; Kobayashi *et al.*, 1998a,b). Zooplankton biomass tends to be negatively correlated with water velocities and positively correlated with temperature and phytoplankton chlorophyll *a* biomass. No evidence was found for significant grazing effects of zooplankton on phytoplankton biomass (Basu and Pick, 1997, 1998). Many microcrustaceans are associated with substrata in benthic and littoral backwater habitats as a means of alleviating downstream movement (Quirós and Cuch, 1990; Richardson, 1991, 1992; Robertson *et al.*, 1995). It is obviously advantageous to remain in a habitat of relatively high food abundance for sufficient time to complete the life cycles. Most dominant planktonic species have relatively rapid life cycles or are predominantly benthic. Microcrustacea and rotifers tend to be moved from prevailing habitats of backwater areas and lower areas of pools during periods of flow exceeding 2.5 cm s^{-1} and exported downstream. Some mortality occurs by net entrapment by polyphagous benthic invertebrate predators, such as certain caddisflies (e.g., Lancaster and Robertson, 1995). It is unclear what proportion of the total zooplankton production is removed by such processes in comparison to many others.

As river ecosystems are regulated with impoundments, zooplankton densities, biomass, and biodiversity usually increase in comparison to unregulated river systems (e.g., Pinel-Alluol *et al.*, 1982). Protists generally increase as a proportion of total zooplankton in higher river orders.

XV. VERTICAL MIGRATION AND SPATIAL DISTRIBUTION



A. Cladocera and Copepods

One of the most conspicuous features of the cladoceran zooplankton, and to a lesser extent the copepods, is the marked vertical migration of these small animals over large distances on a daily basis.[8] There is no question that a light-mediated circadian rhythm underlies at least some cases of vertical migration of microcrustaceans and insect larvae (Dice, 1914; Siebeck, 1960; Ringelberg, 1964; Ringelberg, 1987; Swift and Forward, 1988; Loose, 1993). However, most evidence indicates that changes in light intensity rather than endogenous rhythms trigger diurnal vertical migrations. Movements vary considerably with lake conditions in relation to underwater light characteristics, season, predation pressure, predator presence, and the age and sex of a species. However, certain generalizations do emerge.

Most species migrate upward from deeper waters to more surficial strata as darkness approaches and return to deeper strata at dawn. Maximum numbers are found in the surface layers in nocturnal migration in a single maximum some time between sunset and sunrise. In other cases, twilight migration results in two maxima in surface layers, one at dawn and another at dusk. In a few species, reverse migration occurs with a single surface maximum during the daylight period.

This common pattern of vertical migration may be seen in an example from relatively transparent Lake Michigan (Fig. 16-32). At dusk, the *Daphnia* population migrated from 24 m through the thermal discontinuity of the metalimnion at a rate of over 10 m h^{-1}. Some sinking occurred after the initial ascent, a characteristic common to the twilight type of migration that could be associated with reduced nighttime activity and passive sinking. For example, narcotized *Daphnia galeata mendotae* sink passively between 3.6 and 14.4 m h^{-1}, at a rate inversely related to body length (Brooks and Hutchinson, 1950). The *in situ* populations generally do not sink that rapidly during the night period (usually <0.5 m h^{-1}), which indicates that they are sufficiently active for sinking to only slightly exceed

[8] *Diurnal* refers to an event that occurs in a day (24-h period) or recurs each day. *Diel* (daily) is a more recent term (not yet in most dictionaries) that refers to events that recur at intervals of 24 h or less, with no connotation of either daytime or nighttime (Odum, 1971). In studies of community periodicity, when whole groups of organisms exhibit synchronous activity patterns in the day–night cycle, *diurnal* is often used in a more restricted sense, referring to animals that are active only during the daytime (lighted period) as opposed to others that are active only during the period of darkness (*nocturnal*) and still others only during twilight periods (*crepuscular*).

Daphnia retrocurva

FIGURE 16-32 The vertical distribution and rate of movement of *Daphnia retrocurva* in relation to light quality at depth. *Left, top to bottom*: Number of *Daphnia* m^{-3} at 0.5-m depth; quartile distribution; rate of movement (m h^{-1}); light intensity (lux) in air and at mean population depth (M.D.); and relative energy received by blue (*B*), yellow (*Y*), and red (*R*) photosystems of *Daphnia*. *Right, top to bottom*: Relative energy versus wavelength in air and at mean population depths at different times of the diurnal period; spectral sensitivity of *Daphnia*, expressed as change in optical density (O.D.) of visual pigments extracted with aqueous digitonin upon bleaching, *sr* = sunrise; *ss* = sunset. (From McNaught, D. C., and Hasler, A. D.: Photoenvironments of planktonic Crustacea in Lake Michigan. *Verhandlungen Int. Ver. Limnol.* 16:194–203, 1966.)

upward movements. After another surface maximum before sunrise, the daphnids left the upper waters abruptly about sunrise at velocities of about 5 m h^{-1}. Both the evening ascent and morning descent occurred when light intensity at the mean depth of the population was changing rapidly (Fig. 16-32).

Daphnia has trichromatic vision with spectral peaks of sensitivity in the ultraviolet (370 nm), deep blue–violet (435 nm), yellow (570 nm), and possibly in the red (685 nm) (Fig. 16-32). At the midday depth of habitation, the photoenvironment is predominantly blue–green. The photosystem is most sensitive in the blue and may be best adapted for detecting changes in light intensity at low energy levels (McNaught, 1966). All photosystems may function in the detection of changes in wavelength and intensity at higher levels during daytime vision. The responses to light changes are conspicuous, but there is no evidence that the zooplankters are attempting to remain in a constant photoenvironment.

The vertical migrations also occur under much less transparent conditions of more productive lakes. Under these situations, even though the extent of movement is much less and often only a meter or two, the pattern is conspicuously similar (Table 16-16; Fig. 16-33). The

mean morning maximum at the surface occurred 60 min (SD ± 37 min) after sunrise and the mean evening maximum at the surface occurred 19 ± 61 min before sunset. Deviations from the mean pattern increased under less distinct light conditions of moderate to heavy cloud cover. But clearly, the cue is light intensity. The response can be shown experimentally and under abnormal natural light conditions; for example, the response is identical under twilight conditions during a solar eclipse (see, e.g., Bright *et al.*, 1972).

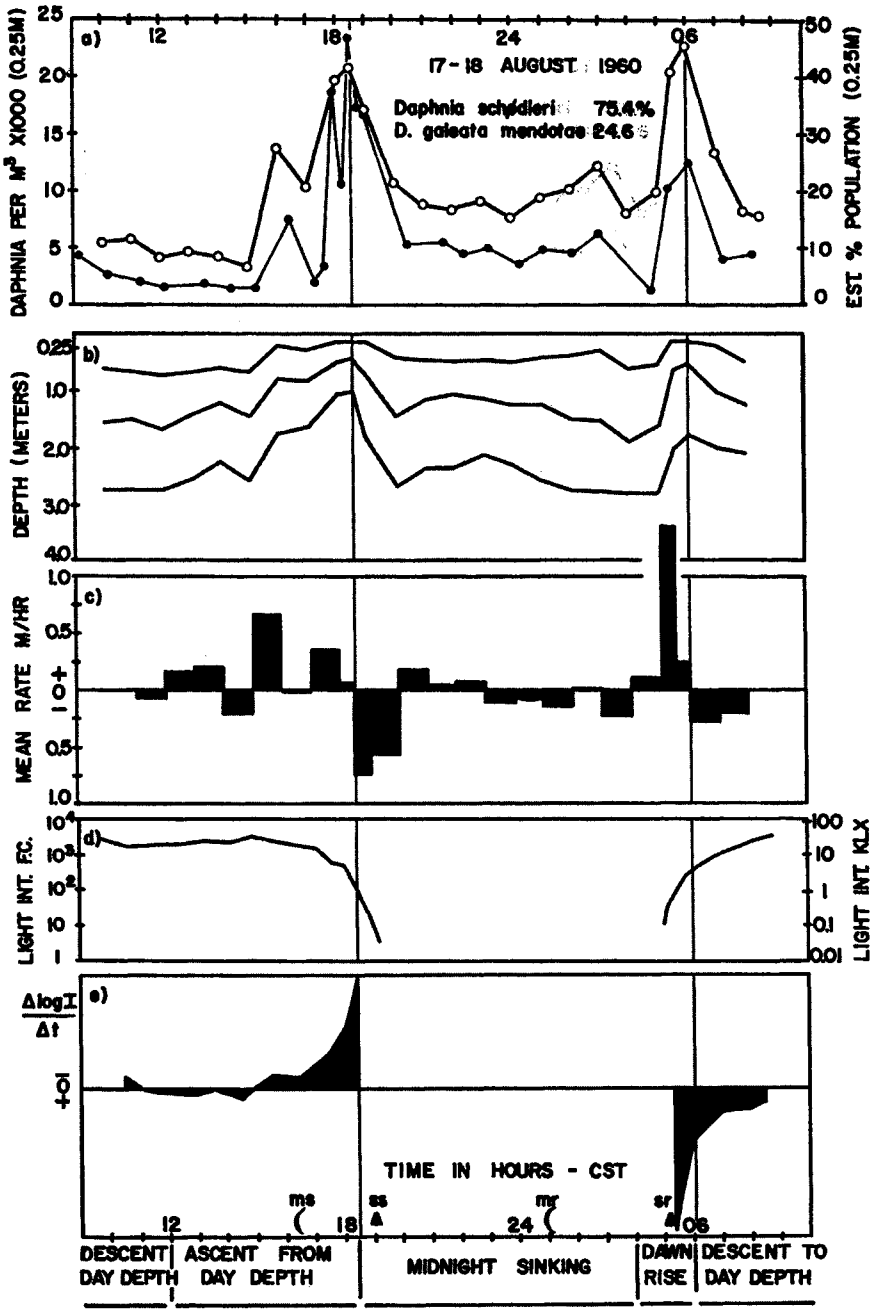

FIGURE 16-33 Diurnal vertical migration of two *Daphnia* populations in Lake Mendota in August in relation to light conditions. (a) Number (●) and estimated population (○) at 0.25-m depth; (b) quartile distribution; (c) net rate of vertical movement (m h^{-1}); (d) light intensity (lux and foot-candles) at 0.25-m depth; and (e) rate of change in the logarithm of the light intensity. *ss* = sunset; *sr* = sunrise; *ms* = moonset; *mr* = moonrise. (From McNaught, D. C., and Hasler, A. D.: Rate of movement of populations of *Daphnia* in relation to changes in light intensity. *J. Fish. Res. Bd., Canada* 21:291–318, 1964. Reprinted by permission of the Journal of the Fisheries Research Board of Canada.)

Variations in vertical migration are great. Generally, young stages have been found to migrate further than adults both in cladocerans and copepods. Differences also occur in the migratory pattern of females and males, especially among copepods. Males tend to be less migratory than females, although the pattern is not consistent. The amplitude and rates of migration vary considerably during the ice-free season. Some of this change may be related to a progressive decrease in oxygen content of lower layers as well as to changing light condi-

tions resulting from seasonal changes in planktonic turbidity. Although temperature influences rates of locomotion, metabolism, and regeneration of photochemical visual pigments, it is minor in affecting vertical migrations in comparison to light. Migrations continue under ice cover and are strongly influenced by light reductions from snow cover. Reverse migration is more common under ice cover, especially among copepods (see, e.g., Cunningham, 1972). Zooplanktonic concentrations are high in surface layers below heavy ice and snow where light levels are low. In lakes of tropical regions, little seasonal variation in diurnal vertical migration has been observed (e.g., Hart and Allanson, 1976).

Evidence for changes in rate of feeding during the diurnal migration of crustacean zooplankton is meager. At certain times of the year in the seasonal succession of zooplanktonic species, the grazing rates are several times greater during the dark period (Haney, 1973; Haney and Hall, 1975; Starkweather, 1975; Crumpton and Wetzel, 1982). At other times, the zooplankton undergo diurnal migration without altering their grazing rates. However, simply because of the massive diurnal movements of major components of the zooplanktonic populations to surface strata at night, a marked increase in grazing pressure on epilimnetic algal, detrital, and protistan populations occurs at night. Certain algae, such as motile unicellular flagellates, can move downward during darkness, and this may represent a survival adaptation to increased nocturnal predation pressure.

Study of the adaptive significance of nocturnal vertical migration has led to a number of hypotheses, all of which probably interact to varying degrees. First, predation by fish and other predators is largely a visual process and requires light. Movement upward into the trophogenic zone in darkness or periods of low light intensities would avoid much of this predation pressure (Zaret and Suffern, 1976; Wright *et al.*, 1980; Zaret, 1980; Lampert, 1989, 1993). Indeed, the evidence for the adaptive significance of this migratory behavior among cladocerans and copepods points largely to a means of reducing mortality from fish predation (Gliwicz, 1986a; Gabriel and Thomas, 1988; Lampert, 1993). Even small amounts of light during the dark period, such as from full moonlight, can increase rates of fish predation and zooplankton mortality (Gliwicz, 1986b). The light of the full moon is of insufficient intensity, however, to suppress zooplankton vertical migration but can alter the amplitude of migration (Dodson, 1990).

Secondary factors influencing vertical migration are food quantity and quality, as well as the physical presence of predators. The food quality of algae is variable diurnally, as is discussed further in the following chapter (see Fig. 17-11). During the day, algae synthesize predominantly carbohydrates; protein synthesis reaches a maximum during the night period (cf. Enright, 1977b). At low food concentrations, increased food acquisition at night would be reproductively advantageous (e.g., Geller, 1986). At high food concentrations such adaptive strategies are less likely (Gabriel and Thomas, 1988a,b; Neill, 1990; Ringelberg *et al.*, 1991). Considerable behavioral flexibility exists under conditions of food availability. Migratory patterns in the presence of predators may be altered substantially by short-term reductions in the availability of food. Conversely, initiation of vertical migration, for example in previously nonmigrating copepods, can be very rapid (<4 h) by *in situ* exposure to an invertebrate predator *Chaoborus*.

Thirdly, although a change in relative light intensity is fundamental to the induction of diurnal vertical migration, in many cases the basic phototactic response is triggered only if a certain threshold concentration of a chemical compound(s), a *kairomone*, released from fish or possibly invertebrate predators, is exceeded (Ringelberg, 1991a,b, 1993; Loose, 1993). This response occurs among microcrustacea and has also been found to induce migration among the phantom midge *Chaoborus* (Dawidowicz *et al.*, 1990; Tjossem, 1990; Kleiven *et al.*, 1996). The chemical composition of the compounds involved is incompletely known but has been characterized as a nonolefinic low-molecular-weight hydroxy-carboxylic acid of intermediate lipophilicity (Parejko and Dodson, 1990; Tollrian and von Elbert, 1994; von Elbert and Loose, 1996). Because no major differences were found in the chemical composition of kairomones from different fish species, and its release and potency is suppressed if the fish were treated with antibiotics, it has been suggested that the source of the kairomones may be from the bacteria associated with fish rather than the fish per se (Ringelberg and van Gool, 1998). Cladocerans such as *Daphnia* have a "memory" for several days once they have been exposed to the kairomones (Hanazato, 1995; Machácek, 1995; Reede, 1995; Ringelberg and van Gool, 1995). Further, life-history traits can be adjusted to different concentrations of kairomones. Age and size at maturity decreased with increasing kairomone levels as a result of reduced growth rate, while the number of eggs increased with smaller offspring.

Fourthly, growth efficiency is somewhat greater at low temperatures, such as are found in the lower strata when summer thermal stratification occurs (McLaren, 1963, 1974). Similarly, feeding rates and efficiency are greater at higher temperatures. According to this differential growth–feeding hypothesis, a significant advantage would be obtained with only one degree of temperature difference between the water strata. Direct experimentation on the growth and reproduction of migrating and nonmigrating *Daphnia* species under simulated food and temperature conditions of diurnal

vertical migration did not support the hypothesis that daphnids gain some metabolic advantage from vertical migration (Orcutt and Porter, 1983; Stich and Lampert, 1984). Since the photoperiod would have little influence on advantages conferred by these mechanisms, the adaptations are most coupled with the fitness advantages of reduced predation and higher food quality that are related to the photoperiod.

The energy expenditure in such migrations of microcrustaceans is uncertain but variable among the various swimming and drag characteristics of migrating zooplankton (cf. Vlymen, 1970; Haury and Weihs, 1976; Enright, 1977a; Lehman 1977; Strickler, 1977; Dawidowicz and Loose, 1992a). Among *Daphnia*, the energy expended in swimming is relatively small. Differences in fitness parameters (fecundity, growth) were small, and growth was only slightly less among long-distance migrating populations in comparison to short-distance migrating populations under low availability of food. However, if diurnal vertical migration between warm epilimnetic and cold hypolimnetic waters is induced by predators, zooplankton growth can be reduced significantly (by ca. 60%) because of the time spent in colder waters in predatory avoidance (Dawidowicz and Loose, 1992b; Loose and Dawidowicz, 1994).

Therefore, vertical migration upward during darkness and downward during the lighted period of the day is common behavior among cladocerans and copepods. Such vertical migration occurs primarily among zooplankton that are most visible to fish, particularly of large size and females that are carrying eggs. The amplitude of vertical migration varies as a function of the water transparency and presence and activity of fish. Evidence suggests that fish can release chemical compounds that influence the vertical migratory behavior of zooplankton.

B. Cuticular Pigmentation

A number of zooplankton, particularly copepods, possess a deep red coloration. The red coloration is caused by several carotenoids synthesized from β-carotene present in the algal diet (Ringelberg, 1980). The carotenoid pigment content increases under conditions of high light intensity (e.g., in clear or shallow lakes, especially high altitude lakes) and, among many copepods, increases in summer. Carotenoid content also often increases severalfold in a diurnal rhythm, showing minima around midday and maxima around midnight (Ringelberg, 1980, 1981). Darkly pigmented copepods survived significantly longer than pale copepods of the same species when both were exposed to natural intensities of visible blue light. While carotenoid photoprotection is established among some species, the adaptive significance of irregular carotenoid distribution and diurnal patterns is not obvious, although it is associated with diurnal vertical migration, possible energy utilization from lipids, and feeding periodicity (cf. Hairston, 1976, 1980, 1981; Ringelberg, 1981).

In arctic lakes, the predacious copepod *Heterocope* occurs in distinct dark red and pale green morphs (Luecke and O'Brien, 1981). The dark red form survived better in bright sunlight, but the pale green form was less susceptible to predation by fish that fed visually. In cases where fish predation was intense, the green forms predominated. Vertebrate predators select pigmented calanoid copepods, but common invertebrate predators are not visually selective (Bryon, 1982). In cold environments with short growing seasons, as at high elevations, the advantages of photoprotection from pigmentation at least partially outweigh the costs of selective predation.

Carotenoid pigmentation in cladocerans such as *Daphnia* may be coupled to nutrition and lipid content as well as photoprotection. The presence of cuticular melanin is found in highly light-stressed populations of alpine and arctic zooplankton in shallow habitats (Luecke and O'Brien, 1983; Hebert and Emery, 1990; Hessen, 1993). Even though constituting only 0.03% of body weight in *Daphnia*, melanin can act both directly as a light screen, with more than 90% removal of incident UV radiation, and as a powerful antioxidant to UV-induced oxidants and free radicals. This pigmentation pattern is an adaptation to living in shallow waters exposed to high light intensities and possessing few visual-feeding predators.

C. Avoidance of Shore

Another conspicuous feature of the movements of *pelagic* cladocerans and copepods is a distinct "avoidance of shore." At the shore, the littoral and near-littoral waters of lakes are almost free of pelagic crustaceans. When released within the littoral zone, these animals migrate horizontally away from the shore area if illumination is adequate. This aspect of spatial orientation has been the subject of intensive experimentation (especially Ringelberg, 1964; Siebeck, 1968; Siebeck and Ringelberg, 1969; Daan and Ringelberg, 1969).

The behavioral analyses showed that these crustaceans orient themselves toward the elevation of the horizon and the position of the sun. The direction of migration coincides with the plane of symmetrical light stimuli in the underwater angular light distribution. Near the shore, this plane of symmetry of angular light depends primarily on the position of the elevation of the horizon. With increasing distance from the shore, the effect of the elevation of the horizon on

the angular light distribution decreases and finally becomes insignificant, at which point the animals no longer select a directional movement away from shore. The higher the elevation of the horizon, as in mountain lakes, the wider the zone near shore that contains a reduced concentration of pelagic crustacean zooplankton.

Light from the sun and sky incident on water is refracted in the direction of the vertical axis as it penetrates downward into the water. In effect, the angular light distribution operates in an inverted conical fashion, in which light impinging at angles greater than 49° from the vertical is absorbed selectively so rapidly that a light–dark boundary or contrast forms at an angle of about 49° to the vertical axis. The contrast or light gradient is used in orientation of the body axis in swimming. For example, *Daphnia magna* is unable to swim normally or maintain its normal body position when light from every direction is of equal intensity. Normal swimming reappears when a light gradient is introduced. The body and swimming positions are oriented by distinct pairs of ommatidia of the compound eye, which are capable of detecting contrasts. The eye is turned in a dorsal body direction so that the light contrast can be projected on the same dorsal part of the eye. The body is then turned in order to maintain a physiologically fixed angle between the eye axis and the body axis. In the littoral zone, the angular light distribution consists of a dark area along the landward side within the cone of illumination. This distribution results in one of the two contrasts present at 49° in the pelagic being shifted to the vertical, and swimming would be away from the shore (Fig. 16-34). In a plane parallel to the shore line, this contrast difference is absent and the contrasts are the same as in the open water.

Zooplanktivorous fish can shift their distributions on a diurnal basis in relation to the horizontal variations in the distribution of prey. For example, the small planktivorous silverside (*Menidia beryllina*) migrated from the littoral toward the pelagic zone and fed vigorously on zooplankton that had moved horizontally offshore of littoral areas (Wurtsbaugh and Li, 1985). After feeding for a few hours, the fish returned to the littoral before being satiated, perhaps to balance predation losses in offshore areas against foraging gains.

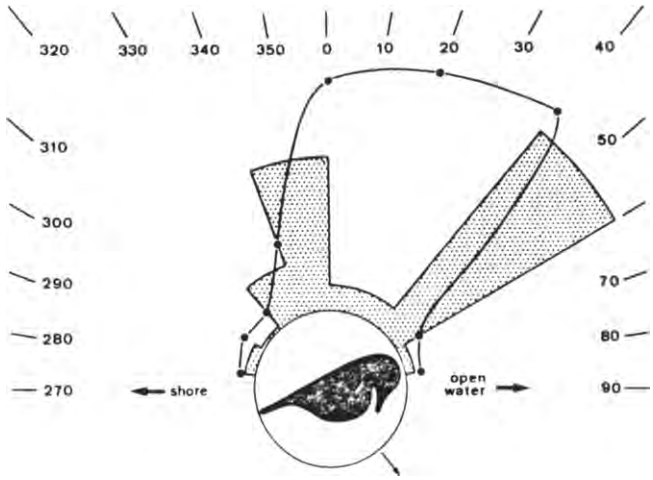

FIGURE 16-34 Orientation of a daphnid zooplankter along a plane perpendicular to the shore. Angular light distribution (solid line), magnitude of contrast expressed as the difference between two succeeding measurements (shaded bars), and the most probable orientation and movement of the daphnid. (From Siebeck, O., and Ringelberg, J.: Spatial orientation of planktonic crustaceans. *Verhandlungen Int. Ver. Limnol. 17*:831–847, 1969.)

D. Rotifers

Although features of diurnal migration are known in some detail for the cladocerans and copepods, relatively little information exists on the daily movements of planktonic rotifers. Commensurate with their relatively small size in comparison with the crustacean zooplankton, the movements of rotifers are relatively slow (Table 16-16). The maximum observed velocity of ascent in *Filinia* of 0.018 cm s^{-1} is nearly equivalent to that of some of the slowest movements among the crustacean zooplankton (George and Fernando, 1970). The maximum velocities of vertical movement, as well as the magnitude, vary among species with descent or ascent and with the season. The general tendency is toward upward movement during the daylight period (e.g., Magnien and Gilbert, 1983), although limited evidence indicates an upward nocturnal migration at one season and the reverse at another season (cf. Pennak, 1944).

No clearcut migration pattern is seen among the rotifers as occurs among the cladocerans and copepods. Presumably, the smaller size of most rotifers removes much of the pressure of visually oriented predation by fishes that probably is associated with nocturnal ascent patterns among Cladocera and some copepods. Analyses of the actual cost of ciliary locomotion among rotifers indicated that it is very inefficient and results in well over half of total metabolism (Epp and Lewis, 1984), much greater that the costs of locomotion among microcrustaceans. The movement of rotifers into the surface waters at midday (e.g., Adeniji, 1978) may, however, reflect an adaptive response to avoid predation by limnetic crustaceans despite the energetic costs.

