As we have seen above, communities of bacterioplankton have specific growth rates on the order of 1 day^{-1}. Although appreciable diurnal variations in growth are seen and reasonably explained, there is relatively little seasonal variation in bacterial abundance, which suggests that growth and morality are relatively balanced. Although few investigators would disagree that resource limits to growth are approximately balanced by mortality losses, differences in opinion arise concerning the relative importance of parasitism, predation, UV lysis, and other potential causes of death. Supporting data are few but are improving for inland water ecosystems.

A. Dormancy and Natural Mortality

As pelagic conditions alter, bacteria either adjust physiologically or by means of rapid genetic modifications to the new environment, die, or enter a state of dormancy. Statements that fissile, vegetative microbes do not age, senesce, and die, but rather are only replaced by two young individuals (e.g., Postgate, 1976) are thermodynamically, biochemically, genetically, ecologically, and intuitively unreasonable. Alternatively, it is often argued that the physiological state of a significant portion of the bacterial community in most aquatic environments is dormant (e.g., Stevenson, 1978). Although there is repeated evidence for the formation of smaller cells, microcysts, and similar diminutive cells under nutrient, substrate, and other environmental limitations, physiological data supporting a dormant state are sparse. As indicated earlier, microautoradiographic analyses of the percentage of natural bacteria that assimilate specific organic substrates nearly always demonstrate uptake by a small (<50%) portion of the composite community of many different bacterial species. Inability or inactivity for assimilation of one substrate does not necessarily indicate inability or inactivity for others, however.

Mortality of bacterioplankton in the absence of grazing by protists and zooplankton is usually <50% per day (e.g., Servais *et al.*, 1985; Pace, 1988; Wetzel, 1995). Much of that loss is likely associated with simple senescence under starvation conditions, particularly if exposed to high light, as well as parasitism.

B. Viral Mortality

The bacterioplankton community is made up of many strains, all exhibiting varying population dynamics and growth rates. Changes in abundance can be rapid, in the range of 0.2–0.6 day^{-1} (Tuomi *et al.*, 1997). Mortality of bacterioplankton from viral infection can be very high. Viruses have been observed to be very abundant, as, for example, ca. $2.5–3.7 \times 10^8$ ml^{-1} in eutrophic Plußsee, Germany (Bergh *et al.*, 1989; Witzel *et al.*, 1994). Average virus-to-bacteria ratios of 50:1 have been observed with a high direct correlation between the abundances of viruses and bacteria (Table 17-6). If viruses do not encounter a bacterial or algal host, viral decay rates among natural viral populations occur, during which viral nucleic acid is released from the capsid (Bratbak *et al.*, 1994; Wommack and Colwell, 2000). The rate of this inactivation of phages is typically on the order of 0.1–2 day^{-1}, although much longer rates can occur before instability sets in (see Chap. 23).

Based on *in situ* observations and experimental results, most estimates indicate that viral phages lyse about one-fourth (range, 2–24%) of the bacterial production per hour (Heldal and Bratbak, 1991). On the average, 50 mature virus particles (range, 10–300) are released from each killed bacterium. Phage-induced mortality of bacterioplankton in Lake Constance, Germany, was estimated to vary between 1 to 24% of total mortality over an annual period (Simon *et al.*, 1998). Other viral mortality estimates of bacterioplankton are in a similar or higher range (11–66%) for lakes, coastal waters, and rivers (e.g., Suttle, 1994; Fuhrman and Noble, 1995; Mathias *et al.*, 1995; Wommack and Colwell, 2000).

C. Grazing by Protists and Larger Zooplankton

Bacterivory by protists and larger zooplankton is clearly a major and often dominant mortality factor within natural bacterioplankton communities. The feeding effectiveness on bacterioplankton and their importance in the nutrition, growth, and productivity of both protistan protozooplankton and larger zooplankton were discussed at length in Chapter 16 (pp. 405–406; 427). Many protists feed on bacteria-sized particles and picophytoplankton (<2 μm) and thus utilize a size class of bacteria, algae, and particulate detritus that is not as effectively utilized by larger zooplankton. This protistan bacterivory, particularly by flagellates, is a dominant mortality factor of bacterioplankton. At this point, the questions are directed to the effects of grazing on the development, growth, and productivity of the bacterioplankton under different conditions.

Although crustacean zooplankton can consume bacteria in seemingly large quantities (Table 17-7), the rates are relatively low in comparison to the bacterial biomass present. In comparison to other bacterivorous grazers over an annual period, on average grazing by daphnids accounted for 9–12% of bacterioplankton mortality; ciliates, 14–19%; and heterotrophic nanoflagellates, 52–68% in Lake Constance (Güde, 1986; Simon *et al.*, 1998). An attempt was made to generalize the relative impacts of different groups of bacterivores on total bacterioplankton productivity (Table 17-8), but variance is very large seasonally and among lakes of differing chemical composition, dissolved organic matter, and other parameters. These values are likely overestimates because the true rates of viral mortality is conservatively estimated and not known directly.

Bacterivory values greatly in excess of 100% are frequently found in the literature. Such values may be real during particular instantaneous measurements but obviously could be sustained only for very short periods before supply is suppressed and feeding efficiencies decline precipitously. Furthermore, many of the estimates of feeding are based on the likely erroneous assumption that bacterivory rates are equal among extant protists and that their physical presence and

enumeration allows a direct estimate of community bacterivory. Careful analyses among several different habitats indicated that rarely are more than half of the bacterivorous nanoflagellates actively feeding at any given time (González, 1999). The fraction of active protistan grazers is time-dependent and reaches a saturation point in a few minutes, depending upon the environmental conditions. Percentages of actively grazing nanoflagellates appear to be lower (ca. 25%) in oligotrophic ecosystems in comparison to those (ca. 40–60%) of more eutrophic pelagic systems.

Bacterivory is dominated by heterotrophic nanoflagellates. Ciliates and rotifers rarely impact bacterioplankton communities significantly by ingestion. Even though *Daphnia* and other cladoceran zooplankton are relatively inefficient bacteriovores, at times seasonally, as for example during the "clearwater phase," very large populations of cladocerans can be effective in reducing the bacterioplankton. Moreover, among very eutrophic lakes where bacterial specific growth rates and production are enhanced by high nutrient loading, the total bacterivory by cladocerans can increase relative to protistans. Many examples of these relationships have been observed (e.g., Pace *et al.*, 1990; Chrzanowski and Šimek, 1993; Pace and Cole, 1996; Simon *et al.*, 1998b).

VI. BIOTICALLY RELEASED DISSOLVED ORGANIC MATTER

Dissolved organic compounds are released by organisms during active growth and by autolysis upon senescence and death.

A. Biotically Released Dissolved Organic Matter: Autolysis

In the past two decades, great enthusiasm arose for explanations of complex food-web structures and interrelationships. The underlying themes of these excellent studies elucidating material fluxes among biota focused on animal predation and predatory impact relationships within the communities. Emerging from these collective studies was a highly erroneous assumption that much of the production was ingested and the most organic matter was utilized by heterotrophic metazoans. In reality, most organic production simply senesces, lyses, and is decomposed by heterotrophic microorganisms (Wetzel, 1995). Longevity and senescence are genetically programmed, and although the temporal sequences can be modified by environmental parameters, genetic and biochemical senescence and death is finite. This area of intensive contemporary research among higher plants and animals is almost totally neglected among aquatic organisms and deserves greatly accelerated study because it is a fulcrum for the detrital dominance of metabolism in freshwater ecosystems.

As organisms, including bacteria and viruses, senesce and die, ***autolysis*** of cytoplasmic cellular contents by deterioration of cellular membranes rapidly releases significant amounts of dissolved organic matter (DOM). This release is followed by rapid utilization of energy- , carbon- , and nitrogen-rich substrates by bacteria. The loss of total substance is very high immediately after "death" in all organisms (Table 17-9). Although such release is high among higher organisms, such is stated to be so, without evidence, for bacteria on the premise that bacteria simply enter states of starvation and dormancy (Güde, 1988; cf. review of Morita, 1982). It is certainly unlikely that autolysis would occur at the same rate as growth, but it must be emphasized that although bacterivory can be and is often dominant, mortality can occur by other means as well, and these means are usually never examined simultaneously with grazing.

The autolytic release of DOM initially by algae, aquatic plants, and zooplankton and its progressive decomposition thereafter has been studied in a few cases (Botan *et al.*, 1960; Krause, 1964; Otsuki and Hanya, 1968, 1972a,b; Golterman, 1971; Otsuki and Wetzel, 1974; Godshalk and Wetzel, 1978a–c; Hansen *et al.*, 1986). Data from these studies illustrate the general relationships believed to prevail. Organic carbon of dead green algal cells decomposing under aerobic conditions declined about 55% in 5 days (20°C) and decreased more slowly thereafter. Cell morphology changed little during the first 50 days, indicating that although the cellular contents were decomposed quickly after death, the cell wall was relatively resistant to microbial degrada-

[a] From Otsuki and Hanya (1972a).

tion. Organic nitrogen of the cells was reduced by about 70% during the first 30 days; thereafter, decomposition of both organic C and N was slower. Dissolved organic C and N released by autolysis, and subsequently from intermediate bacterial products of decomposition, are degraded rapidly at first; rates of degradation then decrease with time (Table 17-10). Similar results were found with the decomposition of submersed vascular aquatic plants (Chap. 21).

B. Utilization of Extracellularly Released Dissolved Organic Carbon

Dissolved organic compounds also originate by secretion (extracellular release) from actively growing algae (discussed in Chap. 15, p. 382ff.) and larger aquatic plants (Chap. 18). In general, extracellular release of dissolved organic carbon from phytoplankton increases nonlinearly with increasing productivity and becomes a very low percentage (<5%) of total photosynthesis in eutrophic lakes (see Chap. 15, pp. 382ff.). The quantities and qualitative composition of extracellularly released organic matter are variable and depend upon the species and their physiological status under existing environmental conditions. Simple organic acids, sugars, and more complex carbohydrates, amino acids, peptides, pigments, and enzymes (see Chap. 15, pp. 382–384) are among the compounds known to be liberated during active growth. Aquatic bacteria possess uptake systems of high substrate affinity and low substrate specificity.

Most of these secreted compounds are assimilated rapidly by the microbial flora, so their concentrations in the water would always be expected to be low. Some extracellular products, such as polypeptides, are more resistant to rapid degradation and can form a more significant portion of the total dissolved organic matter at any given time. Extracellular release of organic compounds during active growth represents an elimination of metabolic products and is a relatively small loss of synthesized organic matter for the plants. Demarcation between true physiological loss of photosynthate from release of dissolved organic compounds during cellular senescence and autolysis is not distinct; certainly both occur simultaneously with rapidly changing rates of release in natural heterogeneous algal and bacterial communities containing hundreds of species at any given time and location.

Dissolved organic compounds are also released by secretion from zooplankton and by leaching of their feces. For example, a significant amount (up to 17%) of the algal carbon ingested by cladoceran zooplankton can be immediately lost as dissolved organic carbon as the algae are damaged during feeding (Lampert, 1978a). More than 10% of the algal particulate carbon removed from suspension by grazing can be transformed to dissolved organic carbon by these processes. Compounds released through these processes can be of significance to the planktonic bacteria, since substrate availability in pelagic waters is usually limiting.

Extracellular organic products of phytoplankton are utilized in different ways (Nalewajko, 1977). Clearly, different phytoplankton release different compounds extracellularly. For example, low-molecular-weight compounds (<1 kD) predominated those released by diatoms, whereas cyanobacteria released high-molecular-weight compounds (Cho *et al.*, 1997). Low-molecular-weight substances are assimilated rapidly by bacteria or cyanobacteria, essentially simultaneously as rapidly as excreted (Nalewajko *et al.*, 1980; Chang, 1981). Binding of low-molecular-weight compounds to colloids or to the surfaces of particulate matter may also occur and can result in abiotic removal of these substances from solution through subsequent sedimentation. One would anticipate marked differences in assimilation rates among bacterioplankton based on the phytoplankton predominance at any particular time or spatial distribution.

Estimates of bacterioplanktonic utilization of secreted organic compounds from natural populations indicate rapid rates of assimilation. For example, in two eutrophic lakes in southern Sweden as well as in natural mixed planktonic communities from an oligotrophic lake in Michigan, from 28 to 80% of the released dissolved organic carbon was recovered in bacterial particulate fractions (Coveney, 1981; Coveney and Wetzel, 1989). First-order rate constants for utilization of extracellularly released organic carbon exhibited a mode of 0.05–0.15 per day. An average of 50% (range, 33–78%) of gross uptake of extracellularly released organic carbon was respired. Variations in utilization were positively correlated with temperature. As a result of this utilization, an appreciable portion of the dissolved organic carbon released from photosynthesizing algae is returned to the pelagic food web as microbial biomass, despite high losses to respiration.

Similar results have been found in many freshwater and marine pelagic ecosystems (e.g., Saunders and Storch, 1971; Meffert and Overbeck, 1979: Larsson and Hagström, 1979; Bell and Satzshang, 1980; Chróst and Faust, 1983; Brock and Clyne, 1984; Jones and Cannon, 1986; Feuillade *et al.*, 1988; Chrzanowski and Hubbard, 1989; Baines and Pace, 1991; Nürnberg and Shaw, 1998). As the quantities of recalcitrant organic substrates of total DOC increase, for example, in lakes and rivers receiving high loads of humic substances, the importance of the DOC released extracellularly from algae decreases markedly as substrates for bacterioplankton (Jones and Salonen, 1985; Miller, 1987; Sundh and Bell, 1992). In summary, it is estimated that under most circumstances, less than half of the carbon required for growth of bacterioplankton results from extracellular release of organic substrates from phytoplankton.

VII. DECOMPOSITION OF PARTICULATE ORGANIC DETRITUS

Kinetic evaluations of aerobic decomposition of algae by bacteria approximate first-order reaction rates during the initial 30 days of degradation. Decomposition of cellular nitrogen and the production of dissolved organic nitrogen demonstrate that dead algal organic nitrogen is separable into labile and rocalcitrant constituents according to their relative resistance to bacterial degradation. Additional dissolved organic nitrogen is generated by bacteria through reassimilation of mineralized nitrogen. The general sequence of decomposition of dead algal material, the major organisms involved in this degradation, and the simultaneous regeneration of organic nitrogen are indicated in Figure 17-8. Following proteolysis by means of various enzyme systems, amino acids are deaminated by deaminases to ammonia; the ammonia then proceeds through a series of nitrification stages to hydroxylamine, nitrite, and nitrate. Organic nitrogen is synthesized during the processes of nitrate reduction, denitrification, and nitrogen fixation (see Chap. 12), each of which varies with numerous environmental parameters. In turn, lysis of the microbial flora generates additional dissolved organic nitrogenous compounds.

Decomposition rates of organic matter are quite different under anaerobic conditions. For example, after 60 days of anaerobic decomposition of green algal cells at 20°C, 30% of algal cell carbon was transformed into dissolved organic carbon (DOC) and 20% was mineralized to CO_2; 50% remained as particulate matter. Of the algal cell nitrogen, only 8% was transformed to soluble form, 48% was mineralized, and 44% remained in particulate form after 60 days. The DOC in solution consisted largely of yellow organic

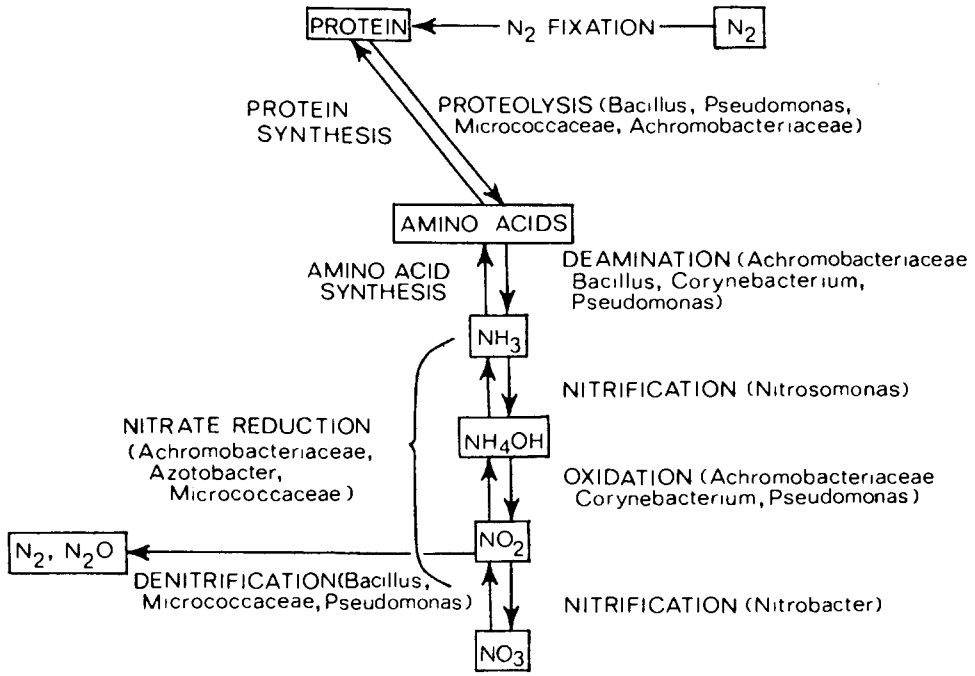

FIGURE 17-8 Decomposition and utilization stages of nitrogenous organic matter of aquatic organisms. (Modified from Botan *et al.*, 1960.)

acids that were resistant to further degradation. The decomposition rates and production of dissolved organic compounds from dead algal cells were only one-fourth as great under anaerobic as under aerobic conditions, and the rate constant of cell carbon and nitrogen decomposition decreased to less than one-half under anoxic conditions. Similar results have been found for the decomposition of aquatic angiosperms under anaerobic conditions (cf. Godshalk and Wetzel, 1978a–c).

The rates of decomposition under both aerobic and anaerobic conditions are strongly influenced by temperature (usually higher rates with increasing temperatures in the natural range), pH (commonly lower at acidic pH values), the major cation concentrations and cationic ratios, and other factors. The rates of cycling and utilization of the numerous dissolved organic intermediate products of bacterial and fungal degradation, such as amino acids, keto acids, various fatty and nonvolatile organic acids, phenolic derivatives, mercaptans, and others, are highly variable (see, e.g., Krause *et al.*, 1961).

Experimental studies on the transformation of artificially generated radioactive algal detritus under conditions approaching a natural community are instructive in understanding the relationships involved (Saunders, 1972). The living components of the water constitute a very small portion of the total organic matter (Fig. 17-9); most organic matter occurs as dissolved organic matter (DOM) and as detrital particulate organic matter (POM). For example, in the surface water of a productive lake, the summer POM averaged 57% of the total seston (inorganic and organic; Table 17-11). The phytoplanktonic dry weight ranged from between 5 and 25% of the organic particulate detritus most of the time and only occasionally exceeded 40–50%. Similar results have been shown for the seston composition of Lake Erie (Leach, 1975) and several Russian lakes (Winberg *et al.*, 1970). In the autumn of Lake Constance, Germany, dead organic seston exceeded microbial biomass by a factor of 4–10 (Simon and Tilzer, 1982). Considering that the POM constitutes only about 10% of the total detrital organic matter (ca. 90% as DOM), and that living organic matter makes up only a small fraction of the particulate component, it is clear that dissolved and particulate organic detritus is a major component of the organic mass of aquatic ecosystems.

[a] After Saunders (1972a).

Decomposition of the particulate organic detritus generated from planktonic communities of surface lake water occurs more slowly, at rates on the order of 10% per day (Table 17-12). Similar rates of decomposition of planktonic algae in an oligotrophic lake ranged between 0.5% day^{-1} (winter) to 6% day^{-1} in summer (Cole *et al.*, 1984). Radiolabeled dissolved organic carbon derived from the particulate organic detritus amounted to about 1% of the initial radioactivity after one day; these values were about 2–6 times greater than the amount of dissolved organic matter released extracellularly by phytoplankton in the trophogenic zone.

Decomposition rates of detrital particulate organic matter (POM) of course are influenced by an array of compositional and environmental factors. Certainly differences in the organic composition of algal cell

walls lead to differences in degradation rates. For example, POM of dead cyanobacteria decomposes much more rapidly than that of green algae and diatoms; desmid algal POM is especially resistant (Mills and Alexander, 1974; Gunnison and Alexander, 1975). The concentrations and species diversity of bacteria also are involved. Among environmental parameters, temperature and oxygen are paramount, and availability of inorganic nutrients, especially nitrogen, can also be an important variable.

Bacterial decomposition of organic detritus (soluble or particulate) can be considered simply as the rate of change between bacteria and detrital substrates, compounds, or particles and can be expressed as a biomolecular second-order reaction (Saunders, 1972b):

$$(m_1, m_2, \cdots)(T,[N], n_1, n_2, \cdots)$$
$$\downarrow \quad \downarrow$$
$$\frac{-d[S]}{dt} = C_1[S] \times C_2[B]$$

when

$[S]$ = concentration of detrital substrate
$[B]$ = concentration of bacteria
T = temperature
$[N]$ = concentration of inorganic nutrients
$m_1, m_2, \ldots ; n_1, n_2, \ldots$ = other variables
C_1, C_2 = coefficients

The rate of decomposition of detrital substrates is a function of their concentration and of the enzymatic activity of the bacteria dispersed in the water or attached to surfaces of detrital particles (Saunders, 1972b). The coefficients C_1 and C_2 are obviously highly dynamic and variable operators on the detrital–bacterial interactions. Control variables that operate on the substrate coefficient C_1 include various biodegradability factors (Alexander, 1965b, 1975), examples of which are many. A structural characteristic of the substrate molecule or of the particle surface parameters (i.e., area, particle size, and adsorption sites) can inhibit the enzymes. Certain enzymes can be inactivated by adsorption to surfaces of minerals or colloids or inhibited by phenolic and polyaromatic substrates or their derivatives (e.g., Boavida and Wetzel, 1998). Substrates may be rendered inaccessible not only by surface characteristics but also by transport of the substrates to microenvironments in which conditions preclude or greatly reduce bacterial or enzymatic activities.

Control variables that operate on the bacterial component C_2 include obvious parameters such as temperature, T, and inorganic nutrient concentrations, $[N]$; as well as other essential growth factors or biologically utilizable terminal electron acceptors. The presence of biologically generated organic inhibitors, microbially formed inorganic inhibitors, high salt concentrations, temperature extremes, acidity, or other environmental conditions outside the range suitable for microbial proliferation can all inhibit bacterial growth (Alexander, 1965b, 1975). A microbial community lacking the appropriate enzyme system may not be able to metabolize certain compounds, or the substrate may not be able to penetrate into cells that possess the appropriate enzymes. Thus, the decomposition rates of organic substrates in natural systems are a function of the physical and biological structure at any instant in time, as well as of the substrate characteristics and physiological state of the microflora and their enzymatic systems.

Within this general framework, it is frequently desirable to know the flux rates of organic carbon among the different components of the system. As we have seen earlier (Fig. 17-9), the system structure is dominated by two very large pools of nonliving carbon, the inorganic and dissolved organic carbon. Algae and particulate organic detritus contain much less carbon, zooplankton and other fauna contain even less; and bacteria contain about 10% of that of the zooplankton (Saunders, 1971). This approximate general distribution of the carbon mass of the trophogenic zone of lakes bears little relation to carbon flux rates, however.

A 1-day intensive study undertaken to evaluate relationships between the carbon structure of a lake's pelagic system and various metabolic flux rates indicates that the microflora control the movement of carbon (Fig. 17-10). The biota utilize the carbon of the various pools within the limits of the environmental conditions. The environmental variables change constantly and result in continually changing rates of

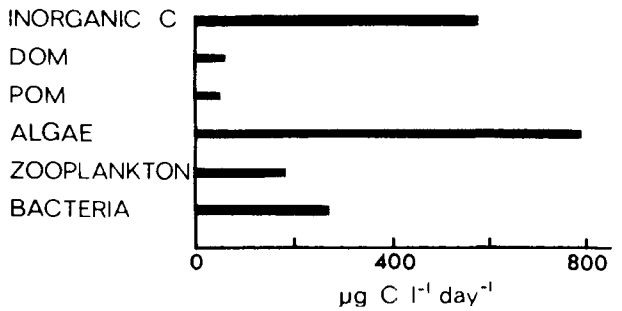

FIGURE 17-10 Assimilation rates of carbon in μg C liter^{-1} day^{-1} by different microbial components at 1 m in Frains Lake, Michigan, on 22 July 1968. (Modified from Saunders, G. W.: Carbon flow in the aquatic system. *In* Cairns, J., Jr. (ed.) *The Structure and Function of Fresh-Water Microbial Communities,* Blacksburg, Va., Virginia Polytechnic Institute, 1971.)

transfer among the carbon pools. The changes in carbon concentrations and metabolic rates in the surface waters over a 24-h period during the summer can be generalized in a theoretical way in Figure 17-11. Photosynthetic rates of algae are coupled with light quantity. Usually, maximum photosynthetic rates are skewed toward the morning period of high light intensity and less photoinhibitory and photorespiratory reductions of photosynthetic efficiencies. Photosynthetic rates decline precipitously with decreasing light in the evening (Saunders and Storch, 1971). Coupled with the cycle of extracellular release of dissolved organic compounds by algae, bacterial assimilation rates increase and reach maximal levels about 3 h following the secretion maximum. The division activity of bacterial populations is highest during the night and early morning, when the output of organic substances by the algae is low, whereas volume growth is highest during the second half of the day, when release of photosynthetic algal products is highest (Krambeck, 1978). These general relationships were supported by diurnal measurements

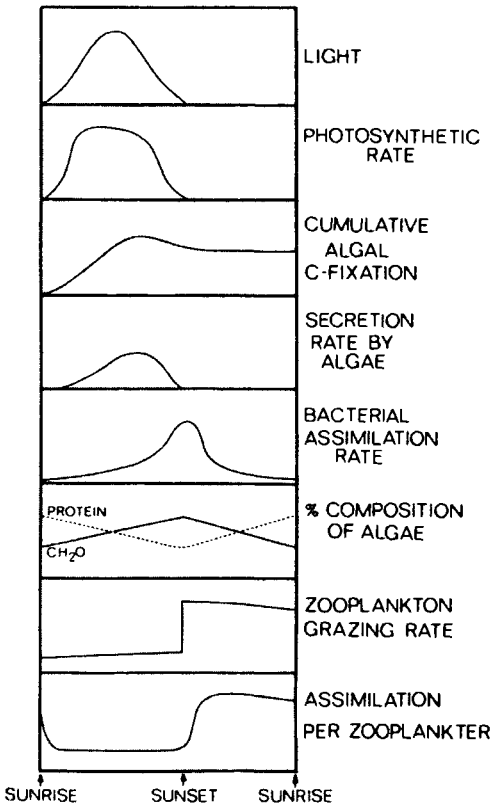

FIGURE 17-11 Generalized diagrams of the daily cycles of various processes and concentrations in the upper trophogenic zone of a lake system in summer. (Modified from Saunders, G. W.: Carbon flow in the aquatic system. *In* Cairns, J., Jr. (ed.) *The Structure and Function of Fresh-Water Microbial Communities,* Blacksburg, Va., Virginia Polytechnic Institute. 1971.)

of bacterial productivity (Simon, 1994). The highest rates of bacterial biomass production were found in the evening during the spring phytoplankton bloom. The ratio of protein to carbohydrate of the algae also shifts diurnally; maximum carbohydrate levels are reached at the conclusion of the daily photosynthetic period. Zooplanktonic grazing rates in the epilimnion can increase markedly at dusk with a rapid diurnal migration of many zooplankters to the trophogenic zone, and thus impact both bacterial and particularly algal growth. Ingestion and assimilation rates of algae by many zooplankton, particularly *Daphnia,* are greater in the night than during the day. Thus, we can envision a series of coupled oscillating reaction systems among the major components of the pelagic system in the trophogenic zone, that respond to an array of environmental variables.

A. Sedimentation and Decomposition of Pelagic Particulate Organic Matter

The vertical distribution of bacterial numbers and activity in stratified lakes commonly shows a maximum in the trophogenic zone, a minimum in the metalimnion, and an increase in the lower hypolimnion. The decomposition of sedimenting organic matter produced in the epilimnion follows a similar distribution. A number of devices have been used to measure the amount of tripton, the term for all nonliving suspended matter (cf. methods discussed in Edmondson and Winberg, 1971; and Bloesch and Burns, 1980). Containers of various types are suspended at several depths to entrap sedimenting materials over a period of one to several weeks, depending on the sedimentation rates. After a period of collection, kept as short as possible to reduce complicating interferences, chemical analyses of the collected seston permit an approximate indirect evaluation of decomposition-induced changes in the organic matter that have occurred during sedimentation.