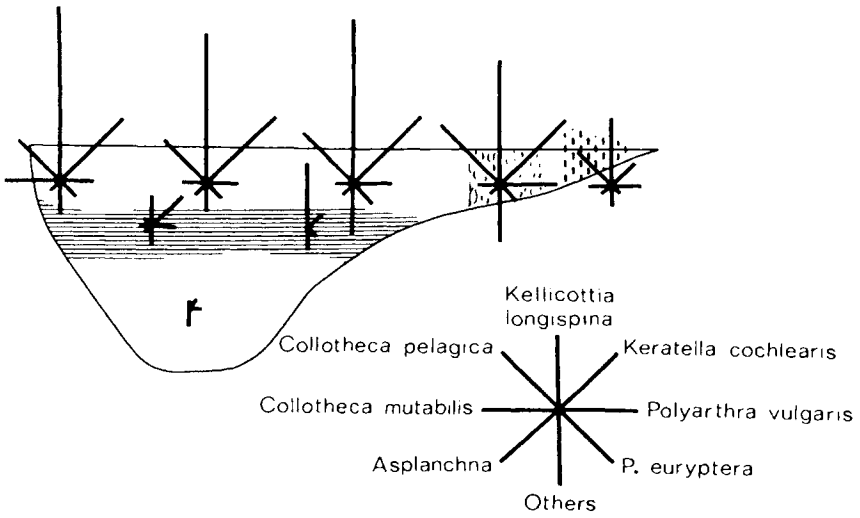

FIGURE 16-35 The relative quantitative distribution of dominant rotifers in percent in different strata along a transect across Skärshultsjön, southern Sweden, 7 August 1950. Horizontal shading indicates the position of the thermal discontinuity. (Modified from Berzinš, 1958.)

XVI. HORIZONTAL VARIATIONS IN DISTRIBUTION

A great deal of horizontal patchiness in rotifer, cladoceran, and copepod zooplankton populations has been found in the pelagic zone of lakes (cf. review of Malone and McQueen, 1983). The four basic types of patches found that are potentially caused by numerous hydrodynamic and biological factors are (a) large-scale, >1 km diameter; (b) small-scale, caused by wind-induced water movements; (c) Langmuir circulation aggregations (cf. pp. 106ff); and (d) swarms, potentially caused by biotic factors. The following few examples illustrate some of the variety found.

Small-scale horizontal variations in the spatial distribution of rotifers is provided by the detailed analyses of zooplankton in a single cross-section across the northern arm of Skärshultsjön, southern Sweden (Berzinš, 1958). The eastern shore of the basin along this 145-m transect is steepsided and drops precipitously to the maximum depth of about 13 m. The western, more gently sloping shore supported a well-developed littoral zone of submersed aquatic plants *Myriophyllum* and *Potamogeton*, grading through waterlilies (*Nuphar*) to the emergent macrophytes *Phragmites*, *Equisetum*, and *Juncus*. The numerous samples were collected within a 2-h period in midafternoon on a single summer day. At this time the lake was stratified, with a freely circulating epilimnion (19°C) to 3 m, below which the metalimnetic thermal discontinuity layer extended to 7 m, at which point the hypolimnion of 8–10°C extended to the bottom. The oxygen content of the hypolimnion was reduced (<2 mg liter^{-1}, <20% saturation) but the hypolimnion was not anoxic.

Within the 41 species of rotifers found, several conspicuous patterns of distribution were noted and are summarized in Figure 16-35, although only a few of the dominant species are considered. The epilimnetic rotifers tended to be more concentrated near the littoral regions on both sides or either side of the basin (*Kellicottia longispina*, *Collotheca mutabilis*, *Polyarthra vulgaris*, and *P. euryptera*). The dominant epilimnetic *Kellicottia* was most concentrated in the open water. Two major species, *Polyarthra major* and *Trichocerca similis*, were restricted to the metalimnion, while several others had distinctly hypolimnetic populations (*Polyarthra longiremis*, *Keratella hiemalis*, and *Filinia longiseta*).

Within the population of *Keratella longispina*, a distinct separation was found according to size. Larger individuals of the population occurred at greater depth, which suggests a greater sinking rate, although this species has some power of vertical movement, which helps it avoid sedimentation to deeper waters. A similar separation according to size was found in the vertical distribution of several species of *Polyarthra*.

Certain pelagic rotifers (e.g., *Asplanchna*), when placed in littoral areas, moved away from the shore toward the open water; others did not demonstrate such horizontal movement (Preissler, 1977). How significant "avoidance of the shore" behavior is in planktonic rotifers is unclear.

In addition to the avoidance of the littoral regions by Cladocera and copepods discussed earlier, a number

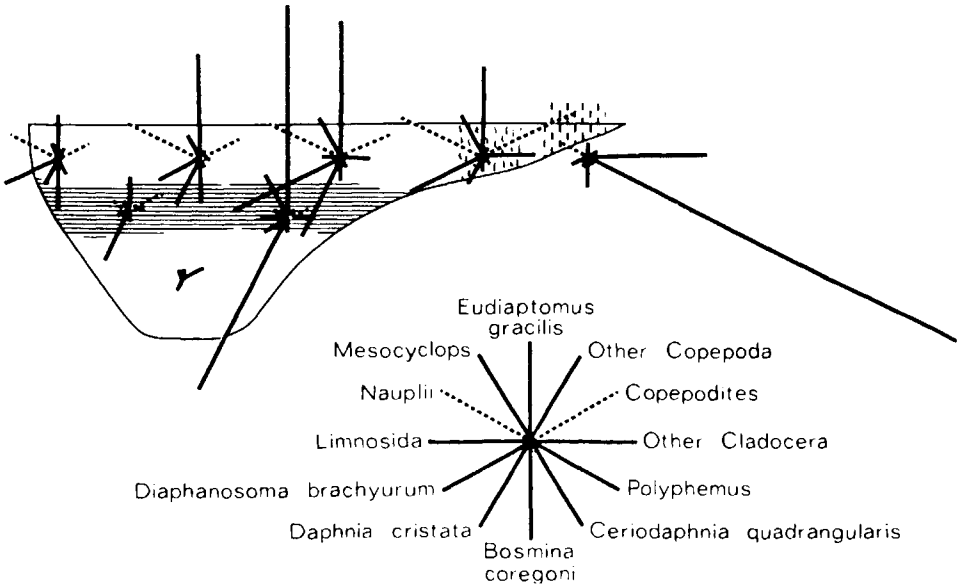

FIGURE 16-36 The relative quantitative distribution of crustacean zooplankton in percentage in different strata along a transact across Skärshultsjön, southern Sweden, midafternoon, 7 August 1950. (Modified from Berzins, 1958.)

of detailed analyses have shown a nonrandom horizontal distribution of zooplankton in the pelagic zone of lakes. An example is seen in the intensive 1-day analysis of Berzins (1958) across Skärshultsjön in Sweden (Fig. 16-36). While *Polyphemus* is distinctly littoral, many of the cladocerans and copepods avoid the littoral and are not uniformly distributed across the pelagic zone. Nonrandom dispersion of phytoplankton and zooplankton within the pelagic zone is in many cases caused by water movements. Microcrustacea tend to accumulate in the epilimnion at the leeward end of the basin and to be rare at the windward end whenever a fairly strong wind persists for an appreciable period of time (see, e.g., Langford and Jermolajev, 1966). Once at the lee side of the basin, weak locomotion is presumably adequate for most of the animals to maintain their depth distribution. Only under exceptionally strong winds and epilimnetic currents can they be swept back along the lower epilimnion to the windward side. Part of the nonrandom dispersion of zooplankton is associated with Langmuir convectional helices whose parallel clockwise and counterclockwise rotations in the epilimnion create linear alternations of divergences and convergences (see p. 106 and Fig. 7-6). Zooplankton clearly concentrate in these areas of upwelling, which occur midway between zones of convergence (George and Edwards, 1973).

This concentration of zooplankton in linear patches affects the feeding behavior of certain fishes. An excellent example is that of the white bass (*Roccus chrysops*), a pelagic fish that, in its younger stages in summer, is largely planktivorous on *Daphnia*. *Daphnia* were found to be concentrated in the linear convergences (McNaught and Hasler, 1961). The schooling white bass were able to locate and feed actively on these concentrations of *Daphnia* and also were keyed to feed most actively in the early morning and evening periods, which coincided precisely with the maximal surface concentrations of the vertically migrating *Daphnia*. Similarly, several species of juvenile cyprinid fishes migrate from the littoral to the pelagic zone only during darkness to feed on zooplankton concentrated in the surface waters by vertical migration (Bohl, 1980; Werner *et al.*, 1980).

XVII. CYCLOMORPHOSIS AND PREDATION AMONG THE ZOOPLANKTON

A. Rotifers

Cyclomorphosis, or seasonal polymorphism, is seasonal morphological variation in successive generations of small aquatic organisms. Cyclomorphosis is a phenomenon that is particularly conspicuous among planktonic Cladocera but is also fairly common among the protozoa, the dinoflagellates (cf. p. 337), and the rotifers. A particularly comprehensive treatment of the subject of cyclomorphosis among plankton is the detailed résumé of Hutchinson (1967). Although it is

more difficult to study the genetic continuity of seasonal forms of the same species of rotifers than of the planktonic crustaceans, cyclomorphosis in several rotifers has been analyzed in some depth.

Seasonal polymorphism is defined by the marked change in shape of some part of an organism in relation to some standard dimension of its size. The common changes in growth form among some rotifers include the following. (a) ***Elongation in relation to body width.*** In some species of *Asplanchna*, midsummer populations can be about five times as long as wide, markedly changed from their nearly spherical morphology in late spring. These elongated forms are nearly always sterile and die back and do not reappear until the next spring. (b) ***Enlargement***, with the formation of body-wall outgrowths or humps. As discussed earlier, at least in *Asplanchna sieboldi*, this seasonal change in growth appears to be caused by the tocopherol content of plant-derived food and most likely is an adaptive response to cope with larger-sized food in summer. (c) ***Reduction in size***, usually at higher temperatures in summer, with a disproportionate reduction in length of lorical spines. This form change is common among several species of *Keratella*. Its adaptive significance is unclear, since reduction in spine length increases sinking speed at higher summer temperatures and is compensated for only partly by the reduction in body size. The causal mechanisms for the reduction in spine length are unclear. (d) ***Production of lateral spines.*** The best-studied case of this type of cyclomorphosis is in *Brachionus calyciflorus*, in which the posterior spines elongate in the presence of its major predator, the large rotifer *Asplanchna*. *B. calyciflorus* always has two pairs of anterior spines and one pair of posteromedian spines. A pair of posterolateral spines may or may not be present (Fig. 16-37).

Gilbert (1967b; cf. also Pourriot, 1974) has demonstrated that the extension of preexisting anterior and posteromedian spines and the *de novo* induction of large posterolateral spines are caused by a substance released into the medium by the predatory *Asplanchna*. These form changes cannot be explained by temperature induction or by an allometric growth response in which the substance works indirectly on the spines by influencing body size. Changes in body size were found to be independent of posterolateral spine production. The substance was shown to affect the spineform change only at the egg stage before cleavage. The substance released by *Asplanchna* is a relatively thermolabile proteinaceous compound of unknown composition. The shape and movements of long posterolateral spines in *B. calyciflorus* significantly decrease predation by *Asplanchna*. Adult *A. girodi*, which captured about 25% of newly hatched, spineless *Brachionus* with which they made direct contact, were completely unable to capture newly hatched, long-spined individuals. Adult *A. sieboldi* can capture nearly 100% of adult, spineless *B. calyciflorus* contacted, but only about 78% of the adult, long-spined forms. The capture rate drops to <15% of the spined form by young *A. sieboldi*. The spines, however, provide no protection against predation by the copepod *Mesocyclops* (Gilbert, 1980b). A number of analyses of natural populations substantiate the fact that the substance released by *Asplanchna* can induce posterolateral spine production in *B. calyciflorus* populations (Gilbert and Waage, 1967; Green and Lan, 1974). Posterolateral spine lengths were found to be unrelated to water temperature but varied directly both with the density of *Asplanchna* and the presence of threshold quantities of the *Asplancha*-released substance.

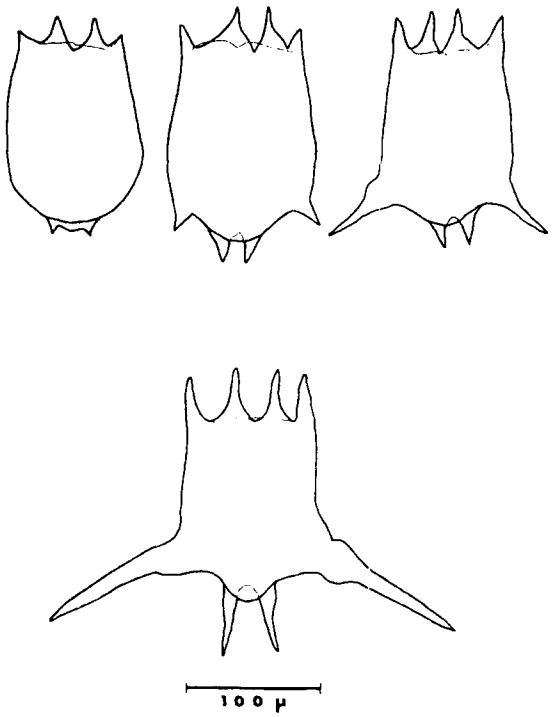

FIGURE 16-37 Spine variation in a clone of the rotifer *Brachionus calyciflorus* induced by increasing concentrations of a proteinaceous substance produced by its predator *Asplanchna*. (From Gilbert, J. J.: *Asplanchna* and posterolateral spine production in *Brachionus calyciflorus*. *Arch. Hydrobiol.* 64:1–62, 1967b.)

The significance of predation upon rotifers varies depending on the species represented in the predator–prey interaction. For example, the predatory copepod *Mesocyclops* feeds effectively on the rotifers *Asplanchna* and *Polyarthra* but not on the rotifer *Keratella* (Gilbert and Williamson, 1978). *Keratella* is released by *Mesocyclops* after it has been captured, since the predator cannot remove soft parts of this rotifer. *Asplanchna* regularly eats *Keratella* but cannot

capture *Polyarthra* because of its effective escape behavior. The abundance of *Polyarthra* and *Keratella* in natural communities can be greatly affected by interactions with and between *Asplanchna* and predatory copepods.

B. Cladocera

Seasonal polymorphism in the Cladocera is perhaps more conspicuous than in any other group. The subject has been studied extensively, especially among the genus *Daphnia* (reviewed in detail by Hutchinson, 1967; Kerfoot, 1980a; and Jacobs, 1987).

With increasing water temperatures, light, and food in the spring, the most common seasonal pattern of variation among successive generations in temperate lakes is a ***gradual extension of the anterior part of the head to form a crest or helmet*** (Fig. 16-38). Carapace length, on the other hand, changes little or decreases only slightly between the spring and summer, and then increases again somewhat in autumn. The number of parthenogenetic eggs per individual generally decreases markedly in the strongly helmeted summer forms, although the number of instars increases with higher temperatures. The extent of head development and the change of head shape are extremely variable among species and within the same species under different environmental conditions. In subtropical and tropical waters, cyclomorphosis is weak or does not occur, except when there is a large temperature change between winter and summer (e.g., Zago, 1976; Mitchell, 1978). ***An increase in the length of the tail spine*** also is observed in some species during summer. Cyclomorphosis in the genera *Bosmina, Ceriodaphnia*, and *Chydorus* is much less distinct than in *Daphnia*, and consists of slight reductions in length of the body and of the antennule in summer. In *Bosmina*, changes often occur by means of the formation of transparent dorsal humps, with no increase in length and reductions in antennule length and number of segments; in mucro (caudal spine) length and number of sutures may also occur (Black, 1980a,b; Kerfoot, 1980b).

The mechanisms causing cyclomorphosis in cladocerans have received much study. It is clear that temperature is a primary stimulus affecting the height of the head helmet in *Daphnia* and that it is effective during the middle of embryogenesis. In a number of species, helmet extension does not occur at water temperatures below 10–15°C. Carapace length is maximal in winter, and the ratio of head length to carapace

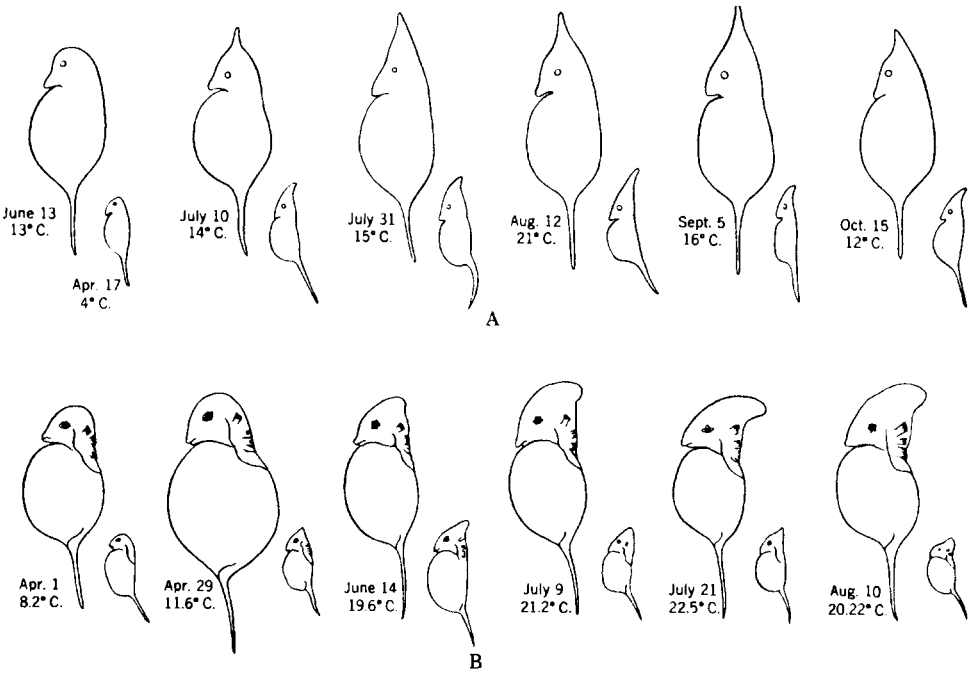

FIGURE 16-38 Cyclomorphosis in (a) *Daphnia cucullata* of Esrom Sø, Denmark and (b) *Daphnia retrocurva* of Bantam Lake, Connecticut. The small individuals at the right are first instar juveniles drawn to the same scale as the adults. (a) From Hutchinson, G. E.: *A Treatise on Limnology*, Vol. 2, New York, John Wiley & Sons, Inc., 1967; (b) From Brooks, John Langdon: Cyclomorphosis in *Daphnia*: *Ecological Monographs* 16:1946. Copyright 1946 by Duke University Press.)

length increases with increasing temperatures. Transfers of animals reared at one temperature to a lower or higher temperature result in a reduction or increase in head length in relation to that of the carapace in later instars. Food supply also affects the specific growth rate and has a relatively greater effect on growth of the head (e.g., Dodson, 1988), but helmet length is more strongly correlated directly with water temperature than with food abundance (Lampert and Wolf, 1986).

Water turbulence also has been shown to be a significant factor in cladoceran cyclomorphosis (see, e.g., Brooks, 1947; Hrbáček, 1959; Jacobs, 1962; Havel and Dodson, 1985). In turbulent cultures and in naturally turbulent environments such as the epilimnion of larger lakes, helmet length relative to that of the carapace is increased significantly in the light in comparison to quiescent situations. Antennal beating rate also increases significantly in turbulent conditions, probably in order to maintain a vertical orientation to light. Helmet development is distinctly more conspicuous in species typically inhabiting epilimnetic turbulent strata (Brooks, 1964). Populations genetically capable of considerable phenotypic variation do not exhibit their extreme phenotype when they live in lower water strata in which growth is slower. Turbulence is virtually ineffective in cyclomorphic induction in the dark (Jacobs, 1961; Hazelwood, 1966). Temperature and turbulence influence relative growth rates from the beginning of the second half of embryogenesis; food becomes effective immediately after birth (Jacobs, 1980). Daphnid cladocerans that are warm, well fed, illuminated, and exposed to turbulence produce the largest helmets. All factors are influential to some extent as long as the animals are capable of growth.

Organic substances released by invertebrate (especially *Chaoborus*) and fish predators can also induce cyclomorphic growth in *Daphnia* more effectively than can changes in temperature, turbulence, and oxygen (Grant and Bayly, 1981; Vuorinen *et al.*, 1989; Hanazato, 1990, 1991; Tollrian, 1990, 1994). Exposure to these chemical cues is most effective at the juvenile growth stages.

A compensatory mechanism exists in daphnid growth: The larger (longer) the helmet resulting from earlier influences, the slower it will grow relative to the body in later instars (Jacobs, 1980, 1987). Certain body proportions are maintained regardless of previous environmental conditions. Since there is no single receptor mechanism for the effective environmental factors, one or more hormones likely interact to regulate specific differential growth.

Morphological variability in cladocerans has been ascribed only to phenotypic plasticity. It is important to note that some cyclomorphic species are, in reality, composed of many genetically differentiated species (e.g., Hebert, 1978a,b; Black, 1980a; Kerfoot, 1980b; Jacobs, 1987). A number of these species often occur in the same community, and seasonal changes in their relative frequencies can cause polymorphic cycles that mimic true cyclomorphosis. Intraspecific genetic variation in head shape likely occurs as well in some species.

C. Copepods

Seasonal polymorphism among adult copepods is minor in comparison with that found among the parthenogenetic Cladocera and rotifers. The most conspicuous feature is a slight inverse relationship of body size to increasing temperature, so that, in the few cases studied, animals of summer populations tend to be somewhat smaller than animals living in colder seasons.

D. Adaptive Significance of Cyclomorphosis

Seasonal polymorphism in cladocerans and rotifers has been assumed to be of major adaptive significance to these organisms. Early investigators assumed that cyclomorphic forms would have greater resistance to sinking because the viscosity of the water decreases at higher epilimnetic temperatures. Cyclomorphosis is confined almost completely to species that inhabit the epilimnion, or at least migrate to it daily. Epilimnetic turbulence, however, decreases the small advantage gained from form resistance (Jacobs, 1967). Such resistance would be somewhat disadvantageous to cladocerans swimming during vertical diurnal migration. Furthermore, there is an energetic and demographic cost to those forms with extreme polymorphic growth, particularly in lowered reproductive rates (Riessen, 1984; Black and Dodson, 1990).

The adaptive significance of cyclomorphic growth appears to center on minimizing two aspects of predatory avoidance. (1) Predation of cladocerans and other large zooplankton by non–filter-feeding fish, which is a visual process (see p. 466). Cyclomorphic growth keeps small the central portion of the body (thorax, abdomen, and basal portion of the head) that is visible to predators. Growth continues by expansion of transparent peripheral structures (Brooks, 1965, 1966; Jacobs, 1966). Thus, when size-dependent planktivory is most intense in summer, the central visible portion of the daphnid body is smallest and the organism is less susceptible to being eaten by fish. Cyclomorphomic organisms are, through selection for high rates of growth in less visible peripheral structures, able to maintain assimilation rates during midsummer

without the disadvantage of greater visible size when predation is intense. In the winter, when the rate of predation is negligible and turbulence essentially is eliminated under ice cover, evidence indicates that cessation of molting in juveniles and adults results from the lack of a turbulence cue. With the loss of ice cover, even at low temperatures, molting, growth, and egg production immediately begin from the overwintering population of large females. (2) Reduction of capture success by invertebrate and young fish predators. Many cladocerans of small size (<1.5–2.0 mm) exhibit more cyclomorphic growth than larger species (reviewed by Zaret, 1980). Invertebrate predation by copepods and phantom midge larvae (*Chaoborus*) is more effective on smaller zooplankton (<2.0 mm) (e.g., Havel and Dodson, 1984). The large caudal appendage of cladocerans such as *Bythrotrephes* increases handling time and decreases predation rates by young fish (Barnhisel, 1991).

The lack of cyclomorphosis in copepods in comparison to marked polymorphism in cladocerans and rotifers is likely related to the fundamentally different ways in which these groups have developed different defenses to invertebrate predation (Kerfoot, 1980b). The thoracic legs of copepods are modified for locomotion, while those of cladocerans are modified for filter feeding. Nauplii, copepodite, and adult stages of copepods have evolved precontact defenses, in which they are capable of swift evasive swimming maneuvers (10–35 cm s^{-1}; Strickler, 1975) away from predators. Locomotion in cladocerans by the pair of second antennae results in only feeble, slow escape reactions (e.g., Kerfoot, 1978). Although some rotifers (e.g., *Polyarthra*) have evasive propelling motions, most rotifer locomotion by ciliary movement is slow. Therefore, the cladocerans and rotifers have evolved postcontact defenses, including (a) larger size, (b) elaboration of spines and other body shapes to frustrate handling by predators, (c) hard, chitinized head shield and carapace, (d) protection of eggs and embryos internally in brood pouches, and (e) reduction of development time of immature stages (in contrast to relatively long naupliar and copepodite stages in copepods).

XVIII. FISH WITHIN AQUATIC ECOSYSTEMS

Fish of freshwater ecosystems are enormously important to humans. Although recreational exploitation of fish communities is often a dominant interest among developed countries, throughout much of the world inland fish serve as a major source of protein. Fisheries have developed to maximize utilization of these fish resources. A complex of interrelated problems has evolved as a result. Examples include fish exploitation that often exceeds production capacities, introductions of exotic species, and marked alterations of the trophic structure within lakes and streams.

It is beyond the scope of this synthesis to summarize the biology of fishes and their multifaceted ecological interactions within freshwater ecosystems. Ichthyology, the study of fishes, has a long detailed history that has been summarized, particularly recently, in a number of excellent treatises on the ecology of fishes (e.g., Lagler *et al.*, 1962; Nikolsky, 1963; Lowe-McConnell, 1975; Moyle and Cech, 1988; Wooten, 1990; Gerking, 1994; Jobling, 1994; Diana, 1995; Bond, 1996; Matthews, 1998). The treatments of fish in the present work, however, will be directed to the overall functions of fish in predation on other animals, of how fish feeding ecology can alter the trophic structures, and how fish can influence nutrient cycling within lake and stream ecosystems. Fish contributions to overall production and energy flows will also be coupled to different pathways.