Most (>75%) soluble organic matter released by secretion and autolysis of phytoplankton decomposes rapidly to a major extent at the site of its generation and release in the trophogenic zone. The particulate organic detritus undergoes slower degradation. During stratification periods in lakes of moderate depth, 75 to >99% of the particulate organic matter synthesized in the trophogenic zone is decomposed in the water column by the time it reaches the sediment interface (Table 17-13). In Lawrence Lake, Michigan, an annual mean of 88% of the sedimenting particulate organic carbon was decomposed by the time it reached the lower epilimnion (5 m; Wetzel *et al.,* 1972). Little additional decomposition occurred on further hypolimnetic sedimentation; an annual mean of 10% of planktonic

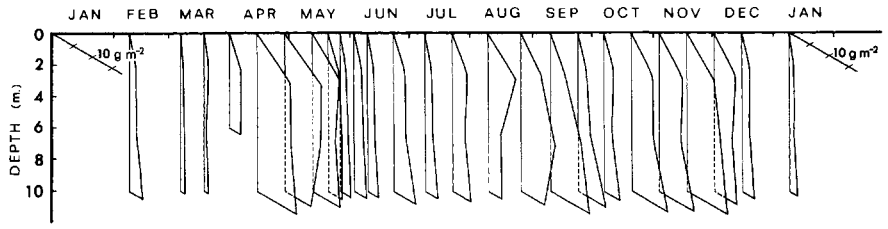

FIGURE 17-12 Seasonal changes in the organic content of sedimenting seston (g m^{-2}), Lawrence Lake, Michigan, 1972. (From White and Wetzel, unpublished.)

particulate organic carbon of the trophogenic zone was found at 10.5 m. Similar results were obtained by Lawacz (1969) using different methods.

Even though the degradation of particulate organic matter is fairly complete with increasing depth, seasonal variations are great (Fig. 17-12). The increasing concentrations of sedimenting organic matter with depth must be considered in relation to the decreasing area of each stratum as the basin morphometry constricts with depth. This relationship is illustrated diagrammatically in Figure 17-13 for Schluënsee; in this lake, the funneling effects of the basin morphology increased the concentration of organic carbon per unit area, even though the total amount of synthesized particulate organic matter was greatly reduced (>97%) by decomposition at a cumulative depth of 40 m (Ohle, 1962). As the size of the basin decreases, the significance of the funneling effects of concentration increases.

As lakes become shallower and the importance of littoral production in relation to that of the phytoplankton increases, a greater proportion of the synthesized organic matter is shifted to the sediments. We would expect decomposition to be more complete in the water column of larger, oligotrophic lakes because of the amount of time required for decomposition of the more recalcitrant materials of algal cells (cf. Jewell and McCarty, 1971) and the distance and time through which a particle travels during sedimentation. Evidence supports these expectations.

For example, in a shallow (z_m 6.5 m), hypereutrophic lake in southern Michigan, the high primary productivity of phytoplankton, the relatively short distances that algal particulate organic matter must fall to reach the sediments, and the close proximity of the anaerobic hypolimnion (anaerobic 4 m) to the photic zone resulted in high sedimentation of incompletely decomposed algal particulate matter to the sediments (Molongowski and Klug, 1980b; cf. also Gasith, 1975, 1976). The quantity of organic seston reaching the sediments was not only high in this shallow lake but was relatively uniform throughout the thermally stratified summer period of high phytoplankton productivity. The residual sedimenting seston had a high protein content (50–60% of that of phytoplankton) and, as a result, a low C/N ratio (4–6). In contrast, in deeper lakes, proteinaceous materials in sedimenting seston are rapidly degraded in the upper water strata (Brehm, 1967; Matsuyama, 1973; Lastein, 1976). The carbohydrate fraction of the sedimenting seston reaching the sediments of this shallow lake consisted primarily of glucose (19.2%),

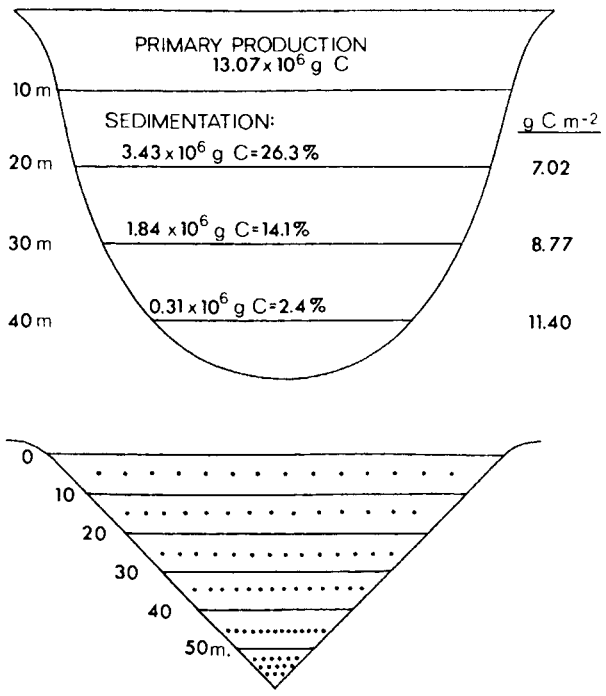

FIGURE 17-13 Schematic diagrams of (*upper*) the relationships between planktonic primary production and sedimentation of organic particulate carbon in Schluënsee, Germany, 16 July–16 August 1960, and (*lower*) the morphometric funnelling effect on sedimentation in lakes. (Modified from Ohle, 1962.) The numbers to the right of the upper figure (g C m^{-2}) indicate the concentrating effect of basin morphometry on the quantity of particulate carbon per unit area in each of the strata at increasing depths. The percentage of the particulate carbon produced in the trophogenic zone and sedimenting to each stratum (inside the diagram) is markedly decreased by decomposition at each step.

other soluble monomers (12.4%), and soluble polysaccharides (43.4%). Cellulosic polysaccharides represented only 7.2% of the total carbohydrate fraction, which indicates that most of the carbohydrates were of algal origin, even though this lake has a massive littoral development that covers over a third of the lake area. As will be discussed later (Chaps. 21 and 23), much of the littoral particulate plant production decomposes on or within the sediments within the littoral zone.

VIII. PRODUCTIVITY OF BACTERIOPLANKTON

Comprehensive evaluations of planktonic bacterial productivity have increased markedly in the last decade, largely as a result of greatly improved radiotracer methodology. Several of these studies yield sufficient detail for functional analyses of carbon fluxes. Although many of the estimates of bacterial productivity will be discussed in Chap. 23 on the organic carbon cycling in aquatic ecosystems, a few statements are appropriate here in relation to the discussion of the distribution of pelagic bacteria and their growth.

A. Planktonic Bacterial Productivity

Bacterioplankton live in natural environments that are relatively hostile to rapid growth—literally a pelagic desert. Natural bacteria grow at slower rates than their maximum potential and may be limited by organic carbon substrate or nutrient availability, as well as physicochemical factors such as temperature. Even under relatively optimal growing conditions in natural pelagic environments, average generation times are often several days. The metabolic and physical factors regulating growth vary so rapidly in natural environments that even under the best of circumstances our measurements of bacterial growth and production are meager composite estimates of the true values. These generation rates may slow to average doubling times of 100–200 days or even more during winter periods when resources as well as temperatures are reduced (Moriarty and Bell, 1993). Clearly, pelagic bacteria communities are usually not growing at maximum rates much of the time. Individual species populations within communities compete inefficiently for resources and survive in a starved state. Both organic substrate and nutrient (especially phosphorus) availability are critical limitations under many circumstances in lakes. Slow growth rates and long periods in stationary phase and starvation are normal conditions for bacteria in the pelagic environment.

The efficiency of bacterial metabolism and growth is highly variable. Although it is theoretically possible for bacteria to convert organic substrates to biomass with high efficiency (>85%) under optimal conditions (Payne and Wiebe, 1978), such high rates are never realized under natural conditions. Growth is rarely in exponential phase and with many resource and physical limitations, growth efficiencies [bacteria production/(bacterial production + bacterial respiration)] are nearly always <50%, and mostly <30% (e.g., Schroeder, 1981; Pomeroy and Wiebe, 1988; Cole and Pace, 1995).

The rates of biomass turnover of bacterioplankton is a useful parameter to evaluate differences in spatial and seasonal dynamics. The ratio of production to biomass (P/B ratio) or turnover time of actively metabolizing bacteria was comparable to the generation time of actively metabolizing cells (Simon, 1988). The biomass of small (0.2–1.0 μm) free-living bacteria usually turned over significantly faster (higher P/B ratios) than that of large (1.0–3.0 μm) bacteria throughout the water column (Fig. 17-14). The turnover rates of attached bacterial biomass exhibited large fluctuations. When large amounts of decaying organic particles were present, turnover rates of attached bacteria were similar to those of large free-living bacteria and shorter than those of small free-living bacteria, particularly in aphotic zones (Fig. 17-14). Bacterial production is usually greater in anoxic hypolimnetic water of stratified lakes over a range from oligotrophic to eutrophic, despite lower hypolimnetic temperatures (Cole and Pace, 1995). Although the growth efficiency of anaerobic bacteria is about the same as that of aerobic bacteria, the relatively high rates of bacterial production in anoxic waters resulted from larger bacterial populations growing more slowly than the aerobic bacteria.

Once the organic matter is converted from dissolved to particulate phases, bacterial biomass is subject to mortality as indicated earlier—natural genetically programmed senescence and death with autolysis, viral parasitism, and particularly grazing by protists and other zooplankton. The methodology of assaying production rates allows some separation of the grazing by zooplankton, but in general the observed production rates represent net production rates after losses from respiration, autolysis, parasitism, and grazing. In addition, a significant proportion of the bacterioplankton community can be in a dormant state. The percentage of the total bacterial community that is dormant can also change rapidly under different conditions. For example, in Lake Constance, Germany, during the spring bloom of phytoplankton when bacterial production reached it maximum, 60–80% of all free-living bacteria were metabolically active (Simon, 1987, 1988). During this period of abundant dead algae and other detrital particles, a high proportion of the detrital particles were colonized with metabolically active attached bacteria.

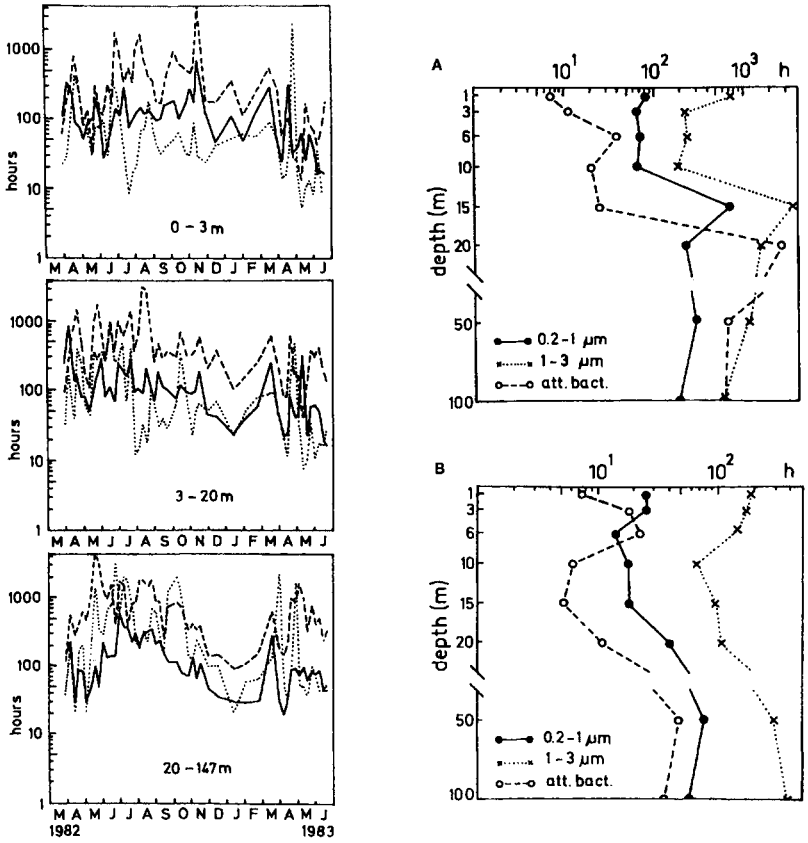

FIGURE 17-14 Bacterial turnover times (*P/B* ratio of biomass/production) in hours (hr) of small (0.2–1.0 µm; ———) and large, free-living (1–3 µm; - - - -) and attached (· · · · · ·) bacteria in mesotrophic Lake Constance, Germany. Curves = mean values from the water strata at the depths indicated. In the depth profiles, (*a*) = 19 July 1982 during a diatom bloom in the epilimnion; (*b*) = 16 May 1983 during a spring phytoplankton bloom. (From Simon, 1988.)

These detrital particles in various stages of decomposition can aggregate and be colonized by microbial consortia. Microenvironmental conditions within such detrital–microbial consortia can be characterized by reductions in dissolved oxygen and steep redox gradients (Paerl and Pinckney, 1996). These microgradients affect rates of organic degradation and nutrient regeneration and are certainly very different from those of the immediately surrounding pelagic water. On an annual basis, however, most (>75%) of the bacteria were small (0.2–1 µm) and free-living, made up over two-thirds of the bacterioplankton productivity, and were most important in recycling of organic matter. Larger (1.0–3.0 µm) free-living bacteria constituted about half of the total bacterial biomass but had much slower turnover times than the smaller forms. During periods of stratification, turnover rates are generally much faster, by an order of magnitude, in the trophogenic zone than in the tropholytic zone.

Examples of annual mean production of bacterioplankton across a spectrum of lakes of different nutrient availabilities show an approximate direct correlation with increasing production of phytoplankton (Table 17-14). It must be emphasized repeatedly that this bacterial production is often a very small portion of total bacterial metabolism; most bacterial metabolism occurs in the sediments and littoral regions of lakes and rivers (see Chap. 21). Although the annual production of the bacterioplankton is usually appreciably less than the estimated annual production of phytoplankton, in many lake and most river ecosystems inputs of organic matter from allochthonous and littoral sources greatly exceed those generated by the phytoplankton. Although the summed respiration of heterotrophic consumers (predominantly microbes) cannot exceed organic inputs to an ecosystem, the total organic carbon assimilated by heterotrophic consumers and their production can exceed the organic inputs to

the ecosystem simply because organic carbon is recycled, although inefficiently, by consumers (Strayer, 1988).[5] However, sources of organic matter, particularly dissolved, from external allochthonous and littoral areas are known to supplement greatly and often dominate over those produced by the phytoplankton. In addition, storage of organic matter can greatly alter the rates of respiration, utilization, and recycling.

The horizontal spatial distribution of productivity of bacterioplankton within a lake or river is markedly influenced by differences in the availability of sources of organic substrates and nutrients. For example, bacterial production rates at coastal sites of Lake Erie were found to be 25–50 times greater than those at the offshore sites (Hwang and Heath, 1997; similarly in Lake Michigan; Scavia and Laird, 1987). Percentage grazing of bacterioplankton by protists was much more extensive in offshore regions than was the case in the inshore areas of much higher bacterioplankton productivity.

B. Chemosynthesis

Microbial production by chemosynthesis occurs to a marked extent in layers having contact with the anaerobic zones of an aquatic system, especially in boundary layers between anaerobic and aerobic zones. As indicated in earlier discussions of the cycling of several elements, the anaerobic processes of decomposition of organic matter provide reduced inorganic compounds that serve as energy substrates for the chemoautotrophic bacteria. Chemosynthetic secondary production becomes significant primarily in steep gradients of redox potential (Sorokin, 1964a, 1965, 1970). Outside of these layers, chemosynthesis is very low in relation to total heterotrophic bacterial production (Romanenko, 1966; Jordan and Likens, 1980). Chemosynthesis by bacteria is normally very low in the pelagic of streams, infertile waters, and lakes of intermediate productivity and becomes a significant contribution to the whole only in productive or meromictic lakes exhibiting steep redox gradients.

The ratio of dark CO_2 fixation (almost all by heterotrophic metabolism of bacteria; see Gerletti, 1968; Romanenko, 1973) to photosynthetic fixation of CO_2 and bacterial chemosynthesis generally is small in oligotrophic waters. For example, the 14-yr average of dark CO_2 fixation was 13.3% of phytoplanktonic carbon fixation in the light in a small Michigan lake (Table 17-15). This percentage is much less for the lake, about one-tenth, if the littoral photosynthesis of this lake is considered in addition to the carbon fixation of the phytoplankton. The ratio of photosynthetic to dark CO_2 fixation decreases in the transition to planktonic eutrophy and hypereutrophy. For example, chemosynthetic bacterial fixation rates of CO_2 in eutrophic Plußsee, northern Germany, fluctuated between 0.4 and 30.0% of the total bacterial productivity over an annual period (Overbeck, 1979). The total carbon flux through planktonic bacteria in oligotrophic Mirror Lake was between 16 and 43% of phytoplankton net production, or 11–31% of all autochthonous and allochthonous organic carbon inputs. In lakes that are deeper than Mirror Lake (z_m, 10 m), planktonic bacterial production probably accounts for a greater proportion of the total decomposition simply because particulate detritus would have a longer residence time in the water column. With further transition of the system or in lakes with a predominance of productivity by emergent macroflora and associated attached and littoral microflora, the relative contribution of dark CO_2 fixation to the DOC pool apparently decreases (cf. Wetzel, 1979).

TABLE 17-15 Dark CO_2 Fixation in the Pelagic Zone of Lawrence Lake, Michigan, Integrated for the Water Column at the Central Depression, 1968–1981[a]

IX. COMPARISON OF BACTERIOPLANKTON AMONG AQUATIC ECOSYSTEMS

General characteristics of the bacterioplankton among river, reservoir, and natural lake ecosystems are set forth in Table 17-16. Such analyses are difficult, however, because of the paucity of extensive, long-term

[5] The growth efficiency figures used in the theoretical discussion by Strayer (1988) are much greater than would be found generally under natural conditions.

TABLE 17-16 Comparison of Characteristics of Bacterioplankton among River, Reservoir, and Natural Lake Ecosystems[a]

	Rivers	*Reservoirs*	*Natural lakes*
Bacterioplankton abundance	High to very high depending on sources of organic substrates and nutrients	Moderate to high; greater proportion of bacteria attached to seston particles	Low; increasing with increasing nutrient loading and productivity of phytoplankton
Bacterioplankton productivity	Low and increasing with stream order; heavy reliance on allochthonous dissolved organic matter and floodplain primary production	Low to moderate; often particle-associated; commonly higher in riverine portions than in lacustrian sections	Low; greater rates in trophogenic zone (epilimnion), decreasing in metalimnion, increasing in hypolimnion; relatively small seasonal changes because of mortality
Respiration	High	Moderate	Low
Mortality	High, from protistan predation, viral parasitism, UV photolysis, and molar action	Moderate, largely from protistan predation and viral parasitism	High; about half from protistan, especially nanoflagellate, predation, 20–40% from viral parasitism, and the remainder from autolysis and photolysis

[a] Gleaned from many individual refereces cited in this chapter and Wetzel (1990b).

data. The abundance and productivity of bacterioplankton are obviously strongly coupled to the availability of energy-rich, readily hydrolyzable organic substrates and nutrients, all of which are highly dynamic and variable among all aquatic ecosystems. Mortality of bacterioplankton is poorly understood but is dominated by protistan, particularly nanoflagellate, predation and viral parasitism.

X. SUMMARY

1. Much decomposition of particulate and dissolved organic matter occurs by means of planktonic bacteria in the aerobic pelagic waters prior to sedimentation of particulate detritus to the bottom of the basin. Rates of degradation are governed by an array of conditions: quality (chemical composition) and quantity of organic matter, physical parameters (e.g., temperature, stratification patterns, and basin morphometry), and chemical parameters (e.g., availability of terminal electron acceptors, particularly oxygen, and inorganic nutrients).
2. Numbers, biomass, and productivity of bacterioplankton generally increase with increasing photosynthetic productivity of fresh waters.
   a. A close correlation often exists between seasonal changes in biomass of phytoplankton and of heterotrophic bacterioplankton. Bacteria increase rapidly in response to enhanced rates of metabolism of phytoplankton.
   b. In thermally stratified lakes, bacterial biomass and productivity are commonly highest in the epilimnion, decrease to a minimum in the metalimnion and upper hypolimnion, and increase in the lower hypolimnion.
   c. Seasonal and vertical distributions in bacterial populations can change very rapidly (e.g., a few days). Seasonal changes, however, generally follow low values during colder periods and increase to maxima in spring and summer.
   d. Bacterioplankton are predominantly free-living (>75%), but in reservoirs and other environments where concentrations of suspended particles are high, bacterial attachment to particles is higher and can dominate (>80%).
3. Growth of bacterioplankton is controlled by resource availability and environmental factors.
   a. Bacterioplanktonic growth is positively correlated with temperature, particularly at low temperatures below 10–15°C). Above this temperature other factors regulate growth to a greater extent.
   b. Restricted nutrient availability, particularly of phosphorus, often limits the growth and productivity of bacterioplankton. Inorganic nitrogen is much less frequently limiting to bacterial growth than is phosphorus. Under transient growth conditions, multiple nutrient limitations are possible, but collective composite community nutrient limitations are usually relatively stable for periods of several weeks.
4. Decomposition of organic matter by bacteria is governed also by chemical characteristics of compounds. Simple organic substrates (amino acids, mono- and oligosaccharides, simple organic acids, and short-chained unsaturated fatty acids) are assimilated and mineralized by planktonic bacteria in aerobic waters more rapidly than larger, more complex soluble organic compounds.
   a. Dissolved organic substrates are utilized more effectively (faster turnover times) in warm, more productive, nutrient-rich fresh waters than they are in oligotrophic systems at lower temperatures.
   b. Both dissolved free and combined carbohydrate, amino, and lipid compounds are important substrates for bacterioplankton growth.
   c. The dynamics and utilization of carbohydrates and simple organic acids are known in some detail for lakes. The ratios of concentration to rate of utilization (turnover times) of total carbohydrates were found to be in the range of 3–20 days in the summer in temperate lakes.
   d. As much as 80% of dissolved organic matter is composed of organic acids that originate largely from higher aquatic and terrestrial plants. Many of these degradation products form humic compounds that often possess phenolic linkages that are more recalcitrant to degradation than simple substrates and have longer residence times in fresh waters. Despite their complexity and relatively high molecular weight, these humic compounds can serve as substrates for more than half of the bacterioplankton production. Humic compounds are often cometabolized with simpler substrates in a coupled metabolic process. Partial photolysis of humic substances by ultraviolet light can generate large quantities of simple, readily utilizable fatty acids and related substrates and support bacterial growth.
5. Dissolved organic compounds released by phytoplankton and other biota during active growth and upon senescence and death (autolysis) undergo rapid initial decomposition; declining mineralization at progressively slower rates of degradation then follows.
   a. Upon death, large amounts (5–35% of the total biomass) of organic matter are released as soluble organic compounds.

b. Extracellular release of dissolved organic substrates from phytoplankton can form a major source (to 95% at certain times) of carbon and energy for bacterioplankton.
c. Usually >75% of the soluble organic matter released by secretion and autolysis of phytoplankton is decomposed in the trophogenic zone. An average of 50% of the gross uptake of extracellularly released organic carbon is respired by the bacteria after assimilation.
d. In the pelagic trophogenic zone, decomposition of the algal-dissolved organic matter can operate in a coupled oscillating manner (Fig. 17-11). Photosynthetic rates are coupled to light, often with high rates in the morning and increased extracellular release of dissolved organic compounds in the afternoon. Bacterial assimilation and growth attain maximum rates slightly after (about 3 h) the maximum of algal product release and during the early period of darkness.

6. Resource limits to growth are approximately balanced by mortality and other losses.
   a. The importance of natural, genetically regulated physiological death and of dormancy under conditions of environmental stress is likely high but is not understood in bacterioplankton communities.
   b. Viral parasitism and mortality results in a major loss of bacterioplankton. Usually at least 25% of bacterial mortality results from viral lysis.
   c. Bacterivory by protists, especially nanoflagellates, and other zooplankton is a dominant mortality factor in natural bacterioplankton communities. Usually about 50% of bacterial mortality results from predation, mainly by nanoflagellates.
7. Decomposition rates of particulate organic detritus approximate first-order reaction rates during the initial stages of degradation and then decline as more recalcitrant compounds accumulate.
   a. Most pelagic organic matter occurs as dissolved organic matter. The particulate organic matter, most of which is nonliving, usually constitutes <10% of the total organic matter.
   b. Decomposition of fine particulate organic matter occurs at rates from 1 to about 15% per day in warm, aerobic lake water and is much slower than degradation of dissolved organic matter released by secretion and autolysis.
   c. The rapidity and completeness of decomposition of particulate organic matter is about the same under anaerobic conditions but can decline, as in anoxic hypolimnia of productive lakes, if the temperatures are very low.
   d. Nitrogen-containing amino and proteinaceous compounds are generally utilized more rapidly than carbohydrate-based compounds. As a result, organic C/N ratios generally increase with time.
   e. As particulate organic matter sinks from the trophogenic zone in stratified lakes, the extent of decomposition before reaching the sediments is controlled by many factors.
      i. In oligotrophic to moderately productive lakes of moderate depth (>10–20 m), 75–99% of the particulate organic matter synthesized in the trophogenic zone is decomposed in the water column before reaching the sediments. Rates of algal decomposition are in the range of 0.5% (winter) to ca. 5% per day (summer).
      ii. In shallower and more productive lakes, the amount of organic matter sedimenting out of the trophogenic zone increases, the residence time in the water column decreases (shorter settling distance), and the close proximity of cold, anaerobic hypolimnetic conditions results in large amounts of partially decomposed organic seston reaching the sediments.
      iii. A portion of the organic matter of surficial sediments is resuspended into the water column during periods of water circulation and undergoes further degradation in the pelagic water.
8. Measurements of productivity of natural bacterioplankton communities over an annual period are relatively few.
   a. Annual production of bacterioplankton is usually less than the estimated annual production of phytoplankton and is greatly subsidized by the organic carbon of allochthonous and littoral sources.
   b. Bacterioplankton productivity as a percentage of all decomposition in lakes increases in deeper lakes that have a longer residence time for degradation of sedimenting particulate organic matter, relatively small allochthonous loading of dissolved organic matter, and large pelagic areas in comparison to those of the littoral.
9. Chemosynthetic bacterial metabolism, in which CO_2 is assimilated in the presence of utilizable dissolved organic substrates, is significant only in strata of steep redox gradients, such as between an anaerobic hypolimnion and the aerobic trophogenic zone. Bacterial chemosynthesis is usually insignificant in aerobic waters and is normally very low in oligotrophic and moderately productive lakes.

VI. Summary

The land–water interface zone is difficult to define precisely. Physically, the boundaries of the intersection of land and water where the soils are water-saturated or water-influenced are highly variable over time as water levels fluctuate. The positions of the land–water boundaries vary in a fractal dimension depending on the scale of examination. At a large scale, for example from an aerial photograph, the boundary may seem quite distinct. However, as we have seen from the discussions of morphometry, slope gradients are often very small along the perimeters of lake and river valleys. Hence, small fluctuations in water levels with changes in precipitation can result in appreciable lateral movements of the interface boundaries. Among natural lakes, water level fluctuations are less than in manipulated water levels of reservoirs, but water levels in natural lakes can easily fluctuate annually in the range of a meter or more.

The gentle, small slopes along most land–water margins are conducive to sedimentation, and organic matter accumulations are common. Hydraulic conductivities of water movements through sediments of wetland and littoral areas are large. During active growth of floating and emergent plants in littoral areas, losses of water to the air by evapotranspiration contribute to a marked imbibition of water from upgradient soils. Thus, the land–water boundary is functionally and often physically diffuse; its position is constantly changing.