A. Feeding Relationships among Fish

Feeding among fish, as among other animals, is the process for acquisition of both energy and nutrients required for growth and reproduction. The efficiency of this process is determined by both physiological and environmental constraints. Particularly pivotal are the costs of energy expended in acquiring food in relation to the benefits accrued energetically and nutritionally, and how that acquisition translates to the effectiveness of growth and reproduction. Optimal foraging theory predicts that behavioral modifications will be taken by a predator to maximize the returns per unit effort expended in acquiring prey of various qualities.

Nearly all fish use suction feeding to ingest food, by which the fish creates a negative pressure in the buccal cavity and draws into the mouth a stream of water carrying organisms (Gerking, 1994). Intake can also be accomplished by swimming with the mouth and opercles open. When prey is scarce and large, fish commonly feed on individual particles. Conversely, when prey density is high and size is small, fish commonly shift to filtering particles from the water by entrapment on mucus or by mechanical sieving. The filtration apparatus are commonly gill rakers (cf. Fig. 16-39). Interraker spaces are highly variable among fish species and growth stages and influence the size of prey particles acquired.

Olfactory and gustatory chemoreceptors are extremely sensitive among fish and respond to many chemical substances, often at very dilute concentrations (to $<10^{-18}$ M). Vision is critical to the location of prey

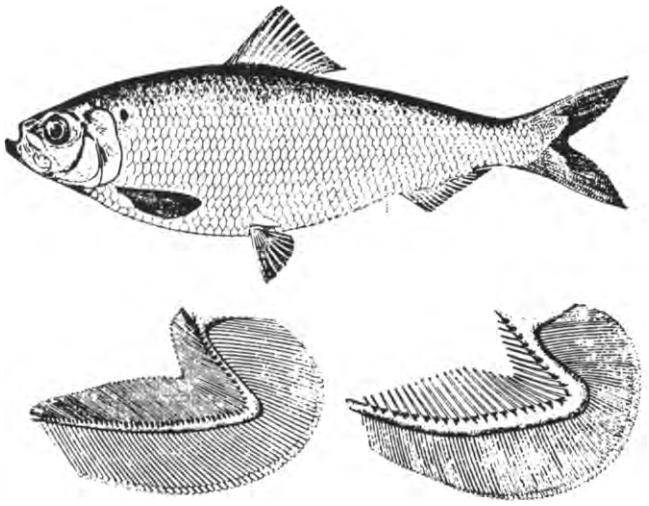

FIGURE 16-39 The alewife, *Alosa pseudoharengus*. *Upper*: A mature specimen, 300 mm in length. *Lower left*: First bronchial arch with closely spaced gill rakers that act as a plankton sieve. *Lower right*: First bronchial arch with widely spaced gill rakers of *A. mediocris*, a species that feeds primarily on small fish. (From Brooks, J. L., and Dodson, S. I.: Predation, body size, and composition of plankton. *Science 150*(3692):28–35, 1965. Copyright 1965 by the American Association for the Advancement of Science.)

among many fish and has led to many behavioral adaptations among prey organisms to seek both spatial and temporal refuges from the visual feeding of fish. The success of visual predation varies greatly with prey size, shape, translucency, and color as well as water clarity, prey behavior, and other factors. Because of the enormous importance of size-biased feeding, by which large prey or large size classes of a single prey species are favored over smaller ones, in food-web structure and energetics in limnology, a separate summary of that subject follows further mention of feeding modes among fishes.

Many fish adapt to a wide variety of food sources and often switch from one food source to another as environmental and food supply conditions change dietary quality and abundance. The species flexibility to switch and to take advantage of the most profitable food source at any particular time, termed *trophic adaptability*, makes it very difficult to accurately group fish into specialist or generalist feeding categories. Specialist fish feed on a restricted diet, whereas generalist fish feed on a broad spectrum of prey species or detrital organic matter. Opportunist fish switch from one food source to another as food populations fluctuate and as their life stages mature. For example, larval fish utilize endogenous sources of nutrient in the yolk sac stages and shift to exogenous mouth ingestion of algae initially as the yolk sac is absorbed and to zooplankton, the latter being selected individually, in the later stages of larval feeding. Mortality among larval fish is very high and some has been attributed to starvation (cf. review of Gerking, 1994). During good reproductive class years, however, abundant fish larvae can severely impact zooplankton, particularly larger species such as *Daphnia* (Mills and Forney, 1983).

A number of fish families are predominantly herbivorous on algae and vascular aquatic plants, or specialize on reproductive parts (fruits, seeds, and flowers) of higher plants. All herbivorous fish ingest some animal food, which may supplement the largely plant diet. These fish commonly possess physical adaptations for mastication of plant materials and partial chemical digestion. Detritivory is common among fish (Gerking, 1994). The diet of adult detritivorous fish consists mainly of decomposed organic matter; living organisms associated with the detritus are also consumed, either actively or fortuitously. Early larvae of detritivores are zooplanktivorous and switch to dead organic matter as they mature.

Diversity of feeding is great among bottom- (benthic) foraging fish. Most species shift among prey types as availabilities change, but certain behavioral adaptations often predominate. Processes include (a) ingesting sediment deposits, (b) scraping periphyton off rock surfaces, (c) grasping invertebrates from surfaces, and (d) crushing mollusks. Extraordinary feeding specializations have evolved among certain fish families, particularly among the nearly 500 endemic cichlid species in East African relict lakes (Greenwood, 1974; Lowe-McConnell, 1987). Fish also feed actively upon moving prey, either those that migrate vertically or horizontally within a lake or are moved by water currents. Zooplankton and some immature insect movements are often coordinated with periods of darkness to avoid heavy fish predation (cf. pp. 488–453). Benthic organisms of streams often are moved downstream by water currents in benthic drift (Chap. 22) and are supplemented by allochthonous invertebrates that fall into the stream from adjacent wetland and land.

Any evaluation of the efficacy of fish predation on the production of benthic invertebrates must be evaluated in the context of total mortality from (a) predation, (b) natural senescence and death, and (c) emigration via emergence, migration, or drift. Fish are clearly capable, under certain conditions, of reducing biomass and production of benthic invertebrates and to markedly alter species composition of prey or even eliminate certain prey by selective predation. Fish predation intensity must be very high, however, to become the main determinant of the zooplankton community, superimposed on lake productivity of food resources (Vanni *et al.*, 1990; Hessen *et al.*, 1995). As in the

zooplankton, size selection of benthic prey by fish is common, although not universally a direct correlation. Bluegill or perch predation on large active benthic fauna shifted invertebrate community structure to smaller, less active forms (Hall *et al.*, 1970; Crowder and Cooper, 1982; Post and Cucin, 1984). Increased resource availability by the removal of larger prey can result in increased growth and production of smaller benthic organisms.

B. Predation by Fishes and Size Selectivity of Zooplankton

Thus far in this discussion, competitive interactions among zooplankton populations have centered on differences in spatial and temporal distributions and on food-size requirements that permit coexistence in the same body of water. The succession and competitive success of zooplankton populations can be influenced significantly by predation of other zooplankters, a point which was demonstrated earlier among the rotifers and the large cladoceran *Leptodora*. A large number of studies have demonstrated the importance of planktivorous fish in regulating zooplanktonic populations and in causing a distinct shift favoring survival of species that are smaller in size. In other words, for a number of reasons focusing on energetic efficiencies, predators selectively consume the largest prey possible within their physical and behavioral capabilities and the abundance of prey.

As noted briefly earlier, Hrbáček and collaborators were the first to demonstrate unequivocally the importance of fish in the regulation of the size and species composition of zooplankters (Hrbáček, 1958, 1961, 1962, 1965; Novotná and Korínek, 1966). When large, shallow ponds were stocked heavily with cyprinid fish, the zooplankton consisted of small cladocerans, *Bosmina, Ceriodaphnia*, and rotifers. Water transparency decreased with the predominant development of small nanoplankton algae. Upon selective removal of the fish, the zooplankton changed suddenly to larger cladocerans, particularly *Daphnia longispina*, and rotifer abundance decreased. Transparency increased as the phytoplankton shifted to smaller densities of larger species.

Another series of remarkably simple but definitive studies conducted by these Czechoslovakian workers involved experimental manipulation of portions of the same small lakes by fencing off portions of the littoral from fish and ducks (Straškraba, 1963 1965, 1967; Poštolková, 1967). Within the protected littoral enclosures, submersed vegetation increased and afforded zooplankton greater protection from fish predation than in the open water. Zooplankton biomass increased in the littoral as the small *Chydorus* and other cladocerans were replaced by larger *Daphnia, Simocepholus*, and many copepods. Differences could not be related to changes in food supply but rather to changes in fish predation.

All planktivorous fish have closely spaced gill rakers. The example of the alewife of Figure 16-39 shows the closely spaced gill rakers of the first branchial arch of the planktivorous *Alosa pseudoharengus* in comparison to those of the closely related *Alosa mediocris*, which feeds principally on small fish. Studies of the pharyngeal sieves of the planktivorous yellow perch (*Perca flavescens*) and the rainbow trout (*Salmo gairdneri*) demonstrated that the trout and perch could remove few zooplankters of a size smaller than 1.3 mm (Galbraith, 1967; Wong and Wood, 1972; Nilsson and Pejler, 1973). It must be emphasized, however, that all freshwater planktivorous fish examined so far actively search for and visually select each plankter that they ingest (Brooks, 1968; Seghers, 1975). Some fish (e.g., ciscoes, *Coregonus artedii*; bluegills, *Lepomis macrochirus*) gulp water by constantly opening and closing the mouth while swimming (Janssen, 1980; Werner *et al.*, 1981). These actions ingest aggregations of prey when prey densities are high. However, in the normal respiratory behavior of passing water through the mouth and across the gills, some zooplankters can be collected by gill rakers. Fish such as the alewife are more or less obligately planktivorous, while others such as the trout and perch eat large zooplankters, and if these are unavailable they readily shift to alternate food sources. Size selection of prey appears to be characteristic of both the obligate planktivores, such as some of the alewives, and those species that feed facultatively on the plankton.

The relation between size selection of prey and foraging efficiency was shown in the bluegill sunfish (*Lepomis macrochirus*), a common centrarchid of many temperate waters that selects prey on the basis of size (Werner, 1974; Werner and Hall, 1974; O'Brien *et al.*, 1976; Werner *et al.*, 1981; Mittelbach, 1981). Growth rates increased significantly in direct relation to food size (see, e.g., LeCren, 1958; Hall *et al.*, 1970), and much of this differential growth has been attributed to greater efficiency of foraging with increasing size of prey captured, that is, improved ratio of expenditure of energy or metabolic cost in obtaining food relative to the return (cf. Pyke *et al.*, 1977). In the bluegill, size selection of prey is related to the optimal allocation of time spent searching for and handling the prey. In other words, the size range of prey that maximizes the energy return per unit of energy expended depends on the costs of searching for and handling times of different prey in the environment. Both searching ability and prey-handling efficiency increase with

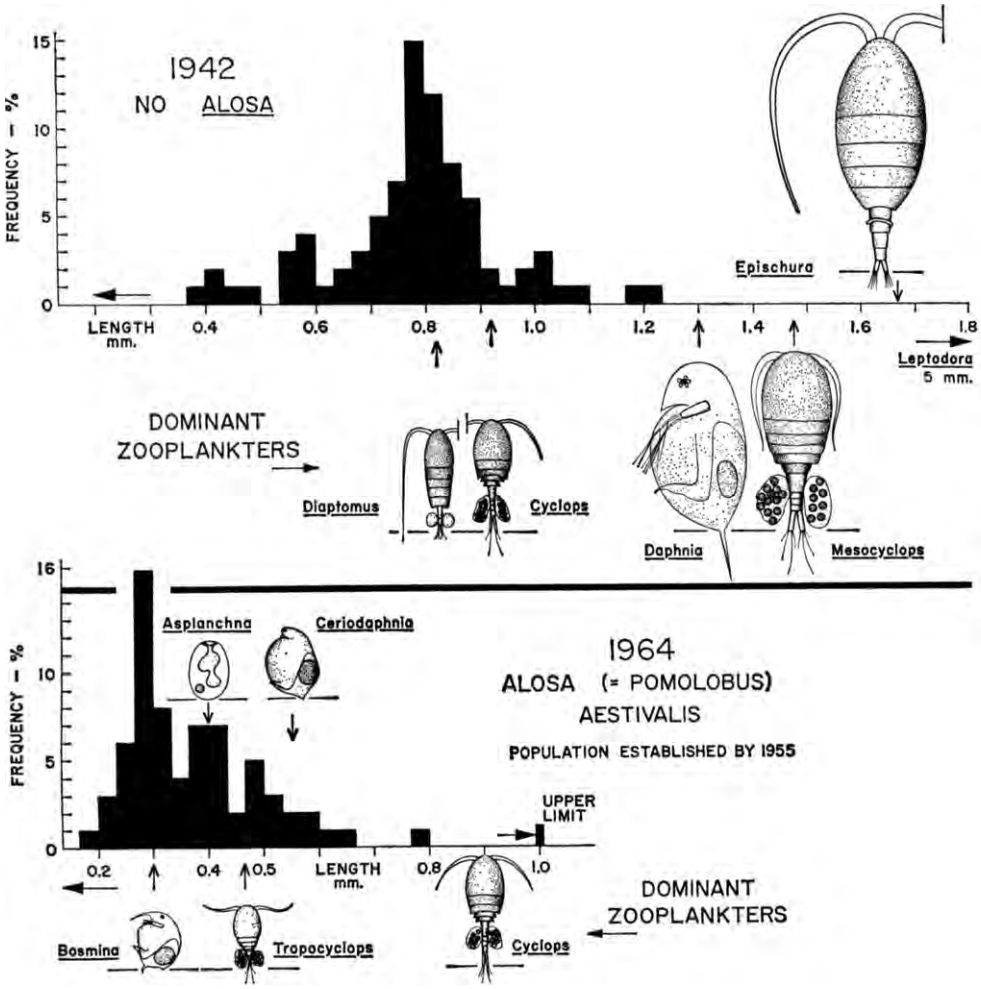

FIGURE 16-40 The composition of the crustacean zooplankton of Crystal Lake, Connecticut, before (1942) and after (1964) a population of *Alosa aestivalis* became well established. Each square of the histograms indicates that 1% of the total sample counted was within that size range. Larger zooplankters are not represented because they were relatively rare. The specimens depicted represent the mean size (length from posterior base lines to the anterior end) of the smallest mature instar. The arrows indicate the position of the smallest mature instar of each dominant species in relation to the histograms. The predaceous rotifer *Asplanchna* is the only noncrustacean included in this study. (From Brooks, J. L., and Dodson, S. I.: Predation, body size, and composition of plankton. *Science 150*(3692):28–35. Copyright 1965 by the American Association for the Advancement of Science.)

increasing fish size (Mittelbach, 1981). The handling time per prey increases exponentially as the ratio of prey size to mouth size increases (Werner and Mittelbach, 1981). At times of low prey abundance, when search time is long, prey of different size are eaten as encountered. As prey abundance increases and search time decreases, smaller-sized classes are eaten less frequently or ignored, such that overall return per time increases (see also Brooks, 1968).

The earlier Czechoslovakian observations on the effects of planktivorous fish on the zooplanktonic species composition were confirmed excellently by a study of the changes in the zooplanktonic populations of Crystal Lake, Connecticut (Brooks and Dodson, 1965). Prior to the introduction of the alewife into the lake, zooplankton included the large calanoid copepod *Epischura, Daphnia*, and the cyclopoid *Mesocyclops*, as well as numerous smaller *Diaptomus* and *Cyclops* copepods (Fig. 16-40). Some 10 yr after the alewife invaded the lake, the larger forms of zooplankters had been replaced and dominants included very much smaller forms, the cladoceran *Bosmina* and two cyclopoid copepods *Tropocyclops* and *Cyclops* (Fig. 16-40). The modal length of the numerically dominant forms had shifted from 0.8 to 0.35 mm in the zooplankton assemblages. Larger forms were found

only in the littoral zone and near the sediments, areas that are avoided by the pelagic *Alosa*.

Such size–feeding relationships have been demonstrated in many different environments. Indeed, the excellent early studies have been repeated, with numerous experimental variations in enclosures of highly varying efficacies. For example, the simple zooplankton community structure of high-elevation lakes is strongly influenced by predators present (Starkweather, 1990). Lakes with resident salmonid fish have crustacean zooplankton always smaller than 0.75 mm and substantial rotifer populations, while lakes without fish contained much larger crustaceans (to 2.8 mm) and few or no planktonic rotifers. Such relationships with similar results have been demonstrated often both in experiments where fish and zooplankton predation is modified within enclosures (e.g., Threlkeld, 1988; Mazumder *et al.*, 1990b; Brett *et al.*, 1994) and by predator introductions into or predator alterations within whole-lake ecosystems (e.g., Elser and Carpenter, 1988; Post *et al.*, 1997). The type of planktivore, fish year–class strengths, and seasonal variability in fish feeding all can have marked effects on the altered zooplankton community structure (e.g., Hambright and Hall, 1992; Rudstam *et al.*, 1993). Although the predatory effects on zooplankton were marked, particularly in relation to size, effects on feeding commonly resulted in little change to bacterioplankton abundance or alterations in *total* algal primary production.

C. Buzz Words: The Plague of Fuzzy Concepts and Ambiguous Terminology

Many studies in the last two decades on the selective size–feeding relationships within planktonic communities led to a number of purportedly new hypotheses. All were in reality quite redundant with the studies of several decades earlier presented in summary here. These relationships were studied in a variety of aquatic habitats and provided highly varying degrees of scientific support for the hypothesis that phytoplanktonic algal mass would be influenced by selective control of fish and zooplankton levels within the pelagic food chain. A considerable number of these studies drew conclusions that were unsupported and proposed quite imaginary couplings, all of which persist as an embarrassment to limnology. Among the worst were repeated studies that claimed, without data, that differential predation (unmeasured) was inducing differential grazing (unmeasured) that was causing major nutrient regeneration (unmeasured) and inducing major alterations of photosynthetic productivity and phytoplankton community structure (unmeasured). The purportedly confirmed relationships, with highly variable support, were reiterated with such frequency that a danger emerged where the speculations could be elevated to ecological laws simply over time (e.g., McIntosh, 1980). Early appropriately critical reviews of the data (e.g., DeMelo *et al.*, 1992; Strong, 1992) were effective in forcing more substantive experimental evaluations. Although results of the early foundational studies were generally supported, many of the subsequent overextensions of strengths of trophic interactions were not. A more reasonable and realistic perspective on these trophic interrelationships is now emerging (e.g., Hansson *et al.*, 1998a; Persson, 1999).

1. Trophic Cascades

The term *trophic cascade* originated in studies of marine intertidal organisms (Paine, 1980) and has been widely and ambiguously applied to a number of fresh waters as a foundation for trophic interactions (e.g., Carpenter *et al.*, 1985, Carpenter and Kitchell, 1993). Although formally defined as the propagation of indirect mutualism between nonadjacent levels in a food chain (Schoener, 1993), it is most often applied to well-known pelagic processes, delineated decades ago, of predation by fish and/or invertebrates that sometimes alter the zooplankton community structure and their effectiveness in grazing on phytoplankton. Many studies in enclosures, ponds, and whole-lake experiments demonstrated significant impacts of planktivorous fish on zooplankton that in turn influenced phytoplankton *composition*. Examples of such effects were clearly indicated in the discussions in this chapter. Two important points have emerged from analyses of these interactions, however: (a) The concept of cascading negative trophic interactions is highly simplistic and often fails completely to operate in natural pelagic ecosystems because of a bevy of compensatory mechanisms that emerge almost immediately following predatory alterations (e.g., Mazumder *et al.*, 1990a; McQueen *et al.*, 1992; Ramcharan *et al.*, 1995, 1996; Hansson *et al.*, 1998; Persson, 1999; among many others); and (b) if operational for a period, the "cascading" influence cannot be sustained for long periods under natural conditions without constant disturbance. Trophic cascades are basically a description of one outcome of indirect interactions out of several possible alternatives (cf. Persson, 1999).

Additional ambiguous terms and concepts plague the literature on this subject. "Top-down" and "bottom-up" regulation of some process or property of different trophic levels, usually among the plankton, are terms with definitions nearly as diverse as the number of workers using them. Set forth by McQueen *et al.* (1986, 1989), *top-down* generally refers to predation

processes by invertebrates or fish that influence zooplankton community structure that in turn may selectively influence feeding efficacy on seston. *Bottom-up* generally refers to resource regulation of growth and production often beginning with biogeochemical controls of photosynthesis, usually of phytoplankton. By implication, usually only vaguely stated, this resource (nutrient or light) limitation of phytoplankton growth can translate to resource (food) limitations for herbivorous zooplankton and consumers of zooplankton. The hypothesis predicts that "bottom-up" forces are strongest at the bottom of the food chain and "top-down" forces are strongest at the top of the food chain. Organic carbon resources *always* influence the productivity at all levels of the food chain couplings, whereas predatory effects ("top-down" effects) may weakly affect *productivity* at the primary level under some circumstances, but usually does not. Productivity is shifted or displaced to other organisms or to different parts of the ecosystem but is not suppressed greatly or eliminated. Importantly for management implications, however, the shifted productivity may be of a type more "desirable" for human uses of the water, and that characteristic can be an important aspect of management decisions.

2. Biomanipulation

Biomanipulation, a term introduced by Shapiro *et al.* (1975), is a type of biological engineering in which manipulations of biota are used to reduce objectionable algal *types* and biomass in addition to, or to supplant, reductions of nutrient loading. Biomanipulation was originally based on the idea that when the number of planktivorous fish are reduced, the density of large cladoceran zooplankton increases, and their grazing during the summer period can reduce certain species of planktonic algae and reduce the algal turbidity of the water. Planktivorous fish can be reduced by introduction of piscivorous fish or by intensively cropping the planktivorous fish by commercial fishing, as has been successfully done under certain conditions. As a corollary, "biomanipulation" postulates that increased fish planktivory should enhance phytoplankton populations and their development by decreasing grazing by larger zooplankters. Furthermore, manipulation of carnivorous fish predators could alter planktivorous fish populations which in turn could reduce predation on large zooplankton and increase the effectiveness of zooplankton feeding on phytoplankton.

Biomanipulation has often been presented with naive promises as a purportedly inexpensive alternative to control of eutrophication. Many studies have indicated that the presence of large grazers results in an apparent temporary reduction of algal biomass, frequently shifting to irruptions of both ultraphytoplankton, with intensified growth and recycling within the microbial loop, and nuisance blooms of cyanobacteria that are not effectively grazed. If nutrient inputs are controlled, then algal reduction results can be improved. For example, commercial fishing of the planktivorous coregonid fish in Lake Vesijärvi, Finland, has been successfully used as a management tool, coupled with nutrient reductions, improved land use in the drainage basin, improved littoral buffers, and other methods to significantly revert the phytoplankton biomass to acceptable levels for public uses (Kairesalo *et al.*, 1999). This excellent example of lake restoration, however, demonstrates that the fish "biomanipulation" technique requires a continual, sustained removal effort and can only be used effectively in tandem with many simultaneously nutrient reduction and control mechanisms (cf. also Hansson *et al.*, 1998b). Such control of algae cannot be readily realized on a sustained basis in lakes that experience continued high nutrient loadings and multiple usage by humans unless intensive management strategies are constantly applied. Even coupled with aggressive programs to reduce nutrient loading, the primary cause of eutrophication, such manipulations of higher trophic levels and feeding dominance are only of short-lived therapeutic value. Nutrient pools are temporarily displaced but not removed from the ecosystem, and continued nutrient loading will be directed to maximizing primary productivity.

Such alterations of algal composition and biomass distributions by "biomanipulation" are ***not*** "biological control of eutrophication," despite the claims of some workers (e.g., Carpenter *et al.*, 1995; Hansson *et al.*, 1998). Such management processes may temporarily reduce biogenic turbidity in eutrophic lakes for "cosmetic" aesthetic purposes, but it is little more than a temporary displacement of nutrients, particularly of phosphorus, to alternative reservoirs within the lake, some of which will certainly recycle and be reutilized in subsequent photosynthetic production. The proposals (e.g., McQueen *et al.*, 1990, among many others) that such "biomanipulation" will be effective in lakes only when chemical and physical factors are altered to produce algal species compositions that permit strong control of prey by predators are not practical solutions to eutrophication of surface waters. The compensatory capacities of the phytoplankton and coupled microbes of the pelagic ecosystem are multiple, varied, and rapidly responsive and will not allow such a simplistic disturbance to persist for any appreciable period of time if the nutrient resource availability persists for sustained potential productivity. With more sophisticated monitoring and regulation programs in the future, biomanipulation will continue to be a useful, albeit

expensive, therapeutic tool to minimize the *effects* of eutrophication.

Terms such as "bottom-up," "top-down," and "biomanipulation" must be used, if at all, with great caution, because they are not only highly ambiguous but they promulgate concepts that are not founded in thermodynamic relationships of nutrient storage and recycling and are used without recognition of the true complexities of the regulation of food-web interactions. Perhaps such simplifications were helpful during the initial development of the concepts; now they inhibit progress toward thorough understanding of the processes involved.

D. Importance of Visibility in Predation

Similar predatory elimination of larger zooplankters, particularly *Daphnia*, from lakes by other planktivorous fish has been shown in many studies since. The planktivorous smelt (*Osmerus mordax*) is particularly effective in this regard (see, e.g., Reif and Tappa, 1966, and especially Galbraith, 1967). However, the relationship of size and planktivore predation is not always that simple. If prey are large but relatively transparent, such as *Leptodora* or planktonic larvae of the dipteran *Chaoborus*, they often are overlooked and predation is reduced (see, e.g., Costa and Cummins, 1972). Furthermore, the slower, steady movements of cladocerans render them more vulnerable to predation than the jerky, irregular movements of copepods.