A very large percentage of the nonmarine biosphere is flat with very low relief profiles. Runoff from upland areas enters recipient river channels and lakes by gravitational flow. Lateral flooding of littoral wetland and shoreline areas are common as inputs from precipitation exceed temporarily the export of water downstream. Such inundated areas are often, particularly in the tropics, much larger, by many times, than the area of the lakes and rivers per se. Inundated and saturated soils almost immediately become anoxic and change to reducing conditions. Under reducing conditions, nutrient fluxes, rates of decomposition, and plant metabolism and community interactions are all altered markedly. These reducing conditions are chemically hostile to most higher plants. Those plants that have adapted to the reducing conditions have great competitive advantage because of the high availability of essential resources (nutrients, water) and reduced competition from less adapted biota that cannot survive under these conditions. As a result, the productivity of wetland and littoral plant communities includes the highest rates of organic matter synthesis in the biosphere (Fig. 8-1). A primary characteristic of wetlands and littoral areas of the land–water interface regions is that the water table is near, at, or above the hydrosoil (sediment) surface. These hydrological conditions are primary drivers of the coupled interactions of nutrient fluxes in the sediments and all aspects of plant physiology, growth, and productivity.

The littoral region is an interface zone between the land of the drainage basin and the open water of lakes and some streams. The size of the littoral zone in relation to the size of the pelagic region varies greatly among lakes and depends on the geomorphology of the basin and the rates of sedimentation that have occurred since the inception of the lake. Most lakes of the world are relatively small in area and shallow (Fig. 3-2). In such lakes, the littoral flora contributes significantly to the productivity and may dominate and regulate the metabolism of the entire lake ecosystem.

The general zonation of the littoral region has been introduced earlier (Chap. 8; Fig. 8-2). The physiological and ecological adaptations of freshwater aquatic angiosperms influence their distribution and often permit very high productivity. These plants also provide excellent habitats for photosynthetic and heterotrophic microflora, as well as many zooplankton (Chap. 19) and larger invertebrates (Chap. 22). In addition, the wetland and littoral flora synthesize large quantities of organic matter, most of which falls to and accumulates on and in the sediments of the littoral areas before degradation occurs (Chap. 23).

I. AQUATIC MACROPHYTES OF THE LITTORAL ZONE AND WETLANDS

A. Habitat Classification of Aquatic Macrophytes

In any inquiry into the botanical aspects of lakes, separate from the phytoplankton, one is confronted with an array of rather arbitrary definitions of the sessile flora of aquatic systems (Arber, 1920; Gessner, 1955, 1959; Sculthorpe, 1967; cf. Hutchinson, 1975). Many definitions are based on reproductive characteristics in relation to the aquatic stages in the life history of groups of angiosperms. From a strictly botanical viewpoint, such definitions are quite satisfactory. From an ecological standpoint, however, such species-orientated categorizations are unrealistic and ignore major system interrelationships. Alternatively, words such as *hydrophytes* are ambiguous; even though the term *hydrophyte* generally refers to vascular aquatic plants, it can include any form of aquatic plant. The term *aquatic macrophyte*, as it is commonly used, including in this work, refers to the macroscopic forms of aquatic vegetation and encompasses macroalgae (e.g., the alga *Cladophora*, the stoneworts such as *Chara*), the few species of mosses and ferns adapted to the aquatic habitat, as well as true angiosperms. Division on the basis of size is admittedly also arbitrary but, as discussed further on, when combined with the definition of the attached microflora, it permits a meaningful separation of primary producers in the littoral zone.

Numerous lines of evidence indicate that aquatic angiosperms originated on the land. Adaptation and specialization to the aquatic habitat have been achieved by only a few angiosperms (<1%) and pteridophytes (<2%). Consequently, the richness of plant species in aquatic habitats is relatively low compared with that of most terrestrial communities. The highly variable, changing habitat, particularly among floodplain inhabitants, results in low speciation and demands plastic adaptability (Henderson *et al.*, 1998). Many aquatic angiosperms possess relics of their terrestrial heritage, such as a cuticle, stomata, and a lignified xylem

tracheal structure. Most are rooted, but a few species float freely in the water. Aquatic macrophytes have evolved from many diverse groups and often demonstrate extreme plasticity in structure and morphology in relation to changing environmental conditions. These factors, in combination with the very heterogeneous conditions of their littoral habitat, make difficult the precise ecological classification of this group into growth forms.

Numerous classification systems have been proposed and used. The primary groups of aquatic angiosperms, rooted and nonrooted, have been subdivided according to types of foliage and inflorescence and whether these organs are emergent, floating on the water surface, or submersed (Arber, 1920). Differences in the extent of emergence or submergence and the manner of attachment or rooting to the substratum have led to the creation of numerous complex subclassifications and a corresponding terminology (cf. Hejný, 1960; Luther, 1949; den Hartog and Segal, 1964). Although useful for certain phytosociological analyses, this terminology is cumbersome, and lines of demarcation are rarely distinct.

The following simple classification of aquatic macrophytes, after Arber (1920) and Sculthorpe (1967), is based on attachment but has also proven useful in morphological, physiological, and ecological studies.

1. Aquatic Macrophytes Attached to the Substratum

1. *Emergent Macrophytes.* These plants occur on water-saturated or submersed soils, from the point at which the water table is about 0.5 m below the soil surface to where the sediment is covered with approximately 1.5 m of water; they are primarily rhizomatous or cormous perennials (e.g., *Glyceria*, *Eleocharis*, *Phragmites*, *Scirpus*, *Typha*, and *Zizania*). In heterophyllous[1] species, submersed and/or floating leaves precede mature aerial leaves; many species may exist as (usually sterile) submersed forms; all produce aerial reproductive organs.

2. *Floating-Leaved Macrophytes.* These aquatic plants are primarily angiosperms that occur attached to submersed sediments at water depths from about 0.5 to 3 m. In heterophyllous species, submersed leaves precede or accompany the floating leaves; reproductive organs are floating or aerial; floating leaves are on long, flexible petioles (e.g., the water lilies *Nuphar* and *Nymphaea*) or on short petioles from long ascending stems (e.g., *Brasenia* and *Potamogeton natans*).

[1] Heterophylly refers to vegetative polymorphism where the same plant can develop morphologically very different leaves or other plant parts when submersed or aerial (see pp. 532ff).

3. *Submersed Macrophytes.* These plants comprise a few pteridophytes (e.g., the quillwort *Isoetes*), numerous mosses and charophytes (stonewort algae *Chara*, *Nitella*), and many angiosperms. They occur at all depths within the photic zone, but vascular angiosperms occur only to about 10 m (1 atm hydrostatic pressure). Leaf morphology is highly variable, from finely divided to broad; reproductive organs are aerial, floating, or submersed.

2. Freely Floating Macrophytes

An extremely diverse group, freely floating macrophytes are typically not rooted to the substratum, but live unattached within or upon the water. They are diverse in form and habit, ranging from large plants with rosettes of aerial and/or floating leaves and well-developed submersed roots (e.g., *Eichhornia*, *Trapa*, and *Hydrocharis*), to minute surface-floating or submersed plants with few or no roots (e.g., Lemnaceae, *Azolla*, and *Salvinia*). Reproductive organs are floating or aerial (e.g., aquatic *Utricularia*) but rarely submersed (e.g., *Ceratophyllum*).

Because of the major impact of the littoral vegetation on the metabolism of most lake and river ecosystems, a brief résumé of the main aspects of their morphological and physiological adaptations is required in order to appreciate their role in the productivity of fresh waters. Excellent reference works include Arber (1920), Gessner (1955, 1959), Sculthorpe (1967), and Hutchinson (1975).

II. AQUATIC PLANT CHARACTERISTICS

A. Emergent Flora

Aerial stems and leaves of emergent macrophytes possess many similarities in both morphology and physiology to related terrestrial plants. The emergent monocotyledons, such as *Phragmites* and the cattail *Typha*, produce erect, approximately linear leaves from an extensive anchoring system of rhizomes and roots. Epidermal cells are elongated parallel to the long axis of the leaf, which allows flexibility for bending. The cell walls are heavily thickened with cellulose, which provides the necessary rigidity. The mesophyll is generally undifferentiated and contains large gas spaces (lacunae) traversed at intervals by diaphragms that are porous to gases but not to water. These lacunae are separated from each other by thin walls of parenchyma cells. The anatomy of vascular bundles is similar to that of typical terrestrial plants: The xylem consists of scattered tracheids and parenchyma cells; the phloem, which consists of sieve tubes, companion,

and parenchyma cells, is ensheathed with supporting sclerenchyma fibers. Emergent dicots produce erect, leafy stems, which show great anatomical differentiation. The mesophyll tissue of leaves is divided into typically dicotyledonous upper palisade and lower spongy layers.

The root and rhizome systems of these plants exist in permanently anaerobic sediments and must obtain oxygen from the aerial organs for sustained development. Similarly, the young foliage under water must be capable of respiring anaerobically for a brief period until the aerial habitat is reached, since the oxygen content of the water is extremely low in comparison to that of the air. Once the foliage has emerged into the aerial habitat, the intercellular gas channels and lacunae increase in size, thus facilitating gaseous exchange between the rooting tissues and the atmosphere.

B. Floating-Leaved Macrophytes

Macrophytes that are attached to the substratum and possess leaves that float on the water surface are nearly all angiosperms, most conspicuously represented by the ubiquitous water lilies. The surface of the water is a habitat subjected to severe mechanical stresses from wind and water movements. Adaptations to these stresses by floating-leaved macrophytes include the tendency towards peltate leaves that are strong, leathery, and circular in shape with an entire margin. The leaves usually have hydrophobic surfaces and long, pliable petioles. This similar suite of adaptations is exhibited by floating-leaved macrophytes from many taxonomically unrelated groups. In spite of these adaptations, severe winds and water movements restrict these macrophytes to relatively sheltered habitats in which there is little water movement.

Floating leaves exhibit well-developed dorsoventral organization, in which the mesophyll usually is differentiated into an upper photosynthetic palisade tissue and an extensive lacunate tissue. Localized masses of spongy tissue aid buoyancy and, in combination with vascular tissues, offer resistance to tearing. The venous network of the leaves of aquatic macrophytes is much less extensive than among terrestrial plants and is least developed among submersed angiosperms (Table 18-1).

Positioning of leaf surfaces parallel to the water surface creates a vigorous competition for space to expose maximum leaf area to incident light. Leaf growth some distance from the root or rhizome system is accommodated by long, very pliable petioles. Between 10 cm and 4 m water depth, a complete proportionality is found between water depth and the length of the leaf petioles of water lilies. Petioles are about 20 cm longer than the water depth, which permits leaves to remain on the surface among undulating waves and small changes in water level. Stems of flowers, separate from the leaves in many species, grow to the surface in the same way. If gaseous exchange to the leaf surface is restricted experimentally, elongation of the petioles continues, and the leaves become aerial instead of floating. Neither oxygen nor carbon dioxide availability is involved in the control mechanisms of petiole elongation. Rather, petiole or stem growth is arrested at the surface when the leaves begin to lose ethylene to the atmosphere, a product that triggers production of the growth hormone gibberellic acid (see p. 532). Under crowded conditions, elongation frequently continues until leaves extend somewhat above the water surface, which reduces leaf overlap and increases light acquisition.

The presence and abundance of stomata vary among different species of floating-leaved angiosperms. The most common pattern is a restriction of stomata to the upper-leaf epidermis. A few stomata are found on the undersides of leaves; these are considered relict features and have no known function.

The epidermis of the leaf underside of many floating-leaved and submersed angiosperms contains groups of many smaller cells nested around a pore about 0.05 μm in diameter; an extremely thin cutin lamella lies over the pore. These "organs," termed *hydropoten*, assume a three-celled lenticular form in some water lilies or shieldlike hairs in certain submersed angiosperms. The hydropoten function in ion absorption in both submersed and floating leaves in contact with water by an active mechanism analogous

to that of root absorption (Lüttge, 1964). Absorbed ions are then translocated to veins of the mesophyll.

C. Submersed Macrophytes

The submersed macrophytes are a heterogeneous group of plants that include (a) filamentous algae (e.g., *Cladophora*) that under certain conditions develop into profuse mats and may become loosely attached to the substrata of the littoral zone, (b) certain macroalgae (e.g., the calcareous stoneworts, *Charales*) that can dominate littoral macrophyte communities in hardwater lakes, (c) mosses that are occasionally the major macroflora of soft-water lakes and streams, (d) a few totally submersed nonvascular plants (e.g., the lycopsid quillwort *Isoetes*) that are most abundant in clear, softwater lakes, and (e) vascular submersed macrophytes of slightly <20 diverse families, mostly monocotyledons.

Among the vascular submersed macrophytes, numerous morphological and physiological modifications are found that allows existence in a totally aqueous environment. Stems, petioles, and leaves usually contain little lignin, even in vascular tissues. Sclerenchyma and collenchyma are usually absent. No secondary growth occurs, and no cambium can be recognized. Conditions of reduced illumination under the water are reflected in numerous characteristics: an extremely thin cuticle, leaves only a few cell layers in thickness, and an increase in the number of chloroplasts in epidermal tissue. Leaves tend to be much more divided and reticulated than those of terrestrial or other aquatic plants. The vascular system is greatly reduced, and all major conducting vessels have been reduced or lost from the stems. As a rule, conducting bundles have coalesced to axial vascular bundles in both mono- and dicotyledonous submersed species. Phloem and xylem are quite functional but difficult to differentiate, since phloem and woody parenchyma are nearly absent.

Leaves of submersed macrophytes occur in three main types: entire, fenestrated, and dissected. The entire leaf form is the most common throughout all groups and habitats. Entire leaves are often elongated to ribbonlike and filiform (threadlike) morphology in which length greatly exceeds width, even among more lanceolate-type leaves. Elongated, pliable leaves resist tearing in moving water, maximally utilize the reduced available light, increase the ratio of surface area to volume, and therefore presumably increase the efficiency of gaseous exchange and nutrient absorption. Fenestrated leaves are rare among submergents and occur only among a few tropical monocots. The adaptive advantages of such perforated, lacelike foliage are unclear. Dissected leaves are common among submersed dicotyledons. The most common form is extreme dissection with segments in whorls radiating from the petiole. Both the fenestrated and dissected leaf forms greatly increase the surface-area-to-volume ratios.

D. Freely Floating Macrophytes

The freely floating macrophytes, which occur submersed or on the surface, also exhibit great diversity in morphology and habitat. Several of these plants, notably *Lemna*, *Pistia*, *Salvinia*, *Eichhornia*, and *Trapa*, develop so profusely in some waterways and lakes that they inhibit the commercial use of these systems (Hillman, 1961; Moore, 1969; Mitchell and Thomas, 1972). The very high production and prolific development of these surface-inhabiting plants can result in excessive loading of organic matter and nearly total attenuation of light below the surface. As a result, periods of severe reduction or depletion of dissolved oxygen can result with large losses of invertebrates and fish.

The most elaborate of the free-floating life forms consists of a rosette of aerial and surface-floating leaves, a greatly condensed stem, and pendulous submersed roots. Most rosette species are perennials and are free-floating throughout growth, except for initial stages of seedling development. Among some freely floating groups, there is a strong tendency for reduction from the rosette habit. In the duckweeds (Lemnaceae), extreme reduction is seen in the trend toward elimination of roots and lack of separation between stem and leaf. Similarly, in the submersed free-floating "carnivorous" *Utricularia*, stems and leaves are not differentiated, and vegetative organs are greatly modified for entrapment of microfauna, especially rotifers. Some species of *Lemna* and *Utricularia* are, like the ubiquitous *Ceratophyllum*, submersed during vegetative growth and rootless. Freely floating macrophytes generally are restricted to sheltered habitats and slow-flowing rivers. Their nutrient absorption is completely from the water; most of these macrophytes are found in waters rich in dissolved nutrients.

Most floating plants possess little lignified tissue. The rigidity and buoyancy of the leaves are maintained by the turgor of living cells and extensively developed lacunate mesophyll tissue (often >70% gas by volume). Vascular tissues of the leaves are very poorly differentiated; in most, the protoxylem is represented by a lacuna. Vegetative propagation by the production of lateral stolons that develop into new rosettes is a common mode of rapid proliferation in

this group. All freely floating rosette plants form well-developed adventitious roots, lateral roots, and epidermal hairs. The root system of the water hyacinth (*Eichhornia*), for example, represents 20–50% of the plant biomass.

E. Heterophylly: Vegetative Polymorphism

Although vegetative polymorphism or *heterophylly* is not unique to submersed macrophytes, extremes in foliar plasticity are particularly conspicuous among aquatic macrophytes that normally grow in shallow, submersed habitats that undergo fluctuations in water level. Such species can readily produce floating or aerial foliage. A marked polymorphism of leaves may often be found on the same stem or petiole. There is a tendency to shift from finely divided submersed leaves in the submersed habitat to more coalesced entire leaves when leaves of the same plant are surface-floating or aerial. Leaf form and anatomy can vary widely with age, water depth, current velocities, nutrient supplies, light intensity, day length, temperature, and other factors.

Heterophylly is particularly conspicuous among such common genera as *Ranunculus*, *Callitriche*, *Hippuris*, and *Potamogeton* and creates chaos when the taxonomy is based on leaf morphology. For example, leaf morphogenesis of the amphibious buttercup *Ranunculus* responds conspicuously to submergence and water temperature (Fig. 18-1). The lobate tripartite aerial leaf of the semiaquatic phase is approximated in the submersed phase at high temperatures. Both lobe numbers and blade lengths increase conspicuously with growth at decreasing temperatures. Analogous morphological differentiation has been shown to be directly related to carbon dioxide concentrations in at least three taxonomically distinct amphibious species (Bristow, 1969). Under conditions of high aqueous CO_2 concentrations, the plants developed dissected submersed leaves, whereas when the CO_2 content was reduced, lobate aerial foliage developed rapidly. These plants were unable to utilize bicarbonate as a source of inorganic carbon for photosynthesis. Among water lilies, continued elongation of petiole length occurs under conditions of low CO_2 of the water until the leaves reach the relatively high levels of atmospheric CO_2 (Gessner, 1959).

Transitions between submersed and aerial-type leaves of *Hippuris* are reversible by altering the ratio of red (660 nm) and far red (730 nm) light, which implies direct phytochromal control (Bodkin *et al.*, 1980; cf. Stross, 1981). A low ratio of red to far red light, such as occurs in very shallow water (far red light is selectively attenuated with increasing depth), induces aerial leaf formation on submersed shoots.

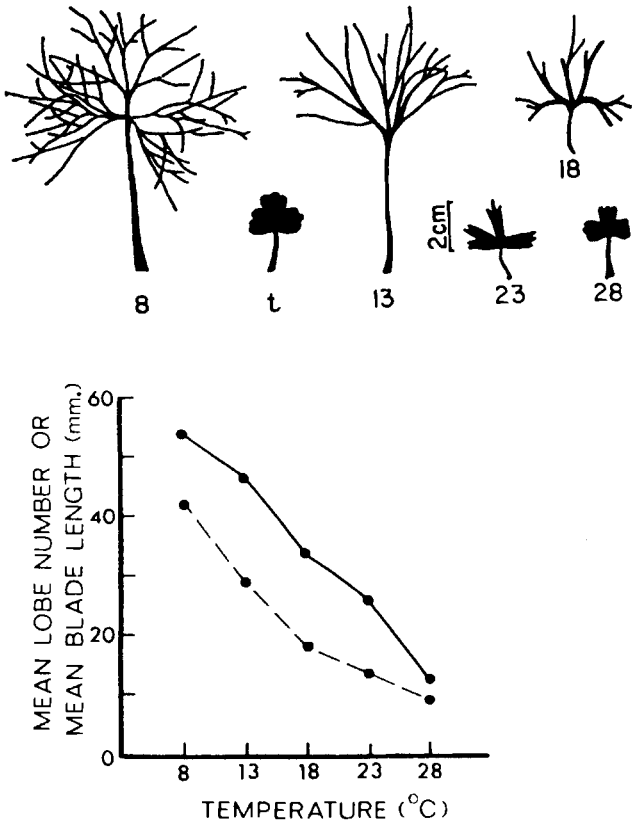

FIGURE 18-1 *Upper*: Silhouettes of leaves of a single clone of *Ranunculus flabellaris* grown in the semiaquatic phase (*t*) and submersed at temperatures of 8, 13, 18, 23, and 28°C. *Lower*: Mean blade length (———) and mean lobe number (- - -) in relation to temperature. (Modified from Johnson, M. P.: Temperature dependent leaf morphogenesis in *Ranunctilus flabellaris*. *Nature (London)* *214*:1354–1355, 1967.)

Ethylene is a plant hormone influencing many plant processes such as growth promotion, development of aerenchyma, abscission, and senescence. Ethylene biosynthesis involves multistep enzyme pathways in which methionine is converted to ethylene (e.g., Fluhr and Mattoo, 1996). When leaves of several aquatic angiosperms are submersed, ethylene concentrations reach high levels in the internal intercellular lacunae (Musgrave *et al.*, 1972; Musgrave and Walters, 1973; Cohen and Kende, 1986). These high levels of ethylene enhance the sensitivity of the tissue to the hormone gibberellic acid and consequently promote petiole elongation. When the tissues reach the water surface, gaseous contact is made between the intercellular air and the atmosphere, and the accumulated ethylene rapidly dissipates into the atmosphere. Gibberellic acid activity and cell elongation then decline. The plant growth regulator abscisic acid also induces the formation of floating leaves in totally submersed germinating tubers of *Potamogeton nodosus*

(Anderson, 1978) and of *Ranunculus flabellaris* (Young and Horton, 1985).

Numerous other factors influence leaf form among aquatic macrophytes (cf. Sculthorpe, 1967; Gaudet, 1968; Hutchinson, 1975). Generalizations are difficult to make, however, because among some plants polymorphism occurs irrespective of external factors; in such cases, polymorphism is distinguishable at the earliest primordial stages and is apparently determined either genetically or by the nutritional status of the shoot meristem.

F. Reproduction, Dispersal, and Dormancy

Many alterations in reproductive strategies have accompanied the invasion of the aquatic environment by higher plants of several unrelated terrestrial plant lineages. Most aquatic plants have simply modified the reproductive features of their terrestrial ancestors (Sculthorpe, 1967; Hutchinson, 1975; Grace, 1993; Philbrick and Les, 1996). Aquatic plants have adopted vegetative and clonal reproduction as a major mechanism for population growth and dispersal. Sexual reproduction and genetic recombination have been retained, although they are commonly subordinate to vegetative expansion and dispersal.

1. Asexual Clonal Reproduction.

Asexual reproduction includes both vegetative reproduction and seed production without fertilization (agamospermy). The latter process is very poorly understood in aquatic plants (Les, 1988). Population expansion of all three major types of aquatic plants—emergent, floating-leaved, and submersed—is largely by vegetative, clonal growth by both (a) the rapid development of aboveground tissues, particularly with apical meristematic growth, followed by fragmentation, and (b) expansion horizontally by creeping stems (e.g., rhizomes), modified shoot bases (corms and small bulbs), and root suckers and tubers. Clonal reproduction performs several functions (Grace, 1993): (a) numerical increase, (b) dispersal, (c) acquisition of resources, (d) storage, (e) protection, and (f) anchorage.

Another important vegetative propagule in aquatic plants is the *turion*. These morphological variations are found among temperate aquatic macrophytes that overwinter by the formation of *winter buds (turions)*. In the fall, many common macrophytes (e.g., *Utricularia*, *Myriophyllum*, and *Potamogeton*) form masses of dormant vegetative buds of aborted leaves with very short internodes in the axils of lower leaves (Weber and Noodén, 1974, 1976a,b; Aiken and Walz, 1979; Winston and Gorham, 1979; Sastroutomo, 1980a,b, 1981). These turions separate from the mother plant and sink or float some distance away and serve as a means of vegetative propagation (Weber, 1972). Many submersed plants persist for years by this means, without a sexual cycle. Turion formation is absent among the same species in the tropics but can be easily induced when plants near maturity are exposed to low water temperatures (<10–15°C) and short daily photoperiods (e.g., Van *et al.*, 1978; Spencer *et al.*, 1994; Netherland, 1997) or long daily photoperiods (e.g., Chambers *et al.*, 1985). Other winter buds of less modified leaves break off of the mother plant and these fragments disperse and subsequently can colonize in a new habitat.

Vegetative propagules are dispersed by many vectors. Mechanisms include both abiotic vectors, such as with water movements or strong winds for surface-floating macrophytes, and biota, such as amphibians, reptiles, birds, and mammals, particularly humans. Humans have dispersed many aquatic plants either intentionally (rice, water cress) or unintentionally (water hyacinth, *Myriophyllum, Hydrilla*). The latter three species have expanded so vigorously in some waters that their excessive development has altered the hydrology and chemistry to such an extent that the waters are unsuitable for many human uses.

2. Sexual Reproduction.

Sexual reproduction tends to be reduced in aquatic plants simply because of the efficacy of clonal and other vegetative reproduction. Some of the most effective competitors and most productive of aquatic plants, such as the cattail (*Typha*) and rushes (*Juncus*), combine very intensive clonal continuous growth (see later discussion) with moderate-to-intensive production of seeds for longer-distance dispersal. For example, the emergent rush *Juncus effusus* can devote as much as <1–7% of its annual production to seed production (several million very small seeds m^{-2}) even though germination and seedling mortality in the immediate vicinity of the mother plants is nearly 100% from autotoxicity from organic compounds released and from shading (Ervin and Wetzel, 2000).

Where flowering and sexual reproduction is retained in submersed aquatic plants, aerial flowering dominates on stems or flower stalks that project across the water surface. Among dioecious species in which only one sex occurs in an area, vegetative means are the only means of immediate reproduction (Haynes, 1988). Monoecious species or species with perfect flowers often produce viable seeds but they function largely in dispersal rather than as a means of increasing the immediate population size. Pollination occurs by insect or wind vectors. Water pollination (hydrophily), in which waterborne pollen is released and captured on the surface of water or under water, is rare and is

found in <5% of aquatic species (Cox, 1993). Self-pollination is known to occur among aquatic species, as occurs in many terrestrial plants, but can be interpreted as adaptive where ecological conditions deter cross-pollination. Even though sexual reproduction is reduced or sometimes absent for long periods among submersed aquatic plants, genetic homogeneity from vegetative reproduction can be ameliorated by immigration of genetically distinct vegetative propagules from other habitats (Les, 1991).

G. Transpiration and Evapotranspiratory Water Losses

Evaporative losses from lakes and wetlands are greatly modified by the transpiration from emergent and floating-leaved aquatic plants. Rates of transpiration and evaporative losses to the atmosphere vary with an array of physical (e.g., wind velocity, humidity, and temperature) and metabolic parameters and structural characteristics of different plant species (Brezny *et al.*, 1973; Bernatowicz *et al.*, 1976; Boyd, 1987; Jones, 1992). For example, in a temperate-lake littoral, a distinct seasonality of evapotranspiration is common, and greatly accelerated rates of water loss from the lake habitat commonly occur in the summer period (cf. Table 4-3). In a humid tropical environment, floating plants and floating-leaved but rooted plants enhanced water losses from surface waters, often by a factor of 2 (Table 18-2), particularly during wet seasons (Rao, 1988).

The epidermal cuticle of emergent and floating leaves is generally well developed. Cuticular transpira-

TABLE 18-3 Comparison of the Ratio of Maximal to Minimal Cuticular Transpiration among Aquatic Macrophytes and Terrestrial Flora[a]

Aquatic flora		*Terrestrial flora*	
Potamogeton natans	1.4	*Quercus ilex*	4.6
Eichhornia crassipes	1.5	*Syringa vulgaris*	4.9
Alisma plantago	1.7	*Viola tricolor*	7.6
Nymphaea marliacea	3.2	*Laurus nobilis*	8.4

[a] Modified from Gessner (1959).

tion is much lower in these plants than in land plants (Table 18-3). Cuticular transpiration is generally greater from floating-leaved macrophytes than from aerial foliage of emergent macrophytes. As a result, water losses by transpiration to the atmosphere by emergent macrophytes occurs largely via the stomata.