The importance of visibility in planktivorous predation by fish is demonstrated by the tropical *Ceriodaphnia cornuta*, which shows two distinct polymorphic forms of the same body length within the same lake (Zaret, 1972a,b). One form has pointed, hornlike extensions of the exoskeleton on the head, body, and tail regions with a small area of black pigmentation in the compound eye. The other phenotype is unhorned but possesses a large, pigmented eye. Predation by the dominant planktivore fish, the silverside (Atherinidae; *Melaniris chagresi*) was more intense on the form with the large, pigmented eye. This form of *Ceriodaphnia cornuta* has a superior reproductive potential and a more rapid population growth with greater longevity than that of the horned, small-eyed form. Without fish predation, the large-eyed form can rapidly outcompete the less conspicuous form, but under predation pressure, the form with the small eye, although growing more slowly, can coexist because of reduced visibility to the predator. Similar results were found in the effects of fish predation on *Bosmina* (Zaret and Kerfoot, 1975; Hessen, 1985b). Prey selection was found to be related to the large, black pigmented eye, and body size was of negligible importance. Size-biased feeding by fish that select the larger species of a zooplankton community or larger members of a single species has been documented in at least 20 species of fish (reviewed in Gerking, 1994). Particulate turbidity, particularly clay turbidity common to many reservoirs, reduces visibility and the distance at which predator–prey interactions occur (Abrahams and Kattenfeld, 1997). This constraint will reduce the predation risk on zooplankton by fish in turbid aquatic ecosystems.

As lakes become more eutrophic, a greater proportion of the phytoplankton biomass and productivity often results from large algae (mostly colonial or filamentous; cf. Chap. 15). The larger algae interfere with food collection to a greater extent in larger cladocerans, causing reduced growth and fecundity, than in smaller cladoceran species that feed on small particles (Gliwicz, 1980; Gliwicz and Siedlar, 1980). In this way, larger cladocerans can experience a reduced efficiency of food collection under eutrophic conditions and may consequently be selected against. Such interspecific competition, in addition to size-selective predation, could contribute to the reduction of larger zooplankton.

E. Size-Efficiency Hypothesis

When size selection by fish is not in effect and large zooplankters are present, a common observation is that the smaller-sized zooplankton are not generally found to co-occur with the larger forms. Brooks and Dodson (1965; Brooks, 1968) developed the size-efficiency hypothesis in an attempt to explain the commonly observed inverse relationship between the abundances of small- and of large-bodied herbivorous zooplankton in lakes. According to this hypothesis (Hall *et al.*, 1976):

a. Planktonic herbivorous zooplankton compete for small particles (1–15 μm) of the open waters.
b. Larger zooplankton filter more efficiently and can also take larger particles. This greater effectiveness of food collection leads to relatively reduced metabolic demands per unit mass, permitting more assimilation to go into egg production by the larger herbivores.
c. Therefore, when the intensity of predation pressure by fish is low, the small planktonic herbivores will be competitively eliminated by large forms (dominance of large Cladocera and calanoid copepods).
d. When fish predation is intense, size-dependent predation will eliminate the large forms, allowing the small zooplankton (rotifers, small

Cladocera) that escape predation to become the dominants.

e. When predation pressure is moderate, larger zooplankton species are often kept at reduced populations that allow the coexistence of smaller competitors.

The basic assumptions of the size-efficiency hypothesis imply a complex successional pattern in which optimal body size increases while the range of persisting sizes decreases with decreasing food concentration (critically analyzed by Hall *et al.*, 1976; Zaret, 1980). Vertebrate predation restricts the maximum adult body size of zooplankton, and invertebrate predation may restrict the minimum size. Both of these effects can augment declines of zooplankton productivity caused by food limitations. Minimal food concentrations needed for growth among different species of *Daphnia* decrease as the size of the animals increases (Gliwicz, 1990). As a result, when predation pressure is low, larger cladoceran species should be more successful competitors for food. In contrast, the threshold food concentrations of small species of rotifers are lower than among large species, which is indicative that smaller rotifers are more energetically efficient per unit body mass than large species (Stemberger and Gilbert, 1987).

The size-efficiency relationships among fish and zooplankton, although not fully understood, have major implications on food-web structure and have led to a plethora of research on potential manipulation of food webs by fish introductions ("biomanipulation"). Fish predation clearly can influence species composition and size structure of zooplankton prey. Morphology, physiology, and behavior of prey can all be affected by size-biased feeding, which can lead to significant evolutionary alterations for predator avoidance. The cyclomorphosis among cladocerans, discussed earlier in this chapter, is at least in part a result of predation pressures. Similarly, vertical migration and other evasive behavior among zooplankton are partially induced by predation pressures (O'Brien, 1987; Ringelberg, 1991; Lampert, 1993). The migration behavior of many cladocerans upward as darkness occurs and downward as daylight approaches is most common among large, adult zooplankton, particularly females carrying eggs, that are most visible to fish. That migration occurs only when fish are abundant.

It is erroneous to assume that fish predation on zooplankton is the dominant means of mortality among larger zooplankton size classes (>1.0 mm). Mortality occurs by other, often unclear, factors even under nearly ideal growing conditions (e.g., Boersma *et al.*, 1996). Such factors include simple physiological death, often after resting egg formation, parasitism, microbial infection, invertebrate predation, and physical degradation (e.g., outflow and molar death in flowing systems).

F. Food Limitations in Zooplankton

Food limitation and food competition have not been demonstrated to be strongly in effect in natural populations. However, as discussed earlier, from experimental culture analyses, food limitations clearly can affect the life cycle and reproductive capacities of cladocerans and rotifers (Duncan, 1989). Under food-limiting conditions, body size and mass are reduced, the number of instars or prereproductive period to reproductive stages increases, the duration of development is prolonged, and fecundity is reduced. The threshold concentration at which food limitation occurs is not a constant for a species, but varies with the quality of the food. For example, lipid ingestion from algal food and storage is positively correlated with reproductive success and the threshold for starvation and food limitation (Tessier *et al.*, 1982, 1983). Even under extreme food limitation, some energy is invested into reproduction.

Clearly, food limitations interact with size-selective predation to regulate population dynamics within zooplankton communities. For example, population densities of zooplankton of a shallow temperate lake were affected much more by experimental manipulations of food availability than by manipulations of fish predation. Increases in birth rates and declines in mortality rates resulted from increased phytoplankton availability among cladocerans, some copepods, and rotifers (Vanni, 1987). The densities and size of a few cladoceran populations were reduced by planktivorous fish predation, and size at time of reproduction was smaller. However, flexibility in *community* life history traits allowed the zooplankton to withstand intense size-selective predation by planktivorous fish.

Food competition in nature is uncommon because of (1) the few times of the year when zooplanktonic populations can even approach the potential of completely removing particulate material from the water of certain strata by filtration, as discussed earlier, and (2) the presence of an excess of algae, bacteria, and particulate detrital organic matter beyond what can ever be consumed (most synthesized organic matter is decomposed in nonpredatory pathways; see Chap. 23). Experimental evidence on these food relationships is weak or negative (see, e.g., Sprules, 1972; Dodson, 1974a; Neill, 1975; Gliwicz and Prejs, 1977; Boersma and Vijverberg, 1996) but does not exclude important food-quality interactions.

A much more plausible explanation is again a size-selective predation, but a predation by the larger zooplankters rather than by planktivorous fish. Such predation occurs among the size range of zooplankton that is smaller than can be utilized effectively by fish. A large number of studies have shown that invertebrate predation can be sufficient to eliminate certain smaller species and that this predation, as with some fish, is size-selective (cf. review of Zaret, 1980). Larger copepods, especially, and other predators such as *Chaoborus* and the cladocerans *Leptodora* and *Bythotrephes* are particularly effective in causing significant mortalities of small zooplanktonic species (see, e.g., McQueen, 1969; Anderson, 1970; Dodson, 1970, 1972; Confer, 1971; Confer and Cooley, 1977; Confer and Applegate, 1979; Murtaugh, 1981; Lehman, 1991). While fish planktivory is visual and size-selective, invertebrate predation is more tactile since the eyes of rotifers, crustaceans, and most insects detect light intensity and movements but do not form images. This relationship of size selectivity and tactile responses in consumption suggested to Dodson (1974b) that the shape of prey within the correct size range can influence whether the prey is taken or rejected. Thus, cyclomorphic polymorphism would have an adaptive advantage for prey in both invertebrate predation by morphology and vertebrate predation by reduction of visibility, while still permitting growth.

It should also be noted that in the absence of intense size-selective predation by fish, large cladoceran species could dominate because they possess greater reproductive rates (intrinsic rates of increase, r) (Goulden *et al.*, 1978). Even though smaller species mature earlier than larger species, the larger forms have higher fecundities (number of young produced per female per day, b), which results in higher rates of increase.

G. Changes in Predation Effects in Shallow Lakes with Macrophytes

The pelagic fish–zooplankton interactions become more complex in shallow lakes (see Chap. 20). Total productivity and particularly fish biomass per unit volume tends to be much higher in shallow lakes than in deep lakes. Similarly, biomass of benthic invertebrates per unit area is higher in shallow lakes, and as a result fish feeding tends to be less dependent on zooplankton prey than in deep lakes (Jeppesen *et al.*, 1996, 1997). Fish tend to shift feeding between zooplankton and benthic animals as changes in prey densities occur seasonally. In pelagic areas of shallow lakes, cladocerans tend to be severely impacted by predation as the effectiveness of vertical migration is reduced. As a result, grazing pressure on phytoplankton is often reduced. Predation of zooplankton by benthic and planktivorous fish is reduced markedly in shallow lakes rich in submersed macrophytes (Jeppesen *et al.*, 1998). The littoral areas serve as a refuge for pelagic cladocerans. As a result, the grazing of both phytoplankton and bacterioplankton among the submersed macrophyte areas can be increased. Much of the nonmacrophyte primary productivity within the littoral areas shifts to the algae and cyanobacteria that are attached to the surfaces of macrophytes and other substrata (see Chap. 19).

The additional presence of piscivorous fish tends to reduce fish planktivory on zooplankton in the pelagic regions of shallow lakes. The presence of piscivores causes small planktivorous fish to make greater use of vegetated habitats and reduced use of pelagic habitats (Turner and Mittelbach, 1990). Planktivory was reduced and larger cladocerans tended to increase in the pelagic areas because of the avoidance of planktivorous fish of predation by piscivores.

XIX. ZOOPLANKTON PRODUCTION

The production rates of specific populations of zooplankton refer to the net productivity or the sum of the growth increments of all specimens of the population. This net productivity excludes maintenance losses (respiration and excretion) and includes the growth increments of the animal itself as well as the biomass produced as gametes and as exuviae during molting. In some larger invertebrates and some vertebrates, the productivity values of specific animal populations are influenced markedly by emigration and immigration. The productivity measurements are complicated when predation causes removal of a significant portion of the population; this loss to the population can be difficult to evaluate accurately.

The methods of estimating the rates of production of a specific population demand an accurate evaluation of the distribution of the organisms, the different stages of development and age, and the generation times. All of these parameters vary among species, seasonally, and under changing environmental conditions and require alterations in methods of sampling, analyses of biomass within each age group, and frequency of sampling. Sampling intervals must be kept shorter than the generation times of the animals.

The manner in which production rates of a specific population are estimated depends on the particular life cycle, reproductive characteristics, and generation

times (discussed at length in Edmondson and Winberg, 1971; Winberg, 1971; Edmondson, 1974; Bottrell *et al.*, 1976; Rigler and Downing, 1984; Benke, 1984, 1993). The productivity of a species with a long life cycle and a short period of reproduction is determined relatively easily if individuals are of the same age or if separate cohorts can be recognized and their biomass determined. In such a situation, after the brief period of reproduction, no recruitment occurs to confound estimates of growth and mortality. When reproduction and recruitment to the population are continuous, estimation of production is more involved. In this latter case, which applies to most zooplanktonic populations, cohorts overlap, which makes it difficult to separate changes in their abundance and biomass over time. Consequently, it is necessary to estimate finite birth and growth rates of individuals and evaluate changes in biomass over the life cycle from birth to death. Several simple examples were cited for growth rates of specific cohorts in earlier discussions.

A. *P/B* Ratios

An index of productivity that has become widespread in European and Russian literature in recent years is the P/B coefficient, the ratio of production (P) to biomass (B) (cf. Chap. 8). As indicated earlier, B is a measure of mass for a population present at one point in time in units of mass per unit area or volume and is therefore a temporary storage of mass or energy. P is a flow or flux of mass or energy per area per time. The ratio (P/B) of production (P) divided by mean biomass (B) is a rate with units of inverse time (e.g., 1/yr). P/B is essentially a weighted mean value of biomass growth rates of all individuals in a population (Benke, 1993).

P/B ratios can be useful as an estimate of the turnover of a population and is used for comparative purposes of population growth in response to environmental conditions and perturbations. In the case of a cohort, the cohort P/B ratio is equal to the cohort production divided by the mean cohort biomass (Waters, 1969, 1977; Benke, 1984). The annual P/B ratio is the annual production divided by the mean biomass of the entire 12-month period, even though the generation under study may have been present for less than a year (Wetzel and Likens, 2000). Mean annual biomass is simply the mean of all monthly average biomass values.

In populations with a constant age structure and biomass, a rarity in nature, the P/B ratio is relatively constant. The ratio varies in most situations when age structure, biomass, and growth are discontinuous; what is obtained is an average ratio over an interval of time (e.g., McLaren and Corkett, 1984). Multiplication of the P/B ratio by biomass yields an estimation of production during that interval of time. This ratio is analogous to the turnover rate and is also the reciprocal of P/B, the turnover time, which is the average duration of the life of a species under a given set of growth conditions. Biomass turnover times vary from a few hours for protistan zooplankton to a large range of 1.7 days for rotifers to well over 100 days for large zooplankton under poor growth conditions (Table 16-17). A comparative analysis of the P/B ratios of all major components of the plankton of mesotrophic Lake Constance, southern Germany, showed relatively similar results (Table 16-18). Although heterotrophic plankton biomass was on average twice as large as phototrophic biomass, phytoplankton contributed ca. 69% to the total plankton production in comparison to 19% for microbial plankton (bacteria and protists) and 11% for metazooplankton (Straile, 1998). Thus, autotrophic plankton production was twice the heterotrophic production in the water column (not the lake).

The P/B ratio is an expression of some value in comparing annual productivity among water bodies. However, it masks the large variations that occur within the population dynamics over a year (see, e.g., Straile, 1998). When used indiscriminately, the ratio relates few of the internal population characteristics or, more importantly, of the causal interrelationships leading to the resulting dynamics and productivity. Over brief periods of time, under relatively steady environmental conditions, the turnover rates reflect the relative growth of the populations.

B. Estimates of Zooplankton Productivity

Very few estimates of the annual production of protozoan and other protistan zooplankton communities have been made in lake ecosystems. Nonetheless, the few values given in Table 16-19 indicate that the production by the microzooplankton can be a significant portion of the total and at times exceed that of the larger zooplankton.

Many studies have estimated the productivity of zooplankton (e.g., Morgan *et al.*, 1980). A few examples illustrate the ranges encountered in aquatic ecosystems of differing primary productivity (Tables 16-17 and 16-20). Of many environmental factors regulating the seasonal production cycle of zooplankton, rates of biomass production are set largely by temperature (Shuter and Ing, 1997). Levels of biomass accumulation in zooplankton are set largely by food resource availability and individual body size. In general, a posi-

tive correlation exists between the rates of production of heterogeneous phytoplankton communities and of the heterogeneous micro- and macrozooplankton communities among many different reservoirs and natural lakes (Table 16-21; see, e.g., Winberg *et al.*, 1970; Makarewicz and Likens, 1979; Brylinsky, 1980; Richman *et al.*, 1984; Rublee, 1992; Canfield and Jones, 1996). Similarly, horizontal gradients in zooplankton productivity within a lake are often directly correlated to differences in the gradients of primary productivity. However, these statements do not necessarily imply that the herbivorous zooplankters are consuming the algae directly in proportion to their biomass and growth. As was discussed earlier, size, quality, and other factors influence both the ingestion and assimilation of algae. Moreover, much of the algal production enters the detrital pathways of nonpredatory particulate and dissolved organic matter (cf. Chap. 23). Phagotrophic utilization of detrital particulate organic matter with associated microbes is clearly a major route of primary productivity, and that much of the resultant protistan productivity never enters rotiferan and microcrustacean productivity.

Certain algal species are clearly impacted by zooplankton grazing, and many algal species are only minimally impacted by zooplankton grazing. The percentage assimilation of phytoplankton primary productivity by herbivores is nearly always <25% (e.g., Table 16-20).

In a detailed and perceptive study of the relationships between phytoplankton and zooplankton of mesotrophic Lake Erken, southern Sweden, Nauwerck (1963) demonstrated that algal productivity was inadequate to support the herbivorous zooplanktonic

Herbivorous zooplankton	26	0.84
Carnivorous zooplankton	25	0.84
Herbivorous benthic organisms	15	0.61
Carnivorous benthic organisms	14	0.72

[a] After data of Brylinsky (1980). All values significant at the 99% level.

productivity.[9] The filter-feeding zooplankton, which accounted for a total productivity of 0.22 g m^{-1} day^{-1} on an annual mean basis, consisted of primarily *Eudiaptomus* (60%), with a turnover time of about 36 days (annual mean; 24 days during the ice-free period). The result, then, is a considerably modified trophic pyramid in which the transfer of energy to higher food levels is short-circuited, to use the words of Nauwerck, via the bacteria and particulate detrital organic matter (Fig. 16-41).

Utilization of bacteria and particulate detrital organic matter was demonstrated in numerous subsequent studies, even though the caloric content of the detrital material is relatively low. In a detailed analysis of carbon pathways among the plankton of a humic lake, most of the particulate organic carbon available for zooplankton was detritus of relatively low nutritional value (Hessen *et al.*, 1990). Ingestion of detrital particles was, however, the major source of food and provided 46–82% of body carbon to the zooplankton. Bacterial organic carbon supplied some 11–42% and phytoplankton organic carbon 6–19% of body carbon to the zooplankton. Pelagic community respiration was high, amounting to some two-thirds of the production.

In another important study, the fate of primary production in the pelagic food web of a mesotrophic lake in midsummer was determined (Lyche *et al.*, 1996). Specific carbon assimilation rates of bacteria were twice those of phytoplankton, and 70% of the bacterial production was fueled by phytoplankton exudates. About half of the gross primary production was lost as excreted dissolved organic carbon and ca. 10% was respired. Only 20% of the net primary production was assimilated by consumers; the remainder was lost as dissolved and particulate detritus or by sedimentation. Of the net bacterial production, a third accumulated as bacterial biomass, a third was assimilated by bacterivores, and a third was lost as detrital dissolved organic matter. Less than 2% of the gross primary production was incorporated into consumer biomass. Clearly, most organic carbon of the microbial food web did not act as a source of carbon to higher consumers but was utilized in the detrital food chain and respired by microbial heterotrophs.

In similar fashion, the greater part of the herbivorous zooplanktonic productivity is not utilized by predatory zooplankton and fish, but instead enters the nonpredatory detrital pathways of decomposition and is partially reutilized by filter feeders as bacteria and detritus. Therefore, Lindeman's classic conceptualization of the generalized lacustrine food-cycle relation-

[9] Certain computational errors have been found in the original paper but these do not alter the general conclusions.

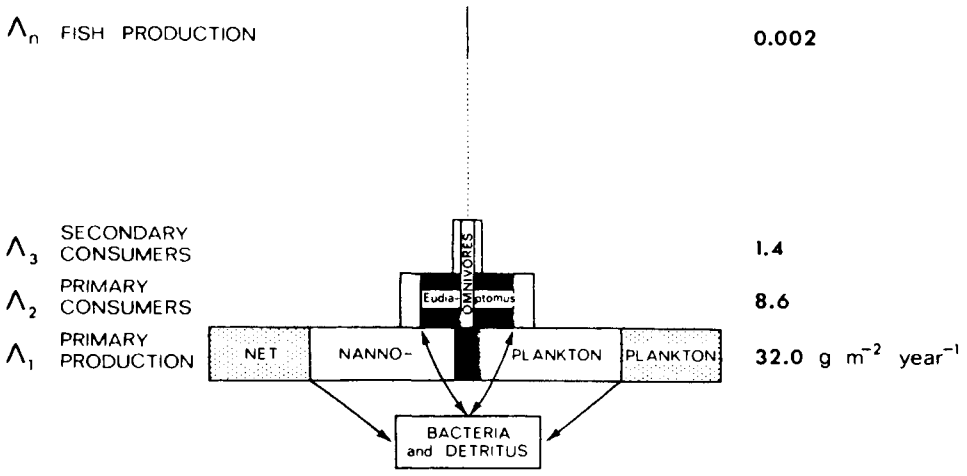

FIGURE 16-41 Diagrammatic representation of the trophic relationships in Lake Erken, Sweden. (Modified from Nauwerck, 1963.) Productivity estimates in g dry weight per m^2 per year of pelagic zone only.

ships must be modified to emphasize the importance of nonpredatory detrital and bacterial pathways (Fig. 16-42); these pathways were underestimated because inadequate data were available when the cycle was formulated (cf. Rich and Wetzel, 1978). This change does not greatly alter the fundamental contribution of Lindeman, but instead properly emphasizes the major contributions of bacteria and detritus in the trophic relationships of primary consuming animals and major losses of organic matter through decomposition that occur without animal consumption (cf. Chap. 22).

Other comparisons of the proportions of herbivorous zooplankton utilized by predators demonstrate similar results. In detailed studies of nine very different lakes in the Soviet Union, the biomass of predators varied from 6.5 to 52% of the total biomass of zooplankton, averaging about 30% (Winberg, 1970). The productivity of the filter-feeding zooplankters is distinctly higher than that of the predacious zooplankters (Table 16-20). Variation is great, however, particularly in relation to temperature, food quantity and quality, and other factors. Comparisons over two or more years with good sampling show the extent of variation that can occur with the same species in the same lake (Table 16-20; Fig. 16-43). These differences are much greater than can be attributed to sampling and measurement errors. Perhaps the lowest production rates of zooplanktonic populations in a permanent lake are those of polar Char Lake at latitude 74° in the Canadian Arctic (Rigler, 1974). The dominant zooplankters *Limnocalanus macrurus* and *Keratella* produced 261 mg ash-free dry weight per m^2 per year and 3 mg m^{-2} yr^{-1}, respectively. This is equivalent

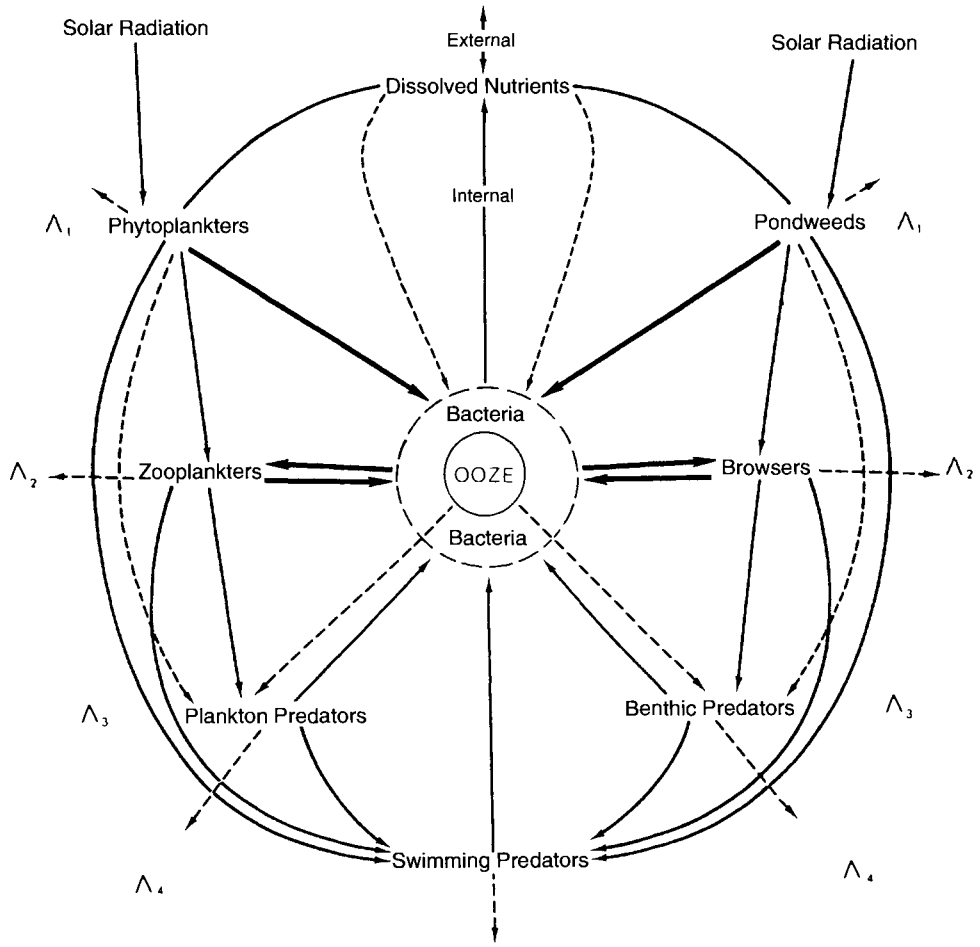

FIGURE 16-42 Generalized lacustrine food-cycle relationships after Lindeman (1942). Added darkened arrows indicate pathways ignored or underestimated in Lindeman's actual calculations, a consequence of accepting existing data on chemical assay of crude fiber in place of direct assimilation or egestion measurements. (From Wetzel, R. G., Rich, P. H., Miller, M. C., and Allen, H. L.: Metabolism of dissolved and particulate detrital carbon in a temperate hardwater lake. *Mem. Ist. Ital. Idrobiol.* 29(Suppl.):185–243, 1972.)