Rates of transpiration by emergent macrophytes are extremely high and result in an efflux of water vapor from the leaves that is much greater than evaporation from an equivalent area of water (Table 8-2). Evaporation from the water surface is lower when the water surface is densely covered by macrophytes, such as water lilies or duckweeds (*Lemna*). These plants restrict the contact of moving air with the water surface. However, this effect is counterbalanced by plant transpiration rates that increase markedly when the vegetation is exposed to moderate wind velocities (e.g., van der Weert and Kamerling, 1974; Benton *et al.*, 1978). Evapotranspiration rates of aquatic plants generally increase with increasing wind velocity up to modest speeds (ca. <2 m s^{-1}) and with decreasing relative humidity (Gessner, 1959; Rao, 1988). Evapotranspiration rates are generally positively correlated with temperatures and solar irradiance on a seasonal basis and furthermore increase with increasing rates of photosynthesis up to a maximum rate that differs among species of aquatic plants. Transpiration is usually lower in the basal leaves than in apical foliage and results in a general tendency toward xerophytic properties with increasing age of the leaves. Stomatal conductance and evapotranspiration rates decline as photosynthetic efficiencies are reduced during midday periods of intense irradiance and maximum diurnal temperatures (e.g., Bernatowicz *et al.*, 1976; Królikowska, 1978; Giurgevich and Dunn, 1982; Jones and Muthuri, 1984; Mann and Wetzel, 1999). These midday depressions in evapotranspiration suppress overall water losses to a greater extent than is counterbalanced by increased rates of evaporation from open water surfaces with the higher temperatures and lower relative humidity values that occur at midday.

Stomata of aquatic macrophytes generally do not close to nearly the extent observed in terrestrial flora during the light period, and higher transpiration rates occur in aquatic macrophytes than are found among land plants. In both aquatic plants and terrestrial flora, however, stomata prevent desiccation when water availability declines. Many aquatic plants with emergent and floating leaves have developed means of increasing surface area and evapotranspiration. Such structures include papillae, either single-celled or multicellular extensions of the epidermis, or perforations into the leaf blade, termed *stomatodes*. Many aquatic angiosperms, both emergents and submersed plants, exude water (guttation) from enlarged ends of veins (hydathodes) around the margins of their leaves.

Among aquatic macrophytes, population density is important in the regulation of transpiration rates. Evapotranspirational water losses by emergent macrophytes in the littoral zone of lakes and wetlands can be so effective that the plants can significantly reduce the water levels of the surrounding terrestrial area and can result in diminished growth of nearby terrestrial plants. During the macrophyte growing season, evapotranspiration by plants can cause a cone of depression such that water will seep to the cone for replacement from the lake or stream.

It is common among emergent macrophytes of large river systems, the borders of reservoirs, and bank riverine wetlands to periodically become inundated with rising water levels. In large river systems, such as the Amazon, herbaceous vegetation can be inundated for several months (Junk and Piedade, 1997). Increases in water level, to the point where large portions of or the entire emergent plant are submerged, result in a varied number of morphological and physiological changes. Many species can survive submergence for long periods of time, but then growth is greatly reduced because of conditions of diminished light and oxygen. Leaves are generally reduced in size and tend to elongate and lose rigidity. Mesophyll tissue often is reduced, and there is a corresponding increase in spongy tissue and intercellular air spaces. The xylem and lignified portions of the phloem fibers also generally decrease, concomitant with an increase in stem diameter and lacunal air spaces.

III. METABOLISM BY AQUATIC MACROPHYTES

A. Aeration, Gas Fluxes, and Metabolism within Higher Aquatic Plants

Clearly, the rooting tissues of aquatic plants nearly always exist in anaerobic organic sediments that contain high concentrations of relatively toxic organic

solutes (e.g., volatile fatty acids) and gaseous substances (e.g., hydrogen sulfide) of fermentation. Movements of gases within and through the plant parts are essential to avoid toxicity effects and to maintain active photosynthetic and respiratory metabolism. The movements of oxygen, carbon dioxide, and other gases within and through the interconnecting aerenchymatous (lacunal) and nonaerenchymatous intercellular cortical gas spaces of shoots and roots of aquatic plants have been the subjects of intensive study in the past decade. Under the intensely and more severely reducing conditions of organic sediments, the gas spaces of the aerenchymatous tissues increase in size and can be induced to increase in size upon exposure to increasing concentrations of fermentative endproducts such as volatile fatty acids, alcohols, and H_2S (e.g., Penhale and Wetzel, 1983; Armstrong *et al.*, 1991a). Littoral and wetland plants that are tolerant of continuously saturated sediments or periodic flooding of the soils adjacent to lakes and rivers combine a range of both metabolic and morphoanatomical adaptations to enable them to tolerate seasonally flooded sediments. For example, the roots of some flood-tolerant species, when flooded seasonally, stop producing high amounts of ethanol and lactate and divert part of the pyruvate produced in respiration to nontoxic malate (Joly, 1994). The amount of pyruvate converted to malate is proportional to the amount of oxygen diffusing from the aerial parts to the roots.

Several mechanisms of gas fluxes are operationally specific to emergent and floating-leaved macrophytes and others are specific to submersed macrophytes (Blom *et al.*, 1990; Armstrong *et al.*, 1991b, 1992, 1996; Grosse *et al.*, 1996):

1. Mechanisms among Plants with Aerial Leaves

1. ***Diffusion-Dependent Throughflow Convections.*** A pressurization differential results from a Knudsen-diffusion of gases from the environment into the emergent shoot and root system. Gases enter newly emergent leaves, such as of floating-leaved water lilies, through minute pores that separate the aerenchyma of the leaves from the ambient atmosphere. A pressurized ventilation is created by the Knudsen-diffusion by both the physical effects of hygrometric diffusion (humidity-induced) and thermal transpiration (thermal osmosis) (Grosse, 1996). In mature leaves, these pores are larger and gas flows through them freely. Air moves into young, influx leaves along humidity and temperature gradients, causing pressurization in the aerenchyma, flows through the continuous intercellular space system, and exits from the mature, efflux leaves to the atmosphere (Fig. 18-2). In some cases, some of the gas exits through rhizomes to shoots of nearby plants.

2. ***Nonthroughflow Convections.*** A longitudinal gradient of gas velocity occurs through the plant in response to changes in concentrations of gases resulting from the reciprocal exchange of metabolic uptake or release of gases, especially carbon dioxide and oxygen. An excellent example is seen in rice, where bulk flows of gases occur into deepwater rice plants (Raskin and Knede, 1983, 1985; Stünzi and Kende, 1989). Gas flows in response to reduced pressure (suction) set up within the plant by the solubilization of respiratory CO_2 into surrounding water and gas films adhering to the leaves (Fig. 18-2). Oxygen diffusing from the atmosphere to submersed parts of the plant is not replaced by a reciprocating diffusion of CO_2 from below, and a sucking of air into the plant occurs alongside the normal diffusive intake of oxygen. The uptake of air into submerged organs of the rice plant is driven by the difference in the solubility of O_2 and CO_2 in water. The conduction of gases through the internal gas spaces of the leaf is negligible compared to the conduction of gases through the external air layers.

3. ***Venturi-induced Throughflow Convections.*** Venturi-induced pressure differentials are created when winds blow over the long (to >2 m) and persistent, dead, often broken, culms of emergent plants. Air is drawn out of these old shoots, which remain connected to the gas-space system of the underground rhizome network, by the Venturi effect and is replaced by an inflow form the atmosphere into other culms broken much closer to the sediment or water surface.

Internal pressurization and convective throughflow of gases are common attributes of wetland plants with cylindrical culms or linear leaves and among floating-leaved rooted macrophytes (e.g., Brix *et al.*, 1992; Armstrong *et al.*, 1996). Convective flowthrough mechanisms are much more efficient than nonthroughflow convection from the atmosphere. A distinct diurnal fluctuation in pressurization and convective flow is commonly observed, where rates are highest in the afternoon and lowest at night. The diurnal responses are thermo-osmotic pressurization differences regulated by changes in solar heating of tissues and alterations in humidity (cf. Dacey, 1981; Brix, 1988; Armstrong and Armstrong, 1990; Brix *et al.*, 1992).

The rate at which oxygen is transported through the lacunal system is influenced by the rate of net photosynthetic oxygen production in the foliage, which undergoes diurnal fluctuation, by the respiratory demands for oxygen of the root system, and by the resistance to diffusion afforded by diaphragms of the lacunae. Experimental analyses have demonstrated that roots and rhizomes can tolerate appreciable periods—as long as

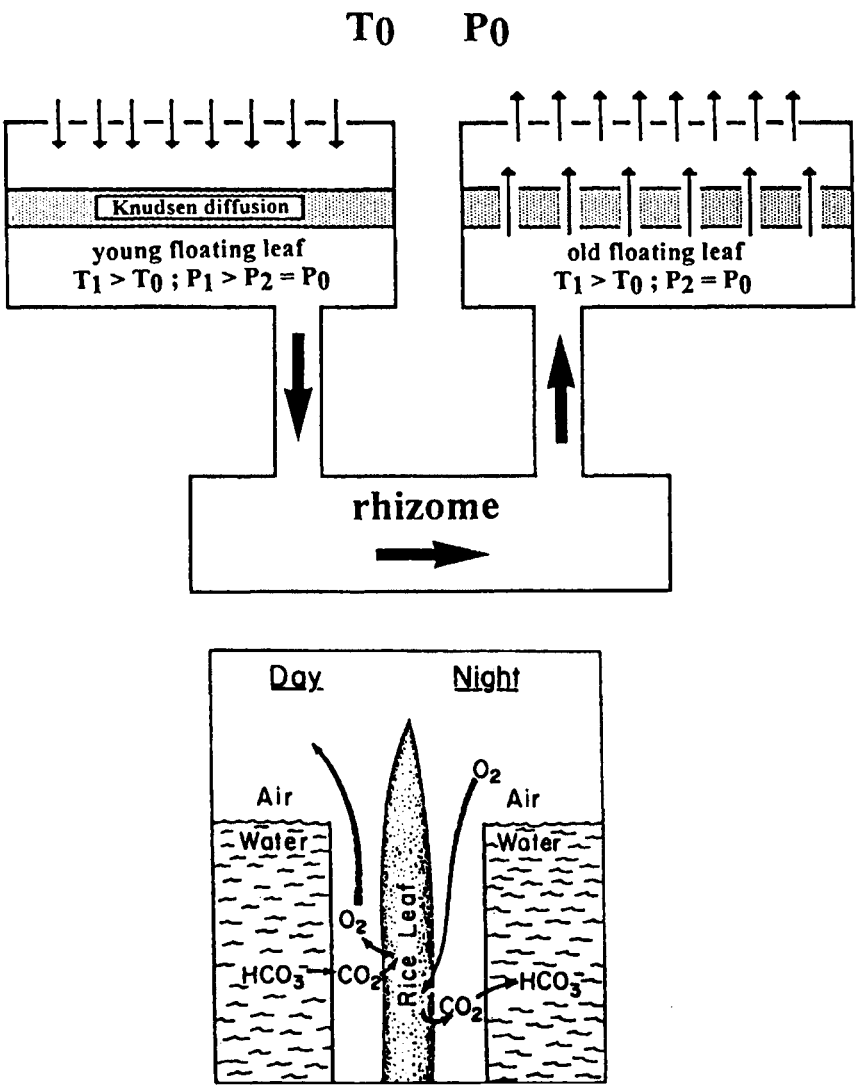

FIGURE 18-2 *Upper*: Convective gas throughflow in floating-leaved aquatic macrophytes resulting form thermal transpiration (thermal osmosis) and humidity-induced diffusion, where P = pressure in the young influx leaf (1), an old efflux leaf (2), and atmosphere (0), and T = temperature inside the leave and ambient air (0). (After Grosse, 1996.) *Lower*: Movement of gases along the exterior of leaves of deepwater rice. In darkness, respiration replaces relatively water-insoluble O_2 with CO_2. Rapid solubilization of CO_2 in water causes a decrease in the pressure inside the air layers and leads to movement of air from the atmosphere into the air layers. In light, photosynthetic CO_2 is absorbed from the water through the large liquid–gas interface provided by the air layers. Photosynthetic O_2 is expelled through the air layers into the abovewater atmosphere. (After Raskin and Kende, 1983.)

a month—of very low oxygen supply or anaerobiosis without any apparent harmful effects.

2. Methane Diffusion, Transport, and Evasion to the Atmosphere

The importance of methane (CH_4) release from inland aquatic plants of wetlands and littoral areas of lakes and rivers has been a subject of intense interest as a potential source of CH_4 additions to atmospheric gases that enhance retention of heat from solar irradiance ("greenhouse effect"). As the transport processes of CH_4 from bacterial production in anaerobic sediments through emergent and rooted floating-leaved aquatic plants were evaluated, a prodigious literature has appeared on this subject, particularly in relation to deepwater rice cultivation and the evasion of large amounts of CH_4 to the atmosphere by this aquatic plant. Among studies of CH_4 releases from aquatic

plants of natural wetlands and littoral areas, reported evasion rates and purported control mechanisms are enormously variable and often conflicting, often as a result of the noncomparability of the methods employed. A few generalities are emerging:

1. Methane production is a microbiological process and results from anaerobic carbon mineralization in sediments. As discussed later (Chap. 21), methanogenic bacteria utilize a number of organic substrates of which acetate and hydrogen are of major importance.

2. Within the sediments, CH_4 diffuses along concentration gradients and can be oxidized by microbiological processes of methane-oxidizing bacteria (Chap. 21) under microaerobic conditions. The rate of methane oxidation increases proportionally to the rate of methane production.

3. Alternatively, in the root–rhizome rhizosphere of aquatic plants, some CH_4 diffuses into the intercellular gas spaces and can be transported along with other gases through the ventilation system to the atmosphere. This evasion to the atmosphere can be extensive in both floating-leaved rooted plants, such as the water lilies (e.g., Dacey and Klug, 1979), and emergent macrophytes (e.g., Segers, 1998).

4. Rates of potential methane production have been determined in a large number of studies in various natural wetlands and rice paddies. Rates are highly variable with environmental conditions within a range of 10^{-2}–10^{-3} μmol m^{-3} s^{-1} (reviews of Sebacher *et al.*, 1985; Schütz, *et al.*, 1989; Whiting and Chanton, 1993; Wang *et al.*, 1996; Hosono and Nouchi, 1997; Segers, 1998). Some of the variation is real and is associated with many differences in environmental factors regulating CH_4 production (e.g., temperature, pH, gas pressures, substrate availability, and nutrient availability, competition with alternate electron acceptors), microbial oxidation, and diffusion into the plants and their gaseous transport mechanisms. Changes in water level and inundation can rapidly alter conditions of anoxia and redox. Some of the variation is also attributable to large differences in the experimental methods used for assaying evasion rates and their control mechanisms. In general, however, CH_4 evasion to the atmosphere is positively correlated with net production of wetland vegetation.