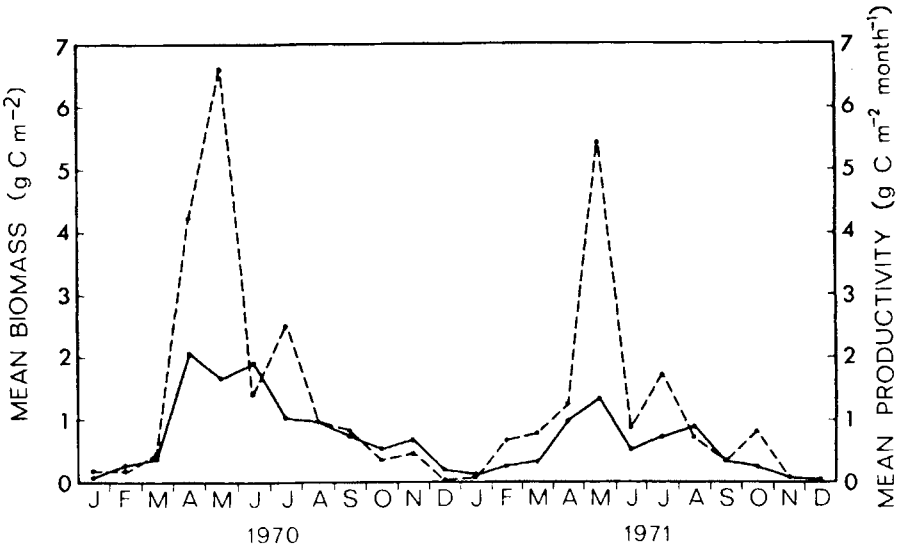

FIGURE 16-43 Seasonal monthly mean biomass (———) and productivity (- - - -) of *Daphnia hyalina* in g C m^{-2} month^{-1}, calculated from daily measurements, of Eglwys Nyndd, Great Britain. (Drawn from data of George and Edwards, 1974.)

to an annual average of about 0.00006 g m^{-3} day^{-1}, an exceedingly low value. In the particular case of *Daphnia hyalina* in a eutrophic reservoir (Fig. 16-43), maximum biomass was found nearly two months before highest numerical density in 1970, but numerical and biomass maxima were coincident the following year (George and Edwards, 1974). Maximum spring biomass occurred during blooms of green algae in late April and early May, when many *Daphnia* survived and grew for some time after reaching maturity. Increases in production coincided with, or lagged somewhat behind, increases in biomass. In the second year, the production was about one-half that of the first year, and the average biomass turnover time also decreased (Table 16-20).

From an intensive analysis of the zooplankton productivity of oligotrophic Mirror Lake, New Hampshire (Makarewicz and Likens, 1979), two major relationships emerged. (a) Rotifers are a major component in energy transfer and intrasystem nutrient cycling. The major importance of rotifers in the transfer of energy is evident in a number of lakes of varying trophic status, from oligotrophic to eutrophic (Table 16-22). One-third of the annual phosphorus flux through the zooplankton of Mirror Lake was by the rotifers. (b) The productivity of the different species of zooplankton, shown in Figure 16-44, indicates how the interacting populations are structured. The population positions or niches are dispersed in relation to complex gradients of time, depth, food, reproduction, and predation (cf., e.g., Zaret, 1975, 1980; Kerfoot and Pastorak, 1978; McNaught, 1978; Seitz, 1980; Kerfoot, 1980a; Sommer *et al.*, 1986; Lehman, 1988). Separation of the niche hyperspace with relatively small regions of species overlap minimizes interspecific competition. Throughout the discussion in this chapter, emphasis has been on the general similarities and often subtle but important differences and separations that occur in feeding, food utilization, reproduction, growth, and behavioral characteristics, the temporal (daily and seasonal) and spatial differences in distribution and growth, seasonal changes in morphology, and various characteristics of predator avoidance and predation effects. All of these factors contribute to the large diversity of population competitive interactions that have evolved to permit coexistence in limnetic zooplankton communities.

The efficiency of energy transformations between components of animal populations is an area of intensive investigation. At present, few cases have been studied in detail among natural populations; much of the

necessary information on ingestion, respiration, and egestion is determined under controlled laboratory conditions that have been applied variously to natural populations. A certain percentage of the food ingested is not utilized. As a percentage, this egestion rate varies greatly with age, the quantity and quality of food available, and other factors within an observed range of about 30–90% loss (Table 16-23). How much of this egested detrital material is reingested by coprophagy is unclear, at least among the pelagic organisms. Consumption of feces after varying periods of colonization and decomposition by bacteria and fungi is a fairly common phenomenon among benthic fauna of lakes and streams.

The rates of assimilation and respiratory loss for biochemical maintenance also vary widely with environmental conditions (Table 16-23). Assimilation efficiency is generally greater among young animals and decreases with age; average values, mostly determined under experimental conditions better than those *in situ*, are in the range of 10–50%. Assimilation efficiency of course decreases with increasing food concentrations (e.g., Sharma and Pant, 1984). Respiratory costs are high and, as would be anticipated, increase greatly relative to assimilation rates under adverse conditions. For example, the population respiration of the dominant zooplankter of the Canadian Arctic Char Lake, with a maximum water temperature of about 4°C for one month of the year, far exceeded net production (Table 16-24). The ratio of production to assimilation was about 13%.

TABLE 16-24 Mean Production and Respiration of the *Limnocalanus macrurus* Population in Polar Char Lake, Canadian Arctic, over a 4-Yr Period[a]

Production and respiration	*Mean mg m^{-2} yr^{-1}*	*% of total*
Growth	220	11.1
Eggs	5.6	0.3
Exuviae	34.9	1.8
Total production	261	13.1

[a] From data of Juday (1940), Teal (1957), Odum (1957), and Lindeman (1942), as interpreted by Koslovsky (1968), and from Comita (1972).
The lake systems are planktonic only and do not consider littoral and allochthonous inputs, and therefore account for as little as 10% of total ecosystem metabolism.

[b] I = insolation for producers or food ingestion for organisms. Egestion includes nonutilized light and egestion. R includes all energy losses; also urine in higher organisms. Production refers here to that portion of productivity passed on to next trophic level, some of net productivity being dissipated in decomposition, tissue accumulation, and loss from the system.

TABLE 16-26 Phytoplankton Photosynthetic Efficiency and Secondary Production Energy Transfer Efficiencies[a]

Component	*Sample size* (N)	*Mean percentage efficiency*	*Range of efficiencies* (%)
Phytoplankton	93	0.34	0.002–1.0
Herbivorous zooplankton	27	7.1	0.10–27.4
Carnivorous zooplankton	24	1.2	0.17–5.0

Carnivorous benthic animals	16	0.3	0.35–1.8

[a] After data of Brylinsky (1980).

Of the production that is utilized for growth and reproduction, usually a small portion is utilized in the diapause stages such as in overwintering eggs. Most of the production enters the nonpredatory pool of detrital organic matter and is decomposed by microorganisms. A variable proportion is utilized by predators. The percentage of the primary consumers to appear as net production of secondary consumers also varies but generally averages around 5–10% or less on an annual basis (e.g., Comita, 1972; Lyche *et al.*, 1996). As was discussed earlier, however, at certain periods of the year, the impact of herbivores and predators can be quite significant, and they can literally decimate populations of the primary producers.

In discussing the roles of zooplankton in the general trophic-level concept (cf. Chap. 8), it should be recalled that trophic levels consist of population groups of different species of organisms that utilize the same mode of nutrition. However, many of the species change their mode of feeding to another trophic level in the course of their life cycles. As was emphasized earlier in this chapter, animal nutrition is strongly dependent upon food density, quality, and many other factors. As a result, the efficiency of food utilization for growth and maintenance varies with the rate of food consumption and population densities. These efficiencies are only reasonably accurate when the populations studied are in a fairly fixed state of equilibrium (Slobodkin, 1960); however, this condition rarely exists among natural populations, since they frequently undergo large fluctuations. Under controlled conditions, metabolic efficiencies of food utilization by particular species have rigorous meanings from a physiological point of view (e.g., Lucas, 1996). Extrapolation of these efficiencies to the complex dynamics of natural systems, however, can only be done in a general way. The evaluation of ecological efficiencies among trophic levels is really only a theoretical way of viewing the interrelationships among organisms. Such an evaluation loses precision as soon as it is extended beyond measurements of solar radiation in studies of primary productivity. Such analyses can be instructive, however, if one can keep in mind the limitations imposed by their simplicity. By way of examples, five freshwater systems are compared in Table 16-25, based on mostly incomplete, rather limited data. In a detailed analysis of the numerous types of efficiency relationships developed by many workers, Kozlovsky (1968) used most of these limited data to illustrate changes taking place in the passage from one trophic level to the next. Some of his conclusions follow, the most important of which is that when the net productivity and assimilation of one level are compared to the net productivity and assimilation of the previous level, the efficiency of transfer is practically constant at about 10% (Table 16-26). In more physiologically based comparisons of food utilization in animals in relation to food ingested, assimilation and respiration increase at higher trophic levels. It then follows that in relation to ingestion and assimilation in animals, production decreases at higher trophic levels.

XX. ZOOPLANKTON AMONG AQUATIC ECOSYSTEMS

Comparative examination of zooplankton communities and their productivity among river, reservoir, and lake exosystems indicate several consistent characteristics (Table 16-27). Although smaller taxa dominate in river ecosystems in comparison to zooplankton in reservoirs and lakes, diversity is large, particularly among the protists and mesozooplankton. The separation of the protistan mesozooplankton from the larger macrozooplankton of rotifers, copepods, and cladocerans becomes most distinct in natural lakes. Zooplankton of rivers and reservoirs tend to rely to a greater extent on detrital particles and associated attached microbes than is the case among zooplankton of natural lakes, where feeding is largely on phytoplankton (Table 16-27). The growth of zooplankton is often limited in rivers and reservoirs of short retention times by water movements, food availability, and relatively high turbidity. The growth of zooplankton in natural lakes is high but fluctuations are strongly influenced by both resource availability and changes in predation pressures.

TABLE 16-27 Comparative Characteristics of Zooplankton among River, Reservoir, and Natural Lake Ecosystems[a]

	Rivers	*Reservoirs*	*Natural lakes*
Zooplankton community structure	Dominated by small forms, such as protists, bosminids, and juvenile copepods; dominant planktonic species have relatively rapid life cycles or are predominantly benthic	Gradient between smaller forms with protistan dominance in riverine portions to common lake forms in lacustrine portions	Strong separation into protistan-dominated mesozooplankton and the macrozooplankton of mostly rotifers, copepods, and cladocerans
Zooplankton community development	Low development; source areas from lakes and floodplain pools; mortality high from molar action and reproduction rates longer than displacement times downstream	Maximum development common in transitional zone; horizontal patchiness high	Vertical and seasonal gradients predominate; horizontal patchiness moderate and coupled to hydrodynamics; relatively high stability and abundance
Zooplankton feeding	Particulate detritus commonly augments algae from planktonic and benthic sources	Particulate detritus, including adsorbed DOM, variably augments phytoplankton as a source of nutrition	Phytoplankton is a predominant food source; consumption of food resources strongly influenced by predator regulation of size of dominating zooplankton
Zooplankton growth	Low; greatest in intermediate- or high-order rivers; limited by unidirectional flow, high turbidity, and low dissolved oxygen	Low to moderate; variable with changing food availability and quality, often limited during periods of high turbidity	Moderate to high; extreme fluctuations mediated by both resource availability and predation pressure variances

[a] Assembled from the syntheses on rivers by Ryder and Psendorfer (1980) and on reservoirs and lakes by Wetzel (1990) and many sources cited in these papers.

XXI. SUMMARY

1. Zooplankton of inland waters are dominated by four major groups of organisms: (a) protists that include protozoa and functionally similar protists, in particular the heterotrophic flagellates, (b) rotifers, and two subclasses of crustaceans, (c) the cladocerans, and (d) the copepods.
2. Protistan zooplankton are the most important microbial consumers and have major functions in organic carbon utilization and nutrient recycling. The instantaneous biomass of planktonic protists is small in comparison to other zooplankton, but generation rates of protists are high.
   a. Flagellates are the most abundant component of the protozooplankton and are often mixotrophic, feeding on bacteria as well as fixing carbon photosynthetically.
   b. Ciliates are largely holozoic and have high feeding rates on bacteria, algae, particulate detritus, and other protists.
   c. Sarcodine protozoa only occasionally reach modest abundance, and their production is usually <10% of combined ciliate and flagellate production.
   d. Many pelagial protozoa are meroplanktonic in that only a portion, usually in the summer, of their life cycle is planktonic. These forms spend the rest of their life cycle in the sediments, often encysted throughout the winter period.
   e. Mixotrophic ciliates and flagellates usually occur in the upper water strata. Migration is common among flagellates on a diurnal basis in relation to light, food, and dissolved oxygen conditions.
   f. Many protists feed on bacteria-sized particles and picophytoplankton and thereby utilize a size class of bacteria, algae, and particulate detritus generally not as effectively utilized by larger zooplankton. Bacterivory by the protozooplankton, particularly the flagellates, is likely a dominant mortality factor for bacterioplankton (cf. Chaps. 17 and 23) and frequently removes 20–60% of the algal picoplankton (<2 μm in size). Assimilation efficiency for growth and reproduction of protists is approximately 40%.
   g. Flagellate and ciliate abundance and production is directly correlated to those of phytoplankton during the winter, spring, and summer. Ciliate predation on flagellates is a major regulatory mechanism, particularly during summer and among more productive lakes.
3. Flagellate growth rates are much greater than those of ciliates. In addition, flagellate densities are greater by a factor of ca. 1000 in comparison to ciliates. As a result the heterotrophic flagellate production equals or exceeds that of ciliates.
4. The "microbial loop" is a model of pathways of carbon and nutrient cycling through microbial components of pelagic aquatic communities (Fig. 16-7). Many direct links exist among algae, bacteria, and heterotrophic protists. Protistan bacterivores can function as decomposers and efficient nutrient remineralizers. Some of the fixed organic carbon can be converted into larger-sized microorganisms that may be consumed by larger metazoans and zooplankton. Under many conditions, the microbial loop functions as both a carbon and nutrient "sink", by which organic matter is respired and is not directly available to higher animals and nutrients are recycled.
5. Although most rotifers are sessile and are associated with the littoral zone, some are completely planktonic; these species can form major components of the zooplankton.
   a. Most rotifers are nonpredatory and omnivorously feed on bacteria, small algae, and detrital particulate organic matter. Most food particles eaten are small (<12 μm in diameter).
   b. A few rotifers are predatory on protozoa, rotifers, and small crustaceans and can alter their size in response to changes in food size.
6. Most cladoceran zooplankton are small (0.2–3.0 mm) and have a distinct head; the body is covered by a bivalve carapace. Locomotion is accomplished mainly by means of the large second antennae.
   a. Most cladocerans feed on particles filtered from the water by means of setae and hairs on five pairs of legs. Particles collect and move in a ventral food groove toward the mouth.
   b. A few cladocerans are predaceous and seize other zooplankton and detrital particles with prehensile legs.
7. Planktonic copepods consist of two major groups, the calanoids and the cyclopoids. These two groups are separated on the basis of body structure, length of antennae, and legs (Fig. 16-12; Table 16-7).
   a. Cyclopoid copepods are raptorial; they seize food particles and draw them to the mouth. Many cyclopoids are carnivorous on other zooplankton; some are herbivorous on a variety of unicellular and filamentous algae. Locomotion is by movement of appendages, which results in short, rapid swimming movements.
   b. Calanoid copepods swim more continuously in rotary motions, which set up currents that carry

particles to modified structures of the maxillae. Particles that are retained are governed by the capture efficiency of the maxillae and differ among calanoid species.

8. Filtration of particles is the dominant means of food collection by rotifers and cladocerans.
   a. *Filtration or grazing rate* is the volume of water containing particles that is filtered by the animal in a given time, regardless of whether or not the particles are retained or ingested. *Feeding rate* is the quantity of food ingested in a given time.
   b. Many zooplankton possess some capacity for selective feeding.
      i. Among suspension-feeding rotifers, food selectivity occurs in some species by several food-rejection mechanisms (screening of particles by cilia or rejection of particles once ingested).
      ii. Among cladocerans, the size of particles cleared from the water is a function of the morphology of the setae of the moving appendages. Feeding rates commonly stabilize or decrease as concentrations of food particles increase.
   c. Filtering rates tend to increase with both increasing body length and increasing temperatures. The size of particles ingested is generally proportional to body size.
   d. The effectiveness of zooplankton grazing varies greatly seasonally and among lakes. Throughout much of the year, zooplankton grazing only filters a small proportion of the water volume (<15% per day), At certain times of the year, grazing can remove large portions of the phytoplankton and can cause marked reduction in phytoplankton productivity.
   e. The effectiveness of zooplankton grazing on phytoplankton is greatest in lakes of intermediate productivity (mesotrophic). In oligotrophic lakes, nutrient availability dominates phytoplanktonic regulation, and in nutrient-rich eutrophic lakes, phytoplanktonic growth greatly exceeds mortality losses by zooplankton.
   f. Algal species succession can also be altered by intensive, selective (usually size-specific) grazing and concomitant regeneration of nutrients. Certain algae can survive gut passage, and their growth can be enhanced by contact with high nutrient levels within the gut of zooplankton.
9. Assimilation efficiency is variable among zooplankton species but is usually <40–50%.
   a. The efficiency of assimilation increases somewhat with higher temperatures and decreases markedly with increasing food concentrations.
   b. Food quality also influences assimilation efficiencies. Rates of assimilation are low when zooplankton are feeding on detritus particles, higher with bacteria, and generally highest when they are feeding on algae of acceptable size and type.
10. Lipids are dominant energy storage compounds in zooplankton (to 60–70% of their mass). Often food-limited in the summer, lipid reserves are essential to survival. Because lipids are largely of dietary origin and differ among species of algal food sources, the essential fatty acid nutritional quality of phytoplankton can be an important regulatory factor in species and seasonal succession of zooplankton.
11. Reproductive rates and life histories of zooplankton are diverse.
   a. Rotifers and most cladocerans reproduce by diploid female parthenogenesis for many successive generations during the main growing season. Under certain conditions of environmental stress, meiosis occurs, which leads to the production of haploid males and females. The fertilized eggs (resting eggs) are diploid and are encased in a heavy cell wall. These resting eggs often enter diapause, and hatching may be delayed for long periods. Under favorable conditions, resting eggs develop into amictic diploid females.
   b. A number of environmental conditions and mechanisms influence the production of sexual mictic females. Reductions in temperature, reduced food availability under crowded population conditions, and reduced availability of various dietary compounds (e.g., vitamin E) can induce sexual production in certain rotifers.
   c. Rates of growth and development of instars in Cladocera are generally proportional to temperature and are often related to food availability. Food supply is, however, of secondary importance to temperature; increased food supply usually increases the rate of population development by increasing fecundity (number of eggs per brood).
   d. Copepods are bisexual. Fertilized eggs are carried externally in egg sacs.
      i. Temperature determines the rate of egg production, and food availability directly influences clutch size.
      ii. Copepod eggs hatch into small, free-swimming larvae (*nauplii*) and molt successively through six naupliar stages. Nauplii then

enlarge and form *copepodites*, and molt through five additional instars before forming an adult. Development time to complete all of the immature stages is far more extended than in the rotifers and Cladocera and varies greatly among species and under different environmental conditions.

12. Analyses of the rates of egg production and the dynamics of instar populations yield information on growth rates, birth rates, mortality, and duration of generations.
    a. The seasonal distribution of planktonic rotifer populations is complex. Many perennial species exhibit maximal densities in early summer in temperate lakes. Other species are more seasonal and include (i) cold stenotherms with greatest populations in winter and early spring, and (ii) species that develop two or more maxima during summer. Certain rotifer species also tolerate low oxygen concentrations, and populations may be separated spatially as well as seasonally.
    b. Threshold food concentrations, at which population growth is zero, vary greatly among planktonic rotifers. High food concentrations and availability enhance growth, shorten juvenile stages, and accelerate reproduction. Predation is important, and generally rotifers cannot become abundant in the presence of large ($\geq$1.2 mm) cladocera and copepods either because of competition for food items or by mortality from mechanical interference during feeding of the larger zooplankton.
    c. The seasonal succession and population dynamics of Cladocera are also variable among species and under different lake conditions.
        i. Some species are perennial (overwinter as adults rather than as resting eggs) and may exhibit one, two, or more irregular maxima.
        ii. Aestival species have a distinct diapause (resting egg stage) and usually develop one population maximum in the spring, and occasionally a second maximum in the late summer or autumn.
        iii. Temperature increases in the spring enhance rates of molting and brood production; increased food supply increases egg number per brood. Shifts in food quality and availability (often size-restrictive), and especially predation by invertebrates and fish, can cause rapid changes in populations of cladocerans. Mortality by predation is normally highest in the summer.
    d. The life cycle of limnetic cyclopoid copepods is separated into two periods: (i) a period of growth followed by (ii) a period of retarded growth or diapause induced by a combination of decreasing water temperatures, photoperiod, reduced food availability, anoxia, and increased predation. The extent to which the population enters a resting stage, and the instar stage at which diapause occurs, is extremely variable. Similarly, the site where the resting stage occurs (water versus sediment) and diapause duration can vary greatly from lake to lake in arctic, alpine, and temperate areas. Diapausing eggs can remain viable in sediments for decades. In tropical lakes, resting stages have not been observed. The seasonal life cycles of the calanoid copepods are usually longer than those of the cyclopoids.
        i. Most cyclopoid copepods are carnivorous and influence the population dynamics of the other copepods by predation. They influence their own dynamics by cannibalism, especially of juveniles.
        ii. Competition between copepods is reduced by (a) variations in timing and duration of diapause, (b) seasonal and vertical (spatial) separation, and (c) differences in utilization of available food particles.
13. Zooplankton of rivers are similar to those of lakes but are dominated by small forms and are negatively correlated with water velocities. As river ecosystems enter reservoir impoundments, protistan and larger zooplankton densities, biomass, and biodiversity usually increase. Clay turbidity, common among reservoirs, often suppresses zooplankton growth and productivity by direct feeding interference and reduced food availability.
14. Many zooplankton, particularly the Cladocera, exhibit marked diurnal vertical migrations.
    a. Most species migrate upward from deeper strata to more surficial regions as darkness approaches and return to the deeper areas at dawn.
    b. Rates of movement over distances in excess of 50 m in certain clear lakes are variable from <2 m per hour among rotifers to >20 m per hour by certain Cladocera and copepods.
    c. Light intensity is the primary stimulus of vertical migration.
    d. Grazing rates of suspension feeders are usually several times greater during the dark period when they have migrated to upper water strata. The protein content of algal food is commonly higher during the dark period of the diurnal cycle.

e. Therefore, vertical migration upward during darkness and downward during the lighted period of the day is common behavior among cladocerans and copepods. Because fish predation is a visual process, such vertical migration occurs primarily among zooplankton that are most visible to fish, particularly those of large size and females that are carrying eggs. Although changes in relative light intensity are fundamental to the induction of vertical migration, the amplitude of phototactic response varies with the presence and activity of fish. Evidence indicates that fish can release chemical compounds (kairomones) that initiate and influence the vertical migratory behavior of zooplankton.

15. The horizontal spatial distribution of zooplankton in lakes is often uneven and patchy.
    a. Pelagial cladocerans and copepods also migrate away from littoral areas (avoidance-of-shore movements) by behavioral swimming responses to angular light distributions.
    b. In many cases, nonrandom dispersion of zooplankton is caused by water movements, in particular Langmuir circulations and metalimnetic entrainment of epilimnetic water.
16. Seasonal polymorphism, or *cyclomorphosis*, occurs among many zooplankton but is most conspicuous among the Cladocera.
    a. Changes in rotifer growth form include elongation in relation to body width, enlargement, reduction in size, and production of lateral spines. A predator-produced organic substance can induce spine production in certain prey rotifers, which reduces predation success.
    b. Cyclomorphosis in Cladocera often results in extension of the head to form a crest (helmet) with little change or only a slight decrease in carapace length (Fig. 16-38). Caudal spine length often increases.
        i. A combination of environmental parameters has been shown to induce internal growth factors (hormones) that influence differential growth: increased temperature, turbulence, photoperiod, and food enhance cyclomorphosis in daphnid cladocerans. Organic substances (kairomones) released by invertebrate and fish predators can also induce cyclomorphic growth as effectively as changes in temperature, turbulence, and oxygen.
        ii. The adaptive significance of cyclomorphic growth likely centers on reducing predation by allowing continued growth of peripheral transparent structures without enlarging the central portion of the body visible to fish. Small cladocerans that increase size by cyclomorphic growth reduce capture success by invertebrate predators (e.g., copepods).
    c. Cyclomorphosis is lacking in copepods, which, by means of rapid, evasive swimming movements, can defend themselves better from invertebrate predators than can most rotifers and cladocerans.
17. Planktivorous fish can be important in regulating the abundance and size structure of zooplankton populations. Prey are visually selected, in most cases, on an individual basis, although the gill rakers of certain fish collect some zooplankton as water passes through the mouth and across the gills.
    a. Size selection of prey by fish is governed by energy return obtained per unit of energy expended in foraging and by the abundance of prey. When prey are abundant, only larger prey are consumed; as prey abundance decreases, smaller prey are taken.
    b. Planktivorous fish select large zooplankters and can eliminate large cladocerans from lakes. Fish predation intensity must be very high to become the main determinant of the zooplankton community but can be sufficient to restructure the zooplankton community on the basis of size. The restructuring can lead to fewer large zooplankton of greater grazing capacities and reduced grazing mortality of phytoplankton.
    c. When size selection by fish is not in effect, and when large zooplankters are present, smaller-sized zooplankton are generally not found to co-occur with the larger forms. The cause is likely a result of size-selective predation of smaller zooplankton by invertebrates (copepods, phantom midge larvae, and predaceous Cladocera). Phytoplankton grazing is more effective by the larger forms and at certain times of the year and markedly reduces phytoplankton productivity.
18. The production rate (net productivity) of zooplankton is the sum of all the biomass produced in growth, including gametes and exuviae of molting, less maintenance losses from respiration and excretion. Emigration (e.g., outflow losses) and immigration of zooplankton from other aquatic habitats are usually negligible.
    a. A general, positive correlation exists between the rates of production of phytoplankton and of zooplankton (Table 16-20).
    b. Much of autotrophic production is not utilized

by herbivorous zooplankton, but instead enters detrital pathways as nonpredatory particulate and dissolved organic matter. Although particulate detritus has less energy content than living algae, detritus often augments the diet of suspension-feeding zooplankton.

c. The productivity of suspension-feeding zooplankton is higher than that of predaceous zooplankton.
d. The efficiency of assimilation of ingested food is somewhat higher in juvenile stages than in adults but is nearly always <50% in zooplankton. Most of the food is egested and enters detrital pathways, and some may be utilized by the protistan microbial community. Assimilated energy expended in respiration is usually <50%; the remainder is used for growth and reproduction. Assimilation and respiration rates generally increase at higher trophic levels, and production decreases.

X. Summary

Biochemical transformations of particulate and dissolved detrital organic matter by bacteria and fungi are fundamental to the structure and dynamics of nutrient cycling and energy fluxes within aquatic ecosystems. Although substantial gains are being made in our understanding, the entire subject of aquatic microbial ecology is an emerging frontier in limnology. The functioning and stability of aquatic ecosystems is governed by the metabolic transformations of organic matter by bacteria and fungi, yet few areas of understanding in aquatic ecology are in such comparative infancy.

Organic matter is synthesized either autochthonously within the lake, or allochthonously in terrestrial and wetland habitats and is imported to the lake as air and water carries organic matter to the rivers and lake basins. As we will see later, organic matter entering rivers and lakes from the landscape is mostly in dissolved form and is chemically modified by the flora and microflora of streams and wetlands before reaching the lake per se (Chap. 23). A major source of autochthonous organic matter is the phytoplankton. This organic matter is augmented with that synthesized by littoral aquatic plants and sessile photosynthetic microflora (Chaps. 18 and 19). Because most lakes are small and shallow, these littoral sources of autochthonous production often exceed those of the phytoplankton. These composite sources of organic matter form the base upon which all other lake-dwelling organisms depend for nutrients and energy.

Most photosynthetic organisms simply die, add their newly synthesized organic matter to the detrital components of the system, and undergo decomposition. Much of the reduced carbon of organic matter is eventually transformed by microbes to the oxidized state, CO_2. A small and highly variable portion of the total dissolved and particulate organic matter of the aquatic ecosystem, 1–10% on the average, is consumed by animals and is decomposed by their heterotrophic metabolism. In aquatic ecosystems, most organic detritus is metabolized by the bacteria and the fungi.

Decomposition is effective. The organic matter formed within or brought to a lake would quickly fill the basin if it were not decomposed, and the lake would cease to exist. Since decomposition is not complete, residual organic matter remains. Gradually the basin fills in, and the lake is transformed from an aquatic to a terrestrial ecosystem (Chap. 24). The rate of this development, or ontogeny, is governed by the heterotrophic microbial capacity to mineralize organic matter, which is in turn influenced by the geomorphology of the ecosystem and particularly the type (quality) of organic matter synthesized within it or imported to it (Chap. 23).

The ensuing discussion highlights contemporary understanding of the bacterioplankton and their metabolism. As we will see later (Chap. 23), much of the organic matter synthesized within the lake or brought to it from the drainage basin is not decomposed in the water, but instead is decomposed on or in the sediments. The biochemical transformations of organic matter displaced to the sediments are crucial to the operation of freshwater ecosystems and consequently deserve separate treatment (Chaps. 21 and 23).

1. THE ORGANIC CARBON CYCLE

It is perhaps most appropriate to begin discussion with the generalized composite organic carbon cycle of a lake (Fig. 17-1), modeled after the general discussions of Kuznetsov (1959, 1970), and to attempt systematically to provide a quantitative range for the reactions and processes involved among lakes of varying productivity. The sources and general composition of allochthonous and autochthonous organic matter in dissolved and particulate form are treated in some detail in subsequent chapters. Dead organic matter forming the

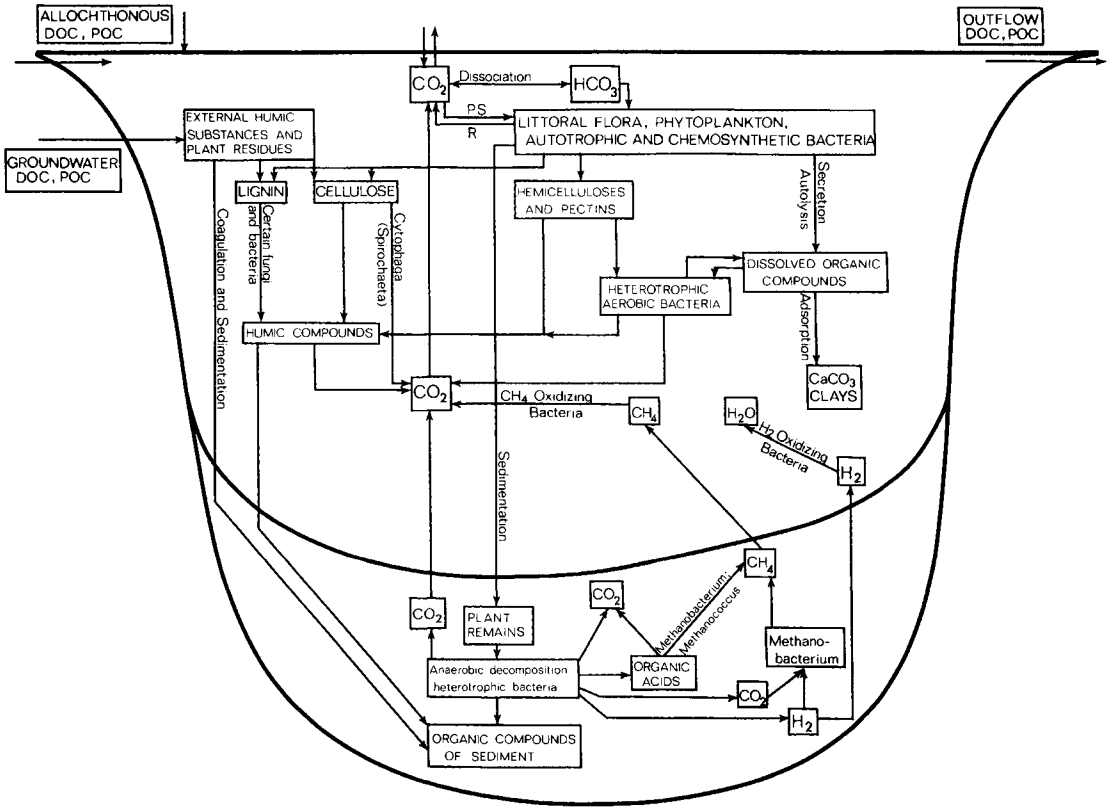

FIGURE 17-1 Simplified organic carbon cycle of a typical freshwater lake. DOC and POC = dissolved and particulate organic carbon; PS = photosynthesis; R = respiration. (Modified from Kuznetsov, 1959, 1970.)

detritus is separable into dissolved and particulate fractions, but it must be emphasized that this demarcation is only an operational separation made by the investigators. From a functional standpoint of the system, the energetic transformations of organic carbon are similar whether they are operating on a large particle or a dissolved organic compound. The rates of enzymatic hydrolysis and transformation differ because of the accessibility of the enzymes to the organic compounds and the chemical structure of the organic compounds.

Bacteria and fungi assimilate dissolved organic compounds, some of which they obtain through enzymatic degradation of particulate organic matter. Only transport of small, low-molecular-weight organic molecules occurs across cytoplasmic membranes in an enzymatic process with permases. Because most (>95%) dissolved organic matter (DOM) is composed of polymeric compounds of high molecular weight, only a small portion of DOM is rapidly utilizable in natural waters (Allen, 1976; Münster, 1985; Münster and Chróst, 1990). However, as will be demonstrated, bacteria can utilize polymeric substrates by a stepwise enzymatic depolymerization and hydrolysis (e.g., Hoppe, 1983, 1991) and by utilization of organic products generated by physical processes such as partial photolysis of the humic polymers (Wetzel *et al.*, 1995; Moran and Hodson, 1998).

Utilization of polymeric substrates can be accomplished by enzymes external to the cells. Most of these enzymes[1] are hydrolases that are bound to the cell surfaces or are in the periplasm of the microbial cells (Chróst, 1991). Monomeric products are cleaved by these enzymes from the ends of the larger molecules.

The decomposition rate of organic substances is greatly dependent on solubility (Vallentyne, 1962). Decomposition will be lowest for those organic compounds or complexes that occur in environmental concentrations exceeding the saturation level in the surrounding water. Degradation rates of soluble organic compounds vary, but for the compound to be preserved and removed from the organic carbon cycle, sedimentation must occur. The prerequisite for sedimentation by gravity is insolubility and aggregation into particles no longer suspended by Brownian motion. Sedimented, relatively insoluble compounds become buried in anaerobic sediments, where rates of degradation are low. Although cellulose can be decomposed very rapidly by anaerobic bacteria under certain conditions (e.g., in sewage digesters and in rumen) in anaerobic aquatic sediments, acidic fermentation products rapidly accumulate and lower the pH sufficiently to reduce or inhibit bacterial metabolism (Brock, 1966). Additionally, temperatures are generally low in many aquatic sediments. Lignin is more resistant to degradation than cellulose, particularly under anaerobic conditions, and both lignin and cellulose form humic substances. The humic materials of the water coagulate to some extent, sink, and form a portion of aquatic sediments.

The primary intermediate products of anaerobic decomposition of sedimented organic matter (especially cellulose) are fatty acids, which are further degraded to CO_2 and hydrogen. Methane is biogenically generated from CO_2 and from hydrogen and then is lost as bubbles or is microbially reoxidized to CO_2 in less reduced strata of overlying sediments or water.

Much of the decomposition of organic compounds occurs in aerobic waters prior to sedimentation to the bottom of the basin. The extent of degradation en route is governed by an array of physical (morphometry, stratification patterns, temperature, and ultraviolet irradiance) and chemical conditions as well as the magnitude and chemical composition of allochthonous and autochthonous inputs of organic matter. Organic inputs to oligotrophic lakes are generally small, and organic matter is exposed during sedimentation to oxic conditions for long distances (greater time). Consequently, degradation of sedimenting organic matter is relatively complete, and organic sediment accumulation is slow. Massive inputs of organic matter in eutrophic lakes result in rapid sedimentation (shorter distances), less volume of aerobic water, and rapid accumulation of organic matter in anaerobic hypolimnia and sediments.

II. DISTRIBUTION OF BACTERIOPLANKTON

Bacterioplankton are often limited by the availability of organic substrates and nutrients, particularly phosphorus. Consequently, one would expect a general increase in bacterial biomass as an aquatic system is increasingly loaded with organic substrates. Evaluation of microbial biomass is commonly done by enumeration and estimation of biovolume by direct microscopic observation (cf. detailed discussions of techniques by Kuznetsov and Romanenko, 1963; Rodina, 1965, 1972; Sorokin and Kadota, 1972; Rosswall, 1973; Romanenko and Kuznetsov, 1974; and particularly Kemp *et al.*, 1993). The culturing of bacteria in media, while useful for species identification in combination with molecular techniques, is extremely selective for specific bacteria under most conditions. These methods underestimate natural heterogeneous bacterial

[1] These enzymes attached to the cells but external to the cytoplasm have been termed *exoenzymes* (Hoppe, 1983), *extracellular enzymes* (Priest, 1984), and *ectoenzymes* (Chróst, 1990).

populations by factors of 10^2–10^5. Direct enumeration by microscopy has the inherent difficulty of discriminating viable cells from detritus and cells that are dead, but recent techniques, such as epifluorescence microscopy with specific fluorescent dyes (Francisco *et al.*, 1973; Porter and Feig, 1980; Labaron *et al.*, 1998; Nobel and Fuhrman, 1998; Weinbauer *et al.*, 1998), have improved accuracy greatly. Biomass of living bacteria can also be separated from nonliving detrital organic matter with a number of specific molecular probes or more generally by measurement of a uniformly distributed cellular constituent, such as adenosine triphosphate (ATP) that decomposes readily on death and can be measured by bioluminescent reactions at extremely low concentrations (Holm-Hansen and Paerl, 1972; Karl, 1993).

In general, the numbers and biomass of bacteria increase with increasing productivity and concentrations of inorganic and organic compounds in lakes (Table 17-1). In spite of great seasonal variations, bacterial numbers and biomass increase from oligotrophic to eutrophic inland waters. The highest levels have been observed in tropical alkaline, saline lakes (e.g., Kilham, 1981) and in eutrophic reservoirs, probably because the large reservoirs studied tend to occur on rivers that receive both industrial and municipal wastes. Numbers of bacteria are markedly lower in acidic dystrophic lakes, which contain high concentrations of humic matter. In a similar manner, production of bacteria as calculated from changes in biomass over short time periods increases with increasing phytoplanktonic productivity of lakes. The average generation time of bacteria decreases

in more eutrophic lakes. A positive relationship has been demonstrated between the average rates of phytoplanktonic productivity and bacterial numbers (Table 17-2)[2] (cf. Overbeck, 1965; Godlewska-Lipowa, 1975, 1976; Jones, 1977; Straškrabová and Komárková, 1979; Overbeck, 1994).

[2] The term *saprophytic bacteria* (zymogenous, copiotrophic), as used in these and similar studies, refers to those bacteria that grow on organic-enriched agar, such as nutrient agar or casein–glucose agar. These techniques are highly selective but reflect bacteria that grow on high concentrations of easily assimilable organic substances. Saprophytes generally require organic substrates at high concentrations for appreciable development. In contrast, *oligotrophic bacteria* develop at minimal organic substrate concentrations (1–15 mg C $liter^{-1}$), even though they can grow on richer media (Kuznetsov *et al.*, 1979). As such, oligotrophic bacteria are conceived as those bacteria adapted to uninterrupted nutrient limitation (Poindexter, 1981). Such bacteria possess physiological and morphological characteristics that maximize their ability to gather nutrients across steep spatial gradients and to utilize nutrients conservatively.

A. Seasonal and Vertical Distribution

The seasonal distribution of bacterial populations is highly variable from lake to lake and from year-to-year within a lake. A few generalizations, however, can be advanced even from population data determined with sampling frequencies that are far greater than the generation times of the bacteria. Although direct correlations are often observed between the numbers of phytoplanktonic algae and heterotrophic bacteria both seasonally (Fig. 17-2) and vertically with depth (Fig. 17-3), careful examination of this correlation among many lakes has shown that it is weak at best and erroneous for rivers. Bacterial numbers and biomass are commonly high in the epilimnion, decrease to a minimum in the metalimnion and upper hypolimnion, and increase in the lower hypolimnion, especially if anoxic (e.g., Niewolak, 1974; Jones, 1978; Kato and Sakamoto, 1979, 1981; Chróst and Rai, 1994; Coveney and Wetzel, 1995; Simon *et al.*, 1998b). Vertical profiles of bacterioplankton and

phytoplankton are usually more strongly correlated than they are seasonally.

The primary assumption is that the release of extracellular dissolved organic compounds from phytoplankton are approximately proportional to their biomass and production and that bacterial productivity is largely limited by organic substrate availability (e.g., Cole *et al.*, 1988). As will be delineated, correlations of this type can be highly misleading, and regulating physical and biotic factors have been shown to be much more complex and dynamic. There is no doubt that the heterotrophic metabolism of the bacteria depends to a significant extent on organic substrates produced by

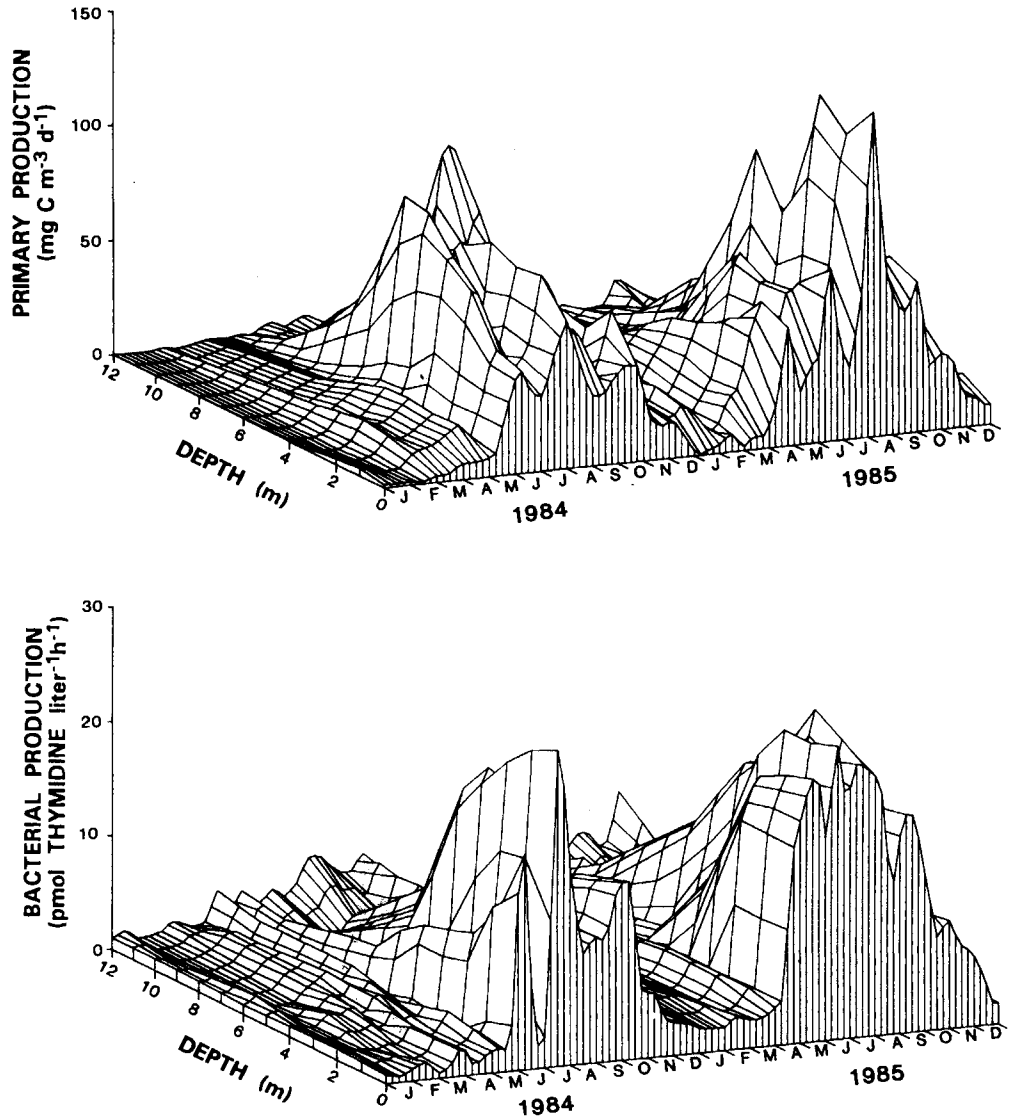

FIGURE 17-2 Comparison of simultaneous measurements of production of phytoplankton (*upper*) and bacterioplankton (*lower*) in oligotrophic–mesotrophic Lawrence Lake, southern Michigan, over a 2-yr period. Bacterial production was determined from *in situ* rates of conversion of radiolabeled thymidine to DNA of the bacteria. (From Coveney and Wetzel, 1995.)

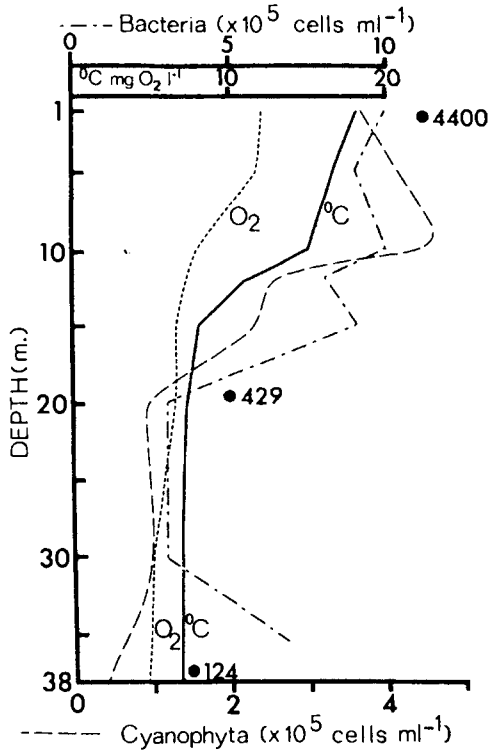

FIGURE 17-3 Vertical distribution of heterotrophic bacteria in relation to planktonic algae in Schluënsee, northern Germany, 18 August 1965. Circles = saprophytes ml^{-1}. (After data of Overbeck, 1968.)

the phytoplankton, as will be described in detail. Often, increases in bacterial populations are delayed and follow phytoplankton maxima by many days or weeks (Straškrabová and Komárková, 1979). More frequent sampling has demonstrated that the vertical distribution of bacteria in dimictic lakes can change very rapidly (Rasumov, 1962; Saunders, 1971). For example, the rapid changes observed in Figure 17-4 became particularly acute in mid-June, following a phytoplanktonic maximum; bacterial numbers increased sharply, then decreased again in a few days. The rapid inversions in vertical distribution of the waxing and waning bacterial populations (Fig. 17-4) indicate that many short-term variables and processes control bacterial abundance, distribution, and productivity (Saunders, 1971; Saunders *et al.*, 1980). Correlations have been found between pulses of bacteria and changes in sources of organic matter, such as death and decomposition of phytoplankton and of littoral plants, as well as changes in precipitation and runoff of organic matter from allochthonous sources, nutrients, temperature, mixing, parasitism, and grazing by protists and zooplankton (e.g., Lane, 1977; Tanaka *et al.*, 1977; Goulder, 1980; Coveney and Wetzel, 1989, 1992, 1995). However, correlations alone yield little insight into the mechanisms controlling the apparent interaction; they only establish hypotheses on possible controlling factors.

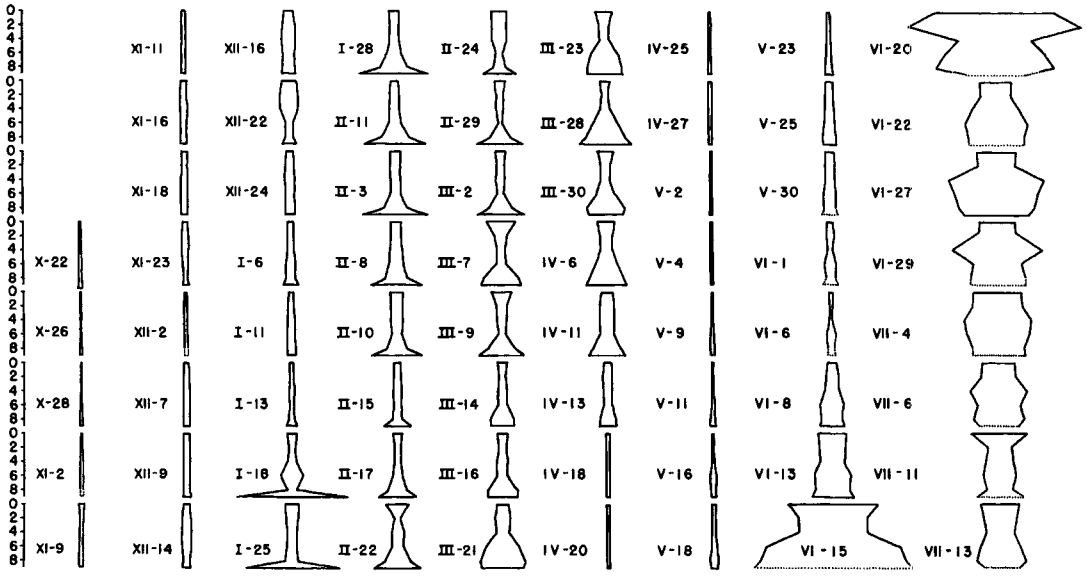

FIGURE 17-4 Relative vertical distribution of bacteria by direct enumeration on different dates in Frains Lake, southeastern Michigan, 1959–1960. Ordinate: depth in meters; abscissa: relative numbers. (From Saunders, G. W.: Carbon flow in the aquatic system. *In* Cairns, J., Jr. (ed.) *The Structure and Function of Fresh-Water Microbial Communities*, Blacksburg, Va., Virginia Polytechnic Institute, 1971.)

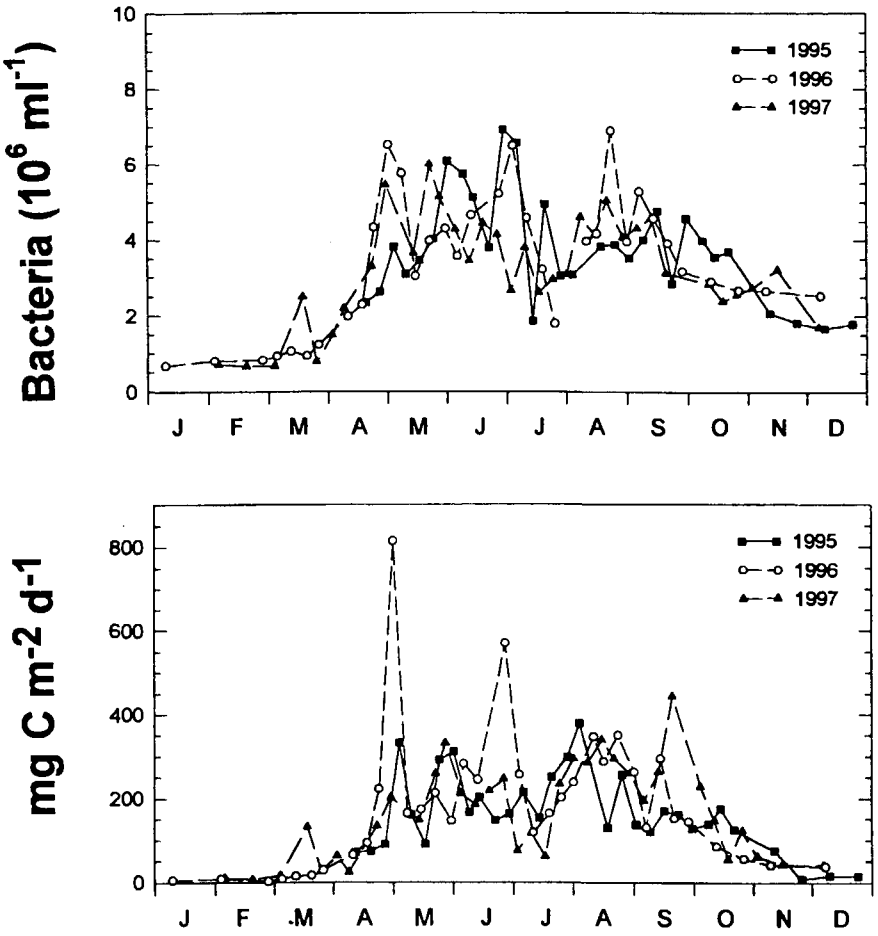

FIGURE 17-5 Seasonal changes in epilimnetic (0–10 m) bacterial numbers (*upper*) and in bacterial production of the trophogenic zone (0–20 m) (*lower*) in Lake Constance, southern Germany. (Modified from Simon *et al.*, 1998b.)

Planktonic bacterial biomass and production is generally lower during winter than during summer in temperate lakes and reservoirs; this relationship is correlated with low winter temperatures and reduced loading of particulate and dissolved organic substrates from autochthonous (phytoplankton and littoral plants) and allochthonous sources when the soils are frozen. A significant portion of the planktonic bacterial community may be physiologically dormant when conditions are cold and limited organic substrates are available (e.g., Stevenson, 1978; Wright, 1978).

Before discussing potential parameters that regulate bacterial biomass and production, it is instructive to examine a detailed analysis of seasonal dynamics and potential controls of bacterioplankton abundance and production in Lake Constance (Simon *et al.*, 1998b). This lake was eutrophic in the 1980s but has been undergoing marked reductions in nutrient loadings in the 1990s and is experiencing oligotrophication. Lake Constance is now a large temperate, mesotrophic lake with bacterioplankton properties generally representative of many lakes. Seasonal changes in bacterial production (Fig. 17-5) generally coincide with those of bacterial biomass (Fig. 17-5) and ascend from low winter values to increases in the spring and summer before declining again in the autumn and winter. Within this general annual cycle, however, a number of rapid changes in both bacterial biomass and production have been observed, and these changes have been coupled to a bevy of physical and biotic variables.

The generic model set forth by Simon *et al.* (1998a) suggests that growth of heterotrophic bacterioplankton is limited by the availability of organic carbon substrates because of reduced winter levels of phytoplankton productivity and release of extracellular organic carbon (Fig. 17-6). As we will see, however, allochthonous loadings of dissolved organic substrates can be high in the winter and readily utilized by many bacteria.

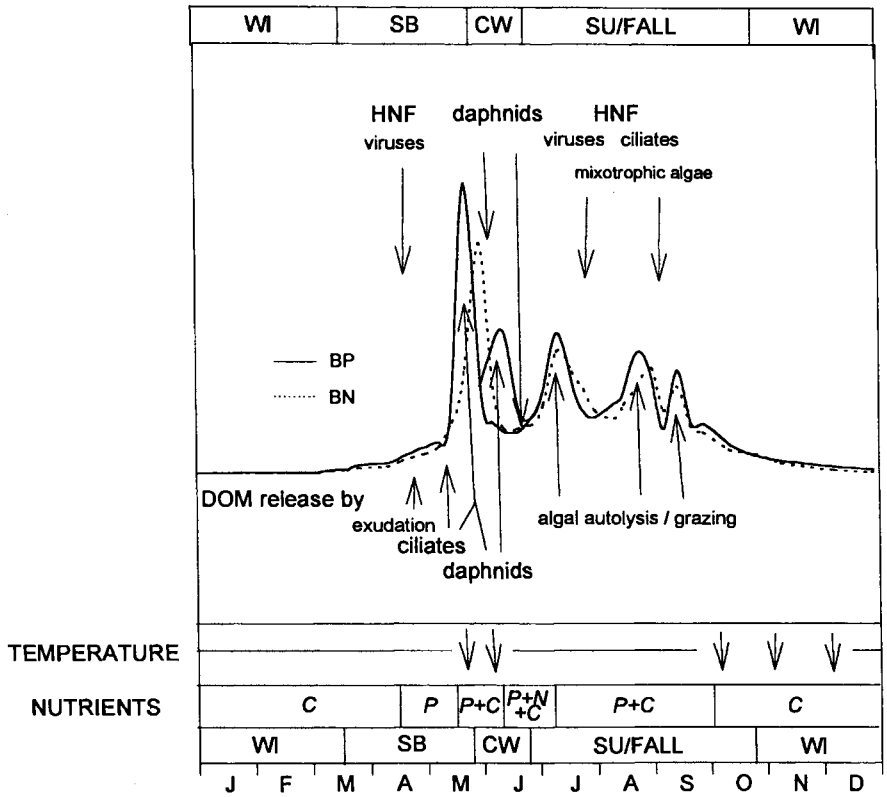

FIGURE 17-6 Idealized patterns of seasonal dynamics and regulation of bacterioplankton abundance and production in temperate, mesotrophic Lake Constance, southern Germany. *BN* = bacterial numbers; *BP* = bacterial production; *WI* = winter; *SB* = spring increase in phytoplankton abundance; *CW* = "clearwater" phase, which is highly variable from year-to-year depending on the relative abundance of daphnid zooplankton and their effectiveness in grazing of phytoplankton algae; *SU/FALL* = summer and autumn periods. Upward arrows = net positive effect, and downward arrows = net negative effects on bacterioplankton. (Modified from Simon *et al.*, 1998a.)

Temperatures are low and also control bacteria to a certain extent, but many bacteria are adapted to low temperatures (5–10°C), particularly in the spring, and capitalize upon the early phases of spring increases in production of phytoplankton. During the spring algal bloom, phytoplankton production enhances availability of extracellular organic substrates, and the supply of organic substrates is enhanced by intensified grazing activities on the algae by protists and zooplankton (Fig. 17-6). Dissolved carbohydrates and amino acids are available and utilized in large amounts at this time (Hanisch *et al.*, 1996; Simon, 1998), but bacterial growth can be limited by the intense algal and bacterial demands for inorganic nutrients, mainly phosphorus limitations. Although cladoceran daphnid zooplankton feed primarily on algae, as they decimate the spring algal bloom, increasing, very short-lived impacts on bacterioplankton occur. Most limitation results from mortality of bacteria from viral lysis, often exceeding 50%, and from grazing by protistan protozooplankton (see discussion in Chap. 16 and later in this chapter). Viral lysis and grazing activities by zooplankton on both algae and bacteria enhance the regenerated supply of dissolved organic substrates and subsequent growth of bacteria. During the summer, the same combination of biotic and abiotic factors influence bacterial growth rates and production, but usually in a more balanced manner. Gradually, as the seasons progress toward winter, declining temperatures and organic carbon substrates reduce production of bacterioplankton.

Controversy prevails concerning whether bacterioplankton are freely planktonic or attached to suspended inorganic or organic detrital particulate matter. Often most bacteria are observed to be freely planktonic, particularly in oligotrophic waters (e.g., Riemann, 1978; Geesey and Costerton, 1979; Saunders

et al., 1980; Johansson, 1983; Lewis *et al.*, 1986). However, bacteria are also often found to be predominantly attached to detrital particulate matter (e.g., Hutchinson, 1967; Paerl, 1975; Lind and Dávalos-Lind, 1991), but marked seasonal variations have been observed (e.g., Kirchman, 1983). For example, in lakes or reservoirs with high, persistent in-lake suspended clay–organic aggregates, <20% of the bacterioplankton may be free in the water. Microbial attachment to particles may be in response to enhanced availability of adsorbed organic substrates relative to substrate concentrations existing in the water.

Horizontal spatial variability in biomass and production of bacterioplankton is usually low in the central pelagic regions of lakes that are not morphometrically complex or disturbed by high effluent loading from point sources (e.g., Jones, 1977; Zmyslowska and Sobierajska, 1977; Jones and Simon, 1980). Closer examination of horizontal variations of bacterial production has demonstrated consistently that production increases markedly along a gradient from the central portions of the basins toward littoral areas. This gradient has been found in all lakes examined, including the very large great lakes (Scavia and Laird, 1988). Loading of both nutrients and organic substrates from the land and littoral producers certainly enhances bacterial productivity. Patchiness in bacterial distribution is found also upon critical sampling and analysis of large-scale differences in organic loading from human effluents (e.g., Palmer *et al.*, 1976; Rao and Burnison, 1976). Sinking rates of individual bacteria are so low (approximately 1 mm day^{-1}; Jassby, 1975) that horizontal differences are usually coupled to differences in water turbulence and variations in availability of nutrients and organic compounds (e.g., phytoplankton, littoral sources and influent sources of organic substrates).

Neuston bacterioplankton in the surface films of inland waters is poorly understood; most studies are of marine waters (Norkrans, 1980). The potential for enrichment of organic substrates and nutrients from atmospheric sources suggests that bacteria adapted to this habitat of high ultraviolet irradiance may grow more prolifically than true bacterioplankton. However, turbulence commonly disperses surface communities frequently. Comparisons of the metabolic activities of neuston bacteria of the surface film with those of bacterioplankton several centimeters below the air/water interface indicated that assimilation and respiratory rates can be higher in the neuston, particularly if the waters are oligotrophic (Crawford *et al.*, 1982; Hermansson and Dahlbäck, 1983). In more eutrophic situations, however, respiration rates were about the same in both habitats.

III. CONTROL OF BACTERIOPLANKTON BY RESOURCE AVAILABILITY AND ENVIRONMENTAL FACTORS

The growth and development of heterotrophic bacteria usually is limited by availability of some resource such as organic substrates for carbon, energy, or nutrients, particularly phosphorus and nitrogen. Second, environmental parameters, particularly temperature and ultraviolet light can affect significantly bacterial growth. Finally, predation upon bacteria by animals can alter the growth, development, and production of bacteria. Each of these regulators should be examined in relation to observed spatial and temporal patterns of growth and production of bacterioplankton.

A. Temperature

A number of studies have shown that bacterioplanktonic growth is positively correlated with temperature, particularly at relatively low temperatures (<10–15°C) (Scavia and Laird, 1987; Morris and Lewis, 1992; Coveney and Wetzel, 1995; Ochs *et al.*, 1995; Felip *et al.*, 1996; Tibbles, 1997; Simon and Wünsch, 1998). As was discussed earlier (Chap. 6), a large volume of lakes in the lower metalimnion and hypolimnion rarely warm to >12–15°C at any time of the year in the temperate regions. Hence, in the lower part of the water column temperature can directly control bacterial growth by a simple Q_{10} relationship for biochemical reactions. Above these temperatures, bacterial growth is less strongly correlated to temperature differences, and presumably in the seasonally warmer upper part of the water column, temperature-adapted bacterial communities develop and are limited to a greater extent by other parameters and resources, particularly organic substrates and nutrients.

Bacterial development can increase under conditions of thermal bar development in large lakes (e.g., Moll and Brahce, 1986; Kapustina, 1996). Although temperatures are cold, they are several degrees warmer than the open pelagic region beyond the thermal bar, and these temperature differences in the lower range are significant to increased bacterial metabolism. Nutrient availability from littoral runoff may also increase within the thermal bar zones as well.

B. Extremes in pH Values

High rates of photosynthesis by phytoplankton in eutrophic lakes or by submersed macrophytes and attached algae can induce high pH values, often in excess of pH 10 on a diurnal basis (cf. Chaps. 11 and 22). Such values are particularly common in eutrophic

waters of intermediate bicarbonate buffering capacity, and this chemical composition dominates surface waters globally. Bacterioplankton production commonly decreases under conditions of high pH (ca. ≥10) (e.g., Jeppesen *et al.,* 1997). Such reductions are likely the result of reduced efficiencies of enzymatic activities at high pH ranges. Bacterioplankton production has been observed to be similar under acidic and neutral to slightly alkaline conditions (Bell and Tranvik, 1993). When softwater lakes that have been acidified from anthropogenically induced atmospheric pollution are neutralized by applications of lime, bacterioplankton production can increase and be more susceptible to disturbance by protistan grazing and viral mortality.

C. Nutrient Availability

Restricted nutrient availability can often limit the growth and productivity of bacterioplankton. Indeed, the pelagic environment can be referred to as a "desert" in relation to the availability of organic substrates for carbon and nutrients, particularly phosphorus, for the bacterioplankton. Studies of the seasonal dynamics of bacterioplankton often suggest relative constancy of cell densities over time within a general seasonal increase during the warmer, more productive periods (e.g., Fig. 17-5). As indicated later, appreciable mortality occurs by viral lysis and protistan grazers. The limited availability of reduced carbon substrates is often invoked as the primary restriction to bacterioplanktonic growth, in part evolving from the cross-system, generally positive correlation between bacterial production and phytoplankton biomass (Cole *et al.,* 1988; White *et al.* 1991). However, an increasing number of analyses indicated that phosphorus, rather than or in addition to organic carbon, was the critical nutrient regulating the growth of bacterioplankton (e.g., Coveney and Wetzel, 1992; Morris and Lewis, 1992; Vrede, 1996; Watanabe, 1996; Simon *et al.,* 1998).

The requirements of bacterioplankton for inorganic nutrients, particularly phosphorus and nitrogen, had been usually assumed to be met either through the utilization of organically bound fractions or through high-affinity uptake systems for inorganic forms. As indicated in the earlier detailed discussions on phosphorus utilization and competition by algae and bacteria (see Chap. 13, pp. 268–269), uptake of inorganic phosphorus in phosphorus-limited aquatic ecosystems is dominated by bacterioplankton because they have much higher phosphorus requirements than do phytoplankton and their uptake systems have greater affinities than those of algae.

Phosphorus commonly limits bacterioplankton. For example, the addition of inorganic phosphorus was shown to stimulate the production of bacterioplankton diluted in filtered lake water (Toolan *et al.,* 1991). Additions of organic nutrients showed those organic substrates alone did not increase specific growth rates[3] of bacterioplankton of an oligotrophic lake, but the addition of inorganic phosphorus alone increased specific growth rates (Coveney and Wetzel, 1992). Bacterioplankton can accumulate phosphorus above that required to meet metabolic demands ("luxury uptake"). That accumulation is much higher when nitrogen availability is low (N:P <40:1) than when nitrogen was abundant relative to phosphorus (N:P > 40:1) (Chrzanowski and Kyle, 1996; Chrzanowski *et al.,* 1996). These results indicated that phosphorus, rather than organic carbon, can limit bacterioplankton growth and that direct competition occurs between phytoplankton and bacterioplankton for inorganic phosphorus. Although phosphate is the preferred substrate for uptake into both bacteria and algae, enzyme-mediated hydrolysis of natural organic phosphate-containing compounds, such as phosphate esters and nucleotides such as ATP, can form a major source of phosphorus for bacterioplankton when inorganic phosphorus availability is reduced (cf. Chap. 13, pp. 260ff).

Inorganic nitrogen is much less frequently limiting to bacterial growth than is phosphorus (e.g., Elser *et al.,* 1995a,b; Jansson *et al.,* 1996). In three temperate lakes of low productivity, nitrogen fluxes into bacterial-size fractions of the seston relative to the N/P ratio of the bacteria indicated a threshold N/P ratio (ca. 22:1, by atoms); below this value, bacteria assimilated added nitrogen, and above it nitrogen was released. Limitation by phosphorus or nitrogen can shift rapidly seasonally, even diurnally, and with changes in the composition of the microbiota. During periods when phosphorus availability increases, it is common to find enhancements of bacterial production from inorganic nitrogen enrichments of the plankton (e.g., Wang *et al.,* 1992; Wang and Priscu, 1992; Simon *et al.,* 1998a). The enhanced bacterial productivity may be direct, in response to utilization by the bacteria, or indirect, from the stimulation of phytoplankton growth and their release of organic substrates that in turn enhance bacterial growth.

Many researchers espouse that one element is more limiting than another and that there can be a shift from one nutrient limitation to another seasonally. Such discussions are governed by scale and can quickly become circular and pointless. If a nutrient such as phosphorus is acutely scarce in an aquatic ecosystem, the growth

[3] *Specific growth rate (SGR)* is calculated from endpoint bacterial densities or bacterial biovolume (initial, D_0; final, D_T) as $(\ln D_T - \ln D_0)/T$, where T is incubation time.

and productivity of many components, from bacteria to plants to large animals, can become chronically nutrient-limited (e.g., Moeller *et al.*, 1998). In many ecosystems, particularly in the pelagic zones of lakes, the many different kinetic rates for nutrient uptake exist among the diverse biota of hundreds of coexisting species of the plankton. At any one time, the composite dominating nutrient limitation may be one element, and with changes in loadings, utilization, and losses, the composite dominating nutrient limitation can shift to another element. Under transient growth conditions, it is possible to demonstrate multiple nutrient-limited growth (Egli, 1995). Under natural conditions, however, usually such a shift requires several weeks, but theoretically it could occur over very short time periods (hours) and oscillate back and forth. What is generally studied and reported is a collective, composite, community nutrient limitation.

Examination of the vertical distributions of bacterioplankton also supports the general scenario that nutrient availability is a common limitation in the epilimnetic waters of stratified lakes and decreases in the hypolimnion. Bacterial cell size is commonly observed to be smaller (greater surface area to biovolume ratio) in epilimnia than in hypolimnia. For example, bacteria from anoxic hypolimnia were found to be 2–10 times larger than those of oxic waters, and cell size was independent of temperature (Cole *et al.*, 1993). A related observation was that bacterioplanktonic abundance and biomass (product of mean cell size and bacterial abundance) were also markedly greater in anoxic hypolimnia than in oxic epilimnia.

IV. DECOMPOSITION OF DISSOLVED ORGANIC MATTER

The decomposition of organic matter by bacteria is governed by many factors, particularly chemical characteristics such as the structure of the compounds and biological parameters such as the synthesis of enzymes capable of hydrolyzing the organic substances. The instantaneous concentrations of labile organic compounds, such as simple carbohydrates and amino acids, are very small, indicative of their rapid assimilation and rapid rates of turnover. The remainder of the dissolved organic matter of inland waters is much more recalcitrant to decomposition and is dominated by humic and fulvic acids, largely of higher plant origins. The labile compounds, however, are important because of their high energy, relatively simple chemical bonding and structure, and relatively high level of nutrient per total carbon content. Insight into the complex differential utilization of these relatively labile organic compounds, such as amino acids, is gained from several detailed analyses of the amino acid and carbohydrate cycling in lakes.

It has long been argued that labile organic substrates occur at "threshold" concentrations (Jannasch, 1970) and dissolved free amino acids and carbohydrates usually occur at nM concentrations. This common observation led to the assumption that bacterioplankton are often living under chronic substrate limitation and to the erroneous assumption that the large residual pool of dissolved organic matter is largely unavailable for bacterial utilization. Nonetheless, the recalcitrant pool of organic matter is used slowly, and much of the bacterial metabolism is strongly coupled to the sources of simple substrates and their rapid turnover rates.

A. Amino Acids and Related Compounds

Concentrations of dissolved free amino acids (DFAA) of lake water and the interstitial water of sediments generally are very low (<10 μg liter^{-1}; range 0.0017–2.4 nM) at any given time (Brehm, 1967; Gardner and Lee, 1975; Münster, 1993; Simon, 1998a), although they can increase to considerably higher levels in eutrophic pond waters (Zygmuntowa, 1972). All of the protein amino acids as well as several nonprotein amino acids have been found. Over an annual period and in several different types of waters, concentrations of serine, glycine, and alanine were relatively high, those of aspartic acid and threonine occurred in less abundance, and those of all remaining amino acids and glutamic acid were very low. Maximum epilimnetic concentrations commonly occur in the winter, especially just below the ice, and during the summer period of maximum algal production. Concentrations in the metalimnion are generally very low but may increase somewhat in the hypolimnion. Just above the sediments, concentrations of amino acids often decline again. Many of the dissolved amino acids were found to be adsorbed to colloidal carbohydrates liberated by the microflora. These colloids are most abundant in the epilimnion during the summer and are reduced to extremely low concentrations in the hypolimnion, where intensive bacterial metabolism occurs.

High-molecular-weight peptides of the free water and interstitial water of the sediments were associated with humic substances and increased in surface waters during autumnal influxes of allochthonous plant material (Brehm, 1967). These compounds and, additionally, mucopeptides of cyanobacterial and heterotrophic bacterial origin undergo relatively slow bacterial degradation. Amino acids are adsorbed selectively by these humic substances of dead particulate matter and by the cell

TABLE 17-3 Dissolved Organic Nitrogen Compounds in the Epilimnion of Two Lakes of Northern Germany, 27 June 1967[a]

Dissolved organic nitrogen compounds	*Schuënsee (mesotrophic)*	*Plußsee (eutrophic)*
Extracellular amino compounds		
Free amino acids	39 μg liter^{-1}	71 μg liter^{-1}

[a] From data of Gocke (1970).

walls of both heterotrophic and cyanobacteria. These polypeptides remain relatively undegraded after autolysis of algae. In contrast, certain amino acids, especially aspartic and glutamic acids, are released very rapidly during autolysis or grazing of phytoplankton and are assimilated immediately by heterotrophic bacteria. Other amino acids are released through autolysis more slowly and result in a higher relative concentration in the dead plankton. Bacterial decomposition of plankton occurs first on the autolytically soluble products. Most of the cell decomposition occurs in the epilimnion; more resistant cell components are degraded more slowly after the soluble autolytic substances are utilized.

A more recent detailed study with markedly improved analytical techniques was performed on mesotrophic Lake Constance (Simon, 1998a). The spatial and temporal distributions of dissolved free amino acids (DFAA) and dissolved combined amino acids[4] (DCAA) were determined over an annual period and coupled to rates of bacterial biomass and productivity. Concentrations of DFAA ranged from <20 to 480 nM, with highest values at the end of the spring maximum of the phytoplankton development. In contrast, concentrations of DCAA ranged from 610 to 3755 nM of amino acid equivalents, and highest concentrations of DCAA occurred in middle to late summer. The low C:N ratios of the amino compounds (2.8–3.3) emphasize the excellent substrate quality of these compounds.

Measurements with individual amino acids of uptake kinetics demonstrated that those in least abundance were assimilated most rapidly (<20 h), and conversely that those compounds found in higher concentrations exhibited longer (30–90 h) turnover times (the time required for the plankton remove and metabolize all the substrate without replacement) (Hobbie *et al.*, 1968). These results are reinforced by Gocke's (1970) demonstration of the rapid bacterial decomposition of free amino acids (reduced to 2% within 6 days) and peptides (to 13% in 6 days) by natural bacterial populations, while amino–colloidal complexes were relatively resistant to degradation and accumulated. The differences in rates of degradation of amino components are reflected in the absolute concentrations found (Table 17-3). Similarly, in the study of dissolved amino acid utilization in Lake Constance, the turnover times for DFAA fluctuated greatly seasonally and ranged between 2.6 and >50 days, with the shortest times occurring during the spring bloom of phytoplankton (Rosenstock and Simon, 1993; Simon, 1998a). From rates of DFAA incorporation into bacterioplankton per rate of bacterial production, it was estimated that between 20 and 40% of the bacterial biomass production was met by the carbon of these amino compounds. This and other studies (e.g., Gardner *et al.*, 1987) indicate bacterial production can be limited by substrate availability at certain times of the year.

Present understanding indicates that both dissolved free and combined amino compounds constitute important substrates for bacterioplankton growth. Simple organic nitrogen compounds are utilized more effectively in more productive lakes (faster turnover; lower instantaneous concentrations as a percentage of the total organic nitrogen). This observation suggests that the enzymatic systems of bacteria of eutrophic lakes are

[4] DCAA were derived from the hydrolyzable amino acids derived from total dissolved proteinaceous compounds minus DFAA, expressed as amino acid equivalents.

adapted or keyed to respond to a much greater variety of substrates than those of oligotrophic waters exposed to conditions of less frequent substrate encounters. The oligotrophic lake species, upon receipt of an influx of a specific substrate for which it does not possess an active enzymatic uptake system, must adapt to that substrate (cf. Hollibaugh, 1979). Hence, the observed assimilation rates are initially low but can increase markedly as adaptation occurs. Those species of eutrophic waters, which are exposed more frequently or continuously to a variety of substrates, respond to and assimilate the substrates immediately.

Little is known about utilization rates of more complex compounds, such as amino sugars. Amino sugars, particularly *N*-acetylglucosamine, have been widely observed at concentrations of 10–100 μg liter^{-1} (Nedoma *et al.*, 1994). Because analytical assays for direct evaluation of these compounds are difficult, the ability of natural microorganisms to use such compounds can be inferred indirectly from the presence of specific extracellular enzymes capable of liberating the compounds from polymer organic matter. Such enzyme activities, such as β-*N*-acetylglucosaminidase, have been found to be tightly coupled to bacterial activity in many different lakes and rivers. It is also noteworthy that bacteria attached to particles had a much higher (>100 times) specific activity of aminopeptidases than that of free-living bacteria (Debroas, 1998). The densities of seston particles, both dead and living phytoplankton containing protein, and attached bacteria tend to increase in eutrophic waters.

Expectedly, therefore, the highest rates of detrital proteolysis and aminopeptidase activity are found associated with the highest phytoplankton productivity both spatially and temporally over seasons and on a daily basis. For example, the highest enzymatic and proteolytic activities are commonly in the trophogenic zone, seasonally following phytoplankton blooms, and diurnally from noon to sunset (e.g., Halemejko and Chróst, 1986).

B. Carbohydrates, Simple Organic Acids, and Lipids

The distribution of carbohydrates and simple organic acids has been investigated in several lake systems (see, e.g., Saunders, 1963; Walsh, 1965a,b, 1966; and particularly Weinmann, 1970; Münster, 1984; Hanisch *et al.*, 1996; Meon and Jüttner, 1999). As with simple amino compounds, the instantaneous concentrations of individual organic acids and carbohydrate compounds are very low (usually <30 μg liter^{-1}) and represent a small portion of the total dissolved organic matter (cf. Hama and Handa, 1980; Münster, 1993). Free monosaccharides and oligosaccharides are assimilated readily by bacteria and occur at very low instantaneous concentrations (<10 μg liter^{-1}; 1–100 nM, Moen and Jüttner, 1999). Dissolved polysaccharides, consisting of numerous hexoses, pentoses, and methylpentoses, and especially phenolic and cresolic compounds, occur in greater abundance. Various organic acids, particularly acetic, levulinic, formic lactic, citric, oxalic, malic, glycolic, and short-chain fatty acids, have also been found to be generated in appreciable quantities by partial photolysis by natural ultraviolet light of humic substances (see later discussion below and Chap. 23).

Detailed evaluation of the vertical distribution of dissolved carbohydrates in spring in eutrophic Plußsee, northern Germany, found moderate concentrations of total dissolved carbohydrates (<0.5–800 μg C liter^{-1}), with higher values in the epilimnion and decreasing values with depth (Münster, 1984, 1985, 1991). Similar vertical distributions were found in Lake Constance (Hanisch *et al.*, 1996). In Plußsee on one spring day, about 75% of the total dissolved carbohydrate occurred as monosaccharides and 10–15% as disaccharides; on a diurnal basis, maxima were observed about 2–4 h after the photosynthetic maximum of the phytoplankton in the surface waters (Münster, 1984, 1991).

Examination of seasonal changes in total dissolved carbohydrates (monosaccharides, disaccharides, cellobiose) in mesotrophic Lake Constance, Germany, showed relatively low concentrations (130–400 μg C liter^{-1}) at all times with relatively small changes in concentrations seasonally (Hanisch *et al.*, 1996). Concentrations of dissolved free carbohydrates were always below analytical detection limits. Rates of utilization of total dissolved carbohydrates by bacterioplankton ranged between 0.5 and 3.4 μg C liter^{-1} hr^{-1}, with the highest rates occurring at the maximum and decline of the spring bloom of phytoplankton. Turnover times of total dissolved carbohydrates (ratio of concentration to rate of utilization) varied between 3.6 and 21 days during the spring and summer periods (not assayed during other seasons).

Another significant source of these compounds is the secretion products of phytoplankton (Chap. 15) and littoral flora (Chap. 18), autolysis of the plants and microflora, and intermediary products of microbial degradation. In bacteria-free algal cultures, carbohydrates, especially mono- and disaccharides, and total dissolved organic matter increase in proportion to algal growth. In the presence of a natural bacterial flora, the extracellular products are degraded rapidly (hours). This reduction is selective. The labile carbohydrates, organic acids, and amino acids decrease much more rapidly than the total dissolved organic matter (Weinmann, 1970; Gocke, 1970; Poltz, 1972; Münster, 1993; Hanisch *et al.*, 1996).

TABLE 17-4 Average Percentage of Lipid Fractions in the Net Plankton, Sedimenting Particulate Organic Matter, and Sediments of Several Lakes of Northern Germany[a]

Fractions	*Net plankton (>20 μm)*	*Sedimenting particulate matter*	*Sediment*[b]
Total organic matter per dry weight	83.1%	36.7%	16.0%
Total lipids per organic matter	22.3	9.0	6.8
Total fatty acids per total lipids	61.2	32.5	12.1
Triglycerides of total lipids	30.8	8.0	1.8

[a] After Poltz (1972).
[b] Grosser Plöner See only; mean values; values greatest near surficial interface and decreased progressively within first meter.

Although relatively little is known about the distribution and metabolism of lipid compounds in fresh waters, the detailed investigations of Poltz (1972) of lakes of northern Germany demonstrate relationships that probably occur frequently. Total lipid, fatty acid, and triglyceride content declines rapidly when cells die and settle out of the trophogenic zone; concentrations of these materials in the sediments are much lower than in living net plankton (Table 17-4). Lipid content variations of net plankton, sedimenting particulate organic matter, and lake sediment were relatively large, because of changes in lipid composition among the phytoplankton (see pp. 353–354) and zooplankton (see pp. 427–428). Vertical migration and population oscillations both contributed to fluctuations in short-term lipid content in these particle types. Changes in the lipid content and fatty acid compositional patterns of the plankton over an annual period were not as great, however, because of opposing changes in lipid content of the phyto- and zooplankton. The relative amount of short-chained fatty acids, especially of the 16:1 isomer, increased from summer to winter so that the mean chain length of the fatty acids declined. The same fatty acids were found in the triglycerides of the plankton and in the total fatty acid fractions, but the relative concentrations of highly unsaturated fatty acids in the triglycerides were lower.

Decomposition of organic matter and fatty acids was most rapid under the warmer, aerobic conditions of the epilimnion. The mineralization of the planktonic particulate organic matter of the pelagial zone was rapid and usually complete (>85%). The intensity of decomposition of triglycerides was greatest (>98%) in the epilimnion and followed the general sequence of degradation: triglycerides > total fatty acids > lipids > total organic substances (Poltz, 1972). Rates of decomposition decreased markedly in the hypolimnion. Only small amounts of the substances produced in the plankton were found settling to the sediments: 4 to 10% of particulate organic matter, 1–2.5% of lipids, 0.1–0.5% of total fatty acids, and <0.1% of triglycerides. After deposition, further degradation rates were most rapid at the surface interface zone of the sediments, although the rates were slower than those occurring in epilimnetic waters during the process of sedimentation.

Much less is known about the production, utilization rates, and losses of dissolved fatty acids in aquatic ecosystems. Many long-chain lipophilic compounds are attached to particulate organic carbon. Short-chain dissolved fatty acids are commonly directly proportional to the release of organic compounds from photosynthesizing phytoplankton (Fogg, 1983). For example, glycolic acid, a product in the competition of oxygen with CO_2 as a substrate in the ribulosebisphosphate carboxylase reaction, can be excreted by algae rather than metabolized to serine or glycine. Released glycolic acid can show a distinct diurnal variation in the trophogenic zone of a eutrophic lake with maxima (ca. 50–100 μg C as glycolic acid liter^{-1}) during the daylight periods of maximum photosynthesis and declining to minima (ca. 1 μg C liter^{-1}) during darkness (Münster, 1991). Because glycolic acid is an excellent substrate for bacterioplankton, the observed diurnal distribution is likely a balance between production and release in excess of bacterial utilization during the day and rapid utilization as an energy source for respiration and transport of other carbon substrates across membranes during darkness.

These analyses were limited to the pelagic zone of lakes and consequently do not reflect the massive amounts of particulate organic matter that can reach the sediments of many lakes when the littoral flora dominates production. The sediment interface is clearly the site of the most intensive respiratory metabolism in many lakes (see Chap. 21), and much of the organic

matter undergoing degradation there originates from littoral and allochthonous sources. Part of the lipid derivatives originate from the bacteria, algae, and fungi; these derivatives may be intermediate metabolic products formed during the degradation of this accumulated organic matter (cf. Schulz and Quinn, 1973).

C. Humic Compounds and Their Photolysis to Simple Organic Substrates

As much as 80% of dissolved organic matter (DOM) in inland waters is composed of organic acids that originate largely from higher aquatic and terrestrial plants. Of these organic acids, some 30–40% are composed of aromatic carbon originating from structural plant tissues (Malcolm, 1990). Concentrations of organic acids are commonly in the range of 4–8 mg liter^{-1} and can exceed 50 mg C liter^{-1} in wetlands, floodplain waters, and interstitial waters of hydrosoils (Wetzel, 1984; Mann and Wetzel, 1995).

The high concentrations of DOM in inland surface waters clearly result from high photosynthetic productivity associated with lake and river ecosystems, particularly associated with wetland and littoral regions, as well as large loadings of DOM from decomposition of plant materials within the drainage basin (Wetzel, 1990a, 1992). Similarly, the high photosynthesis and decomposition within the extensive floodplain marginal areas of river ecosystems also serve as origins of DOM to river runoff water (Wetzel and Ward, 1992). More labile compounds of these heterogeneous organic mixtures are selectively degraded by microbiota as the water is transported along the gradient from land through the littoral to pelagic regions. Residual organic compounds contain high concentrations of the relatively recalcitrant humic substances that originate largely from the partially degraded plant structural tissues (Frimmel and Christman, 1988; Purdue and Gjessing, 1990).

Humic compounds are structurally complex (phenolic linkages; see detailed discussion in Chap. 23) and tend to have long residence times in lakes and streams. In general, their degradation by aquatic microflora proceeds slowly. A portion of the humic materials present in a lake is truly dissolved, but under certain conditions, humic substances can aggregate into colloids or flocs. High-molecular-weight dissolved humic materials readily adsorb to particulate matter (Davis and Gloor, 1981), which may further alter their rates of degradation. Rates of glucose mineralization are also very low in tropical lakes that receive high loading of dissolved humic materials (Rai, 1978, 1979).

Despite the frequently stated erroneous opinion that humic substances are poorly metabolized, in reality total dissolved organic matter, of which 50–80% is made up of humic substances, of most surface waters does not increase even though sources constantly import large quantities to the pelagic pool. Spatial concentrations of total dissolved organic matter with depth change relatively little over seasons (e.g., Wetzel *et al.*, 1972). Losses that balance these influxes are occurring by many mechanisms: microbial decomposition, photolysis, aggregation and sedimentation, and outflows.

Inputs of allochthonous dissolved organic matter to surface waters are directly proportional and coincident with rainfall (see Chap. 23). Bacterioplankton growth and productivity are often more strongly correlated with the inputs of allochthonous dissolved organic carbon (DOC) from the catchment than with phytoplankton productivity in small lakes (e.g., Wetzel and Otsuki, 1974; Mickle and Wetzel, 1978b; Hessen, 1985; Coveney and Wetzel, 1992, 1995), very large lakes (Arvola and Kankaala, 1989; Bertoni and Callieri, 1989; Laybourn-Parry *et al.*, 1994), and rivers (McKnight *et al.*, 1993). Tranvik (1990) found that at least half of bacterioplankton growth utilized DOC of humic substances of a molecular weight between 1,000 and 10,000 D. Rates of uptake and turnover of polymeric and monomeric aromatic dissolved organic compounds were nearly as efficient and rapid as those of simple amino acids (Münster *et al.*, 1999). The ratio between aromatic carbon and amino acid carbon uptake varies between 0.2 and 5.2 (mean 2.8; see Table 17-5). Although these recalcitrant compounds are used less efficiently than more simple substrates, the abundance of the more complex humic substances is so large proportionally that the collective slower rates of mineralization compensate in the large pool available.

Haan (1972) demonstrated that a species of *Arthrobacter* was able to grow slowly on humic fractions and that it was able to hydrolyze the phenolic ether linkages. Studies of the degradation of dissolved humic compounds in heavily stained Finnish lake waters also provided evidence that these compounds, although relatively resistant, are mineralized slowly (Ryhanen, 1968; Sederholm *et al.*, 1973). Enrichments with inorganic nitrogen and phosphorus accelerated the rate of degradation. More recent studies have confirmed that bacterial degradation of dissolved organic matter of humic-rich waters can be prodigious, although these high-molecular-weight and phenolic-dominated compounds are not utilized directly at rates comparable to those of simple extracellularly released DOC (e.g., Tranvik, 1988, 1989, 1990; Sundh, 1992; Amon and Benner, 1996; see later discussion on bacterial productivity).

Studies of the effects of a low-molecular-weight humic fraction on the growth of a species of *Pseudomonas* showed that the presence of the humic fraction caused an increase in the cell yield and in the

cell yield per unit of respiratory consumption of oxygen as compared to growth in organic media lacking the fraction (Haan, 1974). These results suggest that the stimulating effect of low-molecular-weight humic material on bacterial metabolism operated by coupling to the metabolism of less recalcitrant organic substrates. Similar results were found by Stabel *et al.* (1979) and Geller (1983). Cometabolism of many very recalcitrant compounds (e.g., herbicides) is well known (Horvath, 1972; Hulbert and Kraviec, 1977) and is probably an important mechanism for the degradation of the more recalcitrant compounds of fresh waters. The mechanisms of such cometabolism deserve greatly increased investigation and probably represent a major mechanism for biological utilization of these compounds.

It is well-known that ultraviolet irradiance (UV) can photolyse portions of proteinaceous and humic macromolecules (e.g., Manny *et al.*, 1971; Zepp *et al.*, 1981; Geller, 1986; Amon and Benner, 1996). Detailed chemical analyses of these transformations showed that small organic fractions, particularly numerous small fatty acids—such as acetic, formic, citric, pyruvic, malic, levulinic, among others—were generated by photolysis of the humic substances (Wetzel *et al.*, 1995; Moran and Zepp, 1997). Even before these photolytically generated simple organic substrates were identified, many studies demonstrated that DOM exposed to natural UV radiation exhibited immediate stimulation of and sustained bacterial growth (e.g., Stewart and Wetzel, 1981, 1982b; Wetzel *et al.*, 1995; Lindell *et al.*, 1995, 1996; Moran and Zepp, 1997). Different plant species yield very different fatty acids upon natural photolysis of DOM from different stages of their long-term decomposition (Boon *et al.*, 1982; Wetzel, 2000c).

Photolysis of natural humic and related substances by natural irradiance is unquestionably a major physical process that can generate large quantities of simple, readily utilizable organic substrates for bacterial metabolism (see further discussion in Chap. 23). The question is how significant this photolysis is to sustained bacterial metabolism and productivity in surface waters. As we have discussed (Chap. 5), UV-B and UV-A are attenuated rapidly with depth, and rates of attenuation are directly proportional the content of DOC. Short-term photoinhibitory effects of UV irradiance to planktonic bacteria and algae are common in oligotrophic waters (Herndl *et al.*, 1993, 1997; Karentz *et al.*, 1994; Sommaruga *et al.*, 1997). Convective and turbulent mixing of the surface layers can move bacterioplankton to depths where photoenzymatic repair of DNA leads to efficient recovery of bacterial activity. Humic substances that were modified by surface irradiance are also moved to photoprotected regions and are readily utilized by bacterioplankton. Humic substances not only alter the kinetics of photochemical reactions that lead to photolytic degradation but in addition, by utilization of some of the energy, these recalcitrant DOC compounds lessen the photoinhibitory effects of the UV radiation. Exposure of bacterioplankton and phytoplankton to low intensities of UV irradiance enhanced bacterial activity by 20–>100% in a few hours, much of which may have resulted from possible injury to algae and the increased release of organic substrates from the algae. The primary effect of photolysis of humic substances, however, is to potentially generate hundreds of μg liter^{-1} of simple fatty acid substrates for bacterial utilization. Even if only 10% of the large pool of dissolved humic substances is photolysed in the surface half-meter of water, these compounds can be circulated into photoprotected strata of the epilimnetic waters and be readily utilized by bacterioplankton, particularly during periods of darkness. Recent evidence also indicates that portions of photosynthetically active radiation (PAR) also photodegrade humic substances (see Chapt. 23).

D. Utilization Rates of Specific Dissolved Organic Compounds

The relative rates of degradation of the composite pool of hundreds of organic compounds that constitute total dissolved organic matter (DOM) by a heterogeneous composite community of hundreds of species of heterotrophic bacteria are difficult to quantify in natural waters. In natural systems, each species of bacteria potentially has different abilities to assimilate specific substrates. Measurements of total community production rates of the composite heterotrophic bacterial communities are now reasonably estimated by rates of incorporation of amino precursors into bacterial DNA and proteins (e.g., Kemp *et al.*, 1993; Wetzel and Likens, 1999). Measurements of specific substrate assimilation by bacteria, however, are fraught with methodological problems (cf. Bell, 1980; Bell and Sakshaug, 1980; Wetzel and Likens, 1991, 2000). The kinetics of organic substrate utilization by heterogeneous planktonic populations, determined by the uptake rates of radioactivity-labeled organic compounds at substrate concentrations that occur naturally, are instructive in a relative if not absolute way.

The uptake of inorganic ^{14}C-labeled carbon by natural populations over short intervals of time has been used widely as a measure of rates of carbon fixation by photosynthesis. Parsons and Strickland (1962) employed labeled organic substrates to measure uptake by

natural heterotrophic populations in the dark by the relationship

$$v = \frac{cf(S_n + A)}{C\mu t}$$

when

v = rate of uptake (mg C m^{-3} h^{-1})
c = radioactivity of the filtered organisms (cpm, counts per minute)
f = a correction for isotopic discrimination (1.05 or 5% slower uptake of ^{14}C, which has a greater mass than ^{12}C)
S_n = *in situ* concentration (mg $liter^{-1}$) of the organic substrate
A = concentration (mg $liter^{-1}$) of added substrate (labeled and unlabeled)
C = cpm from 1 μCi of ^{14}C-labeled substrate on the radioassay instrumentation used
μ = quantity of ^{14}C added to the sample
t = incubation time (hours)

This equation assumes that natural substrate concentrations (S_n) are much less than A. When the uptake of a solute is mediated by a transport system located on or in the cell membrane, the rate of uptake can be described by Michaelis-Menten kinetics, when

$$v = \frac{V_{max}(S)}{K_t + S}$$

v = velocity at a given substrate concentration S
V_{max} = maximum velocity, attained when uptake sites are continually saturated with substrate
K_t = transport constant, by definition a measure of the affinity of the uptake system for the substrate. Also called K_m, the Michaelis constant, the substrate concentration at which the velocity is one-half of the maximum velocity V. By definition, $v = V_{max}/2$.

As developed by Wright and Hobbie (1966; cf. also Allen, 1969), this nonlinear uptake relation over substrate concentration can be transformed into a linear relationship by the Lineweaver–Burk equation to yield

$$\frac{C\mu t}{c} = \frac{(K_t + S_n)}{V} + \frac{A}{V}$$

With this equation, data from uptake measurements from algae and bacteria at low substrate concentrations can be plotted as $C\mu t/c$ vs. A, giving values for $(K_t + S_n)$ and V (Fig. 17-7). The negative intercept on the abscissa is equal to $(K_t + S_n)$, and the reciprocal of the slope is V, the maximum rate of uptake. The ordinate intercept is equivalent to the turnover time (T_t), which is the time required for complete removal of the natural substrate by the microflora (Hobbie, 1967). The $(K_t + S_n)$ approximates the maximum natural substrate concentration (S_n) if K_t is very small, as is often, but not always, the case. These relationships assume that a constant rate of regeneration of the organic solute is occurring *in situ*, or that steady-state conditions exist. An appreciable portion of ^{14}C organic substrate is respired rapidly by the microflora, and corrections for this loss must be made (Hobbie and Crawford, 1969; Wetzel and Likens, 2000).

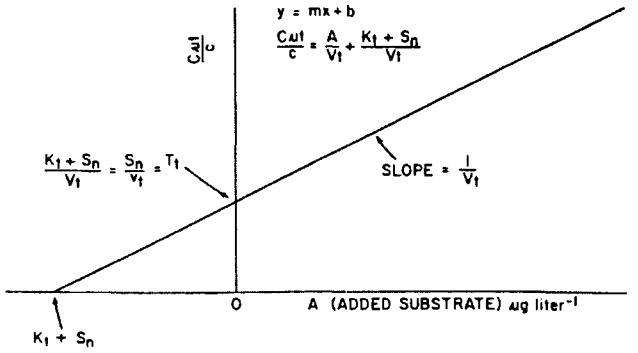

FIGURE 17-7 Graphical analysis of bacterial uptake at low organic substrate concentrations following Michaelis–Menten enzyme kinetics. A plot of $C\mu t/c$ against increasing substrate concentrations, S, illustrating derivation of (1) maximum natural substrate concentrations, $K_t + S_n$, as μg $liter^{-1}$, (2) maximum velocity, V, as μg $liter^{-1}$ h^{-1}, and (3) turnover time for substrate regeneration (T_t) in hours. (After Allen, H. L.: Chemo-organotrophic utilization of dissolved organic compounds by planktonic algae and bacteria in a pond. *Int. Rev. ges. Hydrobiol.* 54:1–33, 1969.)

In contrast to the already discussed nonlinear active uptake velocities at low substrate concentrations, the uptake of organic compounds by natural planktonic populations at high substrate concentrations (approximately >0.5 mg $liter^{-1}$) does not exhibit rate-limitation kinetics or saturation of uptake sites. Passive uptake velocity continually increases with rising substrate concentrations. The slope of the response line is constant (K_d), derived from diffusion kinetics, and has been used to estimate diffusion uptake by natural populations of algae and bacteria.

Analyses of utilization rates of organic substrates under *in situ* conditions with natural populations have been variously applied and usually employ only a few simple substrates such as glucose, other sugars and isomers of glucose, acetate, glycolate, and amino acids. Only a few analyses have been extended over an annual period (Hobbie, 1967, 1971; Wetzel, 1967; Allen, 1969; Overbeck, 1975; Rai, 1978, 1979; Robarts,

1979; Gillespie and Spencer, 1980). Despite inherent physiological limitations, the analyses do yield insight into utilization rates of specific dissolved organic substrates. Foremost, they demonstrate that dark diffusive algal uptake of simple organic substrates for use in heterotrophic growth at low natural substrate concentrations is almost always <10% of active permease-mediated uptake by bacteria. Stated in another way, the algae are generally ineffective in competing for available organic substrates at substrate concentrations maintained by active bacterial heterotrophic uptake (see discussion in Chap. 15, pp. 356ff).

Maximum velocities of uptake are quite variable among lakes and different organic substrates but generally occurred after spring or following late summer algal maxima. Rates decrease by about an order of magnitude during winter in temperate lakes. Concentrations of substrates such as glucose, acetate, and amino acids remain low throughout the year, for the rate of inputs to the labile dissolved organic pool is balanced roughly by the rate of removal by bacteria. Patterns of vertical distribution of uptake velocities tend toward maxima during and following algal maxima in the trophogenic zone, minima in the lower metalimnion–upper hypolimnion, and marked increases in rates near the sediments. Within the sediments, utilization velocities of simple organic solutes are several orders of magnitude greater than in the overlying water (Harrison *et al.*, 1971).

Utilization rates of simple substrates generally increase with greater phytoplankton productivity in an approximately direct relationship (Table 17-5). Great variations are observed in these rates both seasonally and vertically with changes in depth. Uptake rates of simple carbohydrates generally increase with greater bacterial densities and biomass and with increasing concentrations of total inorganic nitrogen and total phosphorus (e.g., Bowie and Gillespie, 1976; Spencer, 1978). Glucose assimilation rates by planktonic bacteria were found to be nearly an order of magnitude greater in littoral areas where submersed macrophytes were abundant than in the pelagic areas (Gillespie and Spencer, 1980). Heterotrophic utilization of glucose by neustonic bacteria at the surface air–water interface was found to be much less than by planktonic bacteria (Dietz *et al.*, 1976). These data may be viewed as general *direct* measurements of the expected positive correlation between increased bacterial metabolism of ubiquitous simple substrates and waters with larger inputs of organic matter. Methodological problems, such as competitive inhibition of one substrate on the uptake of another (Burnison and Morita, 1973), substrate affinities (Button, 1978; Moaledj and Overbeck, 1980), variable substrate uptake in relation to phosphorus availability (Overbeck and Tóth, 1978), and variable corrections for respiratory losses of CO_2, preclude a more detailed evaluation of interactions.

V. CONTROL OF BACTERIOPLANKTON BY BIOTA