5. On a diurnal basis, the highest emission rates of CH_4 are found in daytime, usually soon after sunrise, among many, but not all, emergent macrophytes examined (e.g., Miura *et al.*, 1992; Whiting and Chanton, 1996; van der Nat, *et al.*, 1998; many others).

3. Gaseous Transport in Submersed Macrophytes

It has been assumed, incorrectly, that as photosynthesis proceeds in submersed macrophytes, oxygen is released from the plants into the surrounding water in quantities proportional to rates of photosynthesis. Such a relationship is approximately accurate for micro- and macroalgae and apparently also for the nonvascular bryophytes. The presence of large lacunae in higher aquatic plants complicates the relationship, and oxygen released to the water variably lags behind rates of photosynthesis. During the photoperiod, oxygen accumulates rapidly in the lacunal intercellular atmosphere on a diurnal basis and forms an internal positive pressure and only slowly diffuses out into the surrounding water (Hartman and Brown, 1966; Sorrell, 1991). This pressurization assists with the internal mass flow of gases among plant parts. Consequently, diffusion rates of oxygen into the water are not directly correlated with the intensity of photosynthesis, and a large portion of the oxygen in the intercellular lacunae is utilized for respiration during both the photoperiod and in darkness, without affecting the oxygen concentrations of the surrounding water medium (e.g., Sorrell and Dromgoole, 1989). Although the release of bubbles, largely oxygen, from submersed plants can be significant during periods of intensive photosynthesis in warm water, this release should not be used as a measure of photosynthesis, as has been done (e.g., Odum, 1957, among others) because it can represent only a small proportion of the oxygen actually produced and actual rates of photosynthesis. At high rates of water flow over the plants, exchange of oxygen with the water is fairly rapid (e.g., Moeslund *et al.*, 1981) but still represents only a small portion of that produced by photosynthesis.

Most of the oxygen is retained within the plant and used for respiration, particularly by the rooting tissues, especially at low light intensities. Appreciable amounts of oxygen are released from roots of submersed aquatic macrophytes into the surrounding rhizosphere (e.g, Sand-Jensen *et al.*, 1982; Zhang *et al.*, 1998). Although much of the oxygen is utilized by bacteria, some reacts with ferrous iron to form a highly insoluble iron oxide that precipitates on the roots as an iron plaque. In addition to direct chemical reactions to form $Fe(OH)_3$, Fe-oxidizing bacteria are common in the rhizosphere of aquatic plant roots (Emerson *et al.*, 1999). Iron reduction then occurs in the anaerobic sediments immediately beyond the oxidized rhizosphere mediated largely by iron-reducing bacteria (cf. Chaps. 14 and 21). Such iron reduction can consume much of the organic carbon substrates by dissimilatory reduction of Fe^{+3} compounds.

The magnitude of the intercellular lacunal system is highly variable among species but is almost universally extensive and constitutes a major portion (often >70%) of the total plant volume. The fragility of the

lacunal tissue and the possibility of its becoming filled with water if the plant were damaged at any point is avoided by a number of types of lateral plates and watertight diaphragms, permeable to gases, that interrupt the lacunae at intervals (Arber, 1920; Sculthorpe, 1967; Sorrell and Dromgoole, 1996). Although experimental evidence is meager, it is known that much of the oxygen produced during photosynthesis in submersed angiosperms and retained in the lacunal system diffuses from the leaves through the petioles and stems to underground root and rhizome systems, where respiratory demands are high. Some oxygen is released from the roots into the immediate (usually <0.5 mm) rhizosphere. Radial oxygen loss to the rhizosphere varies by over an order of magnitude (0.01–0.2 $\mu g\ cm^{-2}$ root min^{-1}) among aquatic plant species.

The gases within the intercellular lacunae of submersed angiosperms diffuse along gas–partial-pressure gradients. In some emergent and floating-leaved plants (e.g., the yellow water lily *Nuphar*), however, evidence indicates that the internal gas spaces function as a pressurized flowthrough system (Dacey, 1981). Ambient air enters the youngest emergent leaves against a small gas-pressure gradient as a result of physical processes driven by solar-mediated gradients in temperature (thermal transpiration) and water vapor (hygrometric pressure) between the atmosphere and the lacunae. The lacunal gas spaces are continuous through young emergent leaves, petioles, rhizomes, and petioles of the older emergent leaves. The older leaves vent the elevated pressure generated by the younger leaves. The resulting flowthrough ventilation system accelerates both the rate of oxygen supply from the atmosphere to the root tissue and the rate of CO_2 and methane (Dacey and Klug, 1979) transport from the roots to the atmosphere.

The movement of oxygen (from the atmosphere in emergent and floating-leaved plants or from sites of oxygen production in submersed plants) to roots is essential to prevent the accumulation of toxic end products either from metabolism of the plant (e.g., ethanol produced during glycolysis) or from those that diffuse into the plant from the anaerobic rhizosphere (e.g., hydrogen sulfide). Of the two types of aerenchyma, schizogenous aerenchyma forms constitutively in some aquatic plants by specific patterns of cell separation and cell expansions to create intercellular spaces that fill with gases from surrounding cells (Raven, 1996). In contrast, lysigenous aerenchyma arises from the spatially selective death of grown cells. Any process that restricts root aeration stimulates production and accumulation of the plant hormone ethylene. The additional ethylene accelerates aerenchyma formation by a series of sensing and transduction processes that initiate cell death and degeneration and create the intercellular gas lacunae (Jackson and Armstrong, 1999).

Wetland and submersed plants often increase the volume of the lacunal gas system when sediments become more reducing (e.g., Katayama, 1961; Armstrong, 1978; Penhale and Wetzel, 1982; Jackson and Armstrong, 1999). In addition, a number of aquatic plants have developed metabolic adaptations to tolerate periods of anaerobic conditions: Diverse nontoxic end products (malate and shikimic acid) can be produced during glycolysis (Crawford, 1978; Penhale and Wetzel, 1982; Sale and Wetzel, 1982; McKee *et al.*, 1989), or ethanol can be released to the environment (Bertani *et al.*, 1980).

Bacterial end products of fermentation (H_2S and volatile fatty acids) in anoxic, reducing sediments are toxic to many plants (e.g., Koch and Mendelssohn, 1989). For example, H_2S suppresses alcohol dehydrogenase, an enzyme that catalyzes alcoholic fermentation and suppresses nutrient uptake. Some oxygen diffuses from the roots and forms an oxidized microzone in the surrounding sediments (reviewed by Armstrong, 1978; Sorrell and Dromgoole, 1989; Jespersen *et al.*, 1998). This oxidized microzone suppresses methanogenesis and reduces the toxicity of fermentation products but simultaneously reduces the availability of certain nutrients, such as iron and manganese, by the formation of oxidized precipitates in the microzone on the surfaces of the roots (Tessenow and Baynes, 1978; Crowder and Macfie, 1986; Caffrey and Kemp, 1991). Iron "plaques" are very commonly heavily deposited on the surfaces of roots, and such deposition is distinctly seasonal, reaching maximum deposition in midsummer. Certain sulfur bacteria (*Beggiatoa*) of the plant rhizosphere can oxidize hydrogen sulfide to sulfur granules and consequently lower H_2S concentrations adjacent to root tissues (Joshi and Hollis, 1977).

Photosynthetic carbon fixation of aquatic macrophytes is offset by growth, losses of CO_2 from mitochondrial respiration and photorespiration, and secretion of soluble organic compounds. Photosynthetic efficiency is influenced directly by the rates of these dynamic, constantly changing processes. In calculations of primary productivity, the respiration rate has usually been assumed to be the same in light as in the dark. Physiological evidence, however, indicates that such an assumption is erroneous. Mitochondrial (dark) respiration may be inhibited in the light in some plants, perhaps by suppression of glycolysis (Jackson and Volk, 1970). Efficient refixation of respired CO_2 in the light restricts the loss of respiratory CO_2 from submersed aquatic plants (Søndergaard, 1979; Søndergaard and Wetzel, 1980; Wetzel *et al.*, 1984a; Laing and Browse, 1985; Boston and Adams, 1986).

Photorespiration, well-known in terrestrial plants (Goldsworthy, 1970; Jackson and Volk, 1970; Hatch *et al.*, 1971), enhances the loss of photosynthetically fixed carbon as CO_2 and reduces photosynthetic efficiency of aquatic macrophytes. In this process, CO_2 is generated in the light from glycolic acid, a direct product of C_3–Calvin-cycle photosynthesis. The rate of this reaction is influenced by, and is proportional to, oxygen concentration, light intensity, and temperature. Glycolate metabolism is also enhanced when low CO_2 limits photosynthesis. The rate at which photorespired CO_2 is lost from the plant depends on the efficiency of CO_2 refixation in the intercellular spaces of the plant.

Terrestrial plants in which all cells photosynthesize by the C_3–Calvin cycle can lose up to 50% of fixed carbon immediately by photorespiration, depending on environmental conditions. In contrast, little or no CO_2 is lost in the light from plants in which photosynthesis proceeds through the C_4–β-carboxylation pathway in mesophyll cells. These plants efficiently refix CO_2 both from dark respiration and from photorespiration in the C_3 bundle sheath cells.

C_3 and C_4 plants can be distinguished by the following combination of characteristics, any one of which is often reasonable evidence for making the distinction (Black, 1971): (a) C_4 plants have highly developed bundle sheath cells in leaf cross sections, with unusually high concentrations of organelles and starch accumulation; C_3 leaves lack this differentiation. (b) Photosynthesis is difficult to light-saturate in C_4 plants, while in C_3 plants, saturation illuminance is in the range of 200–900 μmol quanta m^{-2} s^{-1}. (c) Photosynthetic temperature optima are 30–40°C in C_4 plants and 10–25°C in C_3 plants. (d) Photosynthetic CO_2 compensation points are low for C_4 plants (0–10 ppm CO_2) and high for C_3 plants (30–70 ppm CO_2). (e) Response of apparent photosynthesis to O_2 concentration is not detectable in C_4 plants and shows increasing inhibition >1% O_2 in C_3 plants. Response of photorespiration (CO_2 release in light) to O_2 concentration is not detectable in C_4 plants, but shows increasing enhancement with increasing O_2 in C_3 plants. (f) Glycolate synthesis and glycolate oxidase activity are low in C_4 plants as compared to C_3 plants.

Emergent and floating plants are partially exposed to environmental conditions similar to those of terrestrial plants. Possessing largely C_3 photosynthetic metabolism, photorespiration can be extensive (Longstreth, 1989). High CO_2 concentrations are common in the intercellular spaces of many of these emergent species, enhanced by high concentrations moving from roots and rhizomes to leaves through internal gas channels and lacunae. This CO_2 enrichment, in addition to common, relatively vertical leaf orientation with a high leaf-area index (leaf area per unit surface area) and relatively unlimited water supply, results in high productivity.

The C_4 photosynthetic system is likely of adaptive value in many emergent hydrophytes, particularly in regions of high temperature and high light intensity or in situations in which the salt content of the environment adversely affects internal CO_2 and water balance (Hatch *et al.*, 1971). In the latter context, *Spartina*, the dominant plant of the salt marshes of many marine coastal regions, and papyrus (*Cyperus papyrus*) of the tropics are C_4 plants (Black, 1971; Jones and Milburn, 1978). There is some evidence that *Typha latifolia* is a C_3 plant with relatively low rates of photorespiration (McNaughton, 1966a, 1969; McNaughton and Fullem, 1969); limiting mechanisms are not known in this case.

Submersed macrophytes are exposed to lower concentrations of ambient oxygen, lower levels of light, and lower summer temperatures than are terrestrial and emergent aquatic plants. Furthermore, submersed and emergent aquatic plants are rarely ever subjected to the water stress to which terrestrial C_4 plants of arid environments have become adapted. The much slower diffusion of CO_2 in water than in air and the presence of massive internal gas lacunae can retard loss of CO_2 from submersed angiosperms and facilitate refixation of respired CO_2 (Carr, 1969; Hough and Wetzel, 1972; Hough, 1974; Søndergaard, 1979; Søndergaard and Wetzel, 1980; Wetzel *et al.*, 1984a). In a submersed species of *Scirpus*, for example, 30–40% of the carbon dioxide for photosynthesis was CO_2 released from photorespiration and refixed.

In softwater lakes, concentrations of total inorganic carbon in the water are very low; certain softwater submersed angiosperms and ferns (e.g., *Juncus bulbosus, Littorella, Lobelia, and Isoetes*) utilize CO_2 of the sediment–interstitial water to supplement CO_2 assimilated from the water (Wium-Andersen, 1971; Sondergaard and Sand-Jensen, 1979a; Wetzel *et al.*, 1984b; Boston *et al.*, 1989). Carbon entry per unit root surface area can be several times more rapid than entry per unit shoot surface area at equal external CO_2 concentrations (Boston *et al.*, 1987). Sediment-derived CO_2 can make up 65–95% of the total carbon assimilated in these plants from very soft waters. Uptake of CO_2 by root tissue for photosynthetic fixation by submersed plants of hardwater lakes, in which concentrations of inorganic carbon were high, could not be demonstrated (Beer and Wetzel, 1981; Loczy *et al.*, 1983; Steinberg and Melzer, 1983).

The photosynthetic CO_2 compensation points of submersed angiosperms are variable from moderate to high in comparisons to terrestrial plants (Brown *et al.*, 1974; Helder *et al.*, 1974; Van *et al.*, 1976; Lloyd

et al., 1977; Hough and Wetzel, 1978; Bowes *et al.*, 1979; Maberly, 1985; Owttrim and Colman, 1989). In addition, photorespiration is enhanced under conditions of increasing concentrations of dissolved oxygen and with increasing temperatures within the normal limnological range. Nearly all submersed angiosperms possess the C_3–Calvin-type of photosynthetic pathway (Hough and Wetzel, 1977; Winter, 1978; Browse *et al.*, 1979; Valanne *et al.*, 1982; critically discussed in Beer and Wetzel, 1980, 1982; Spencer and Bowes, 1990).

Reduced CO_2 compensation points can result from the presence of oxygen-insensitive phosphoenolpyruvate carboxylase (PEPcase), characteristic of C_4-type metabolism, in the cytoplasm of certain submersed plants. Oxygen-sensitive ribulosebisphosphate carboxylase-oxygenase (RuBPcase) is found in the chloroplasts (Bowes, 1987). The presence of appreciable amounts of PEPcase permits the fixation of CO_2 from both photorespiration and mitochondrial respiration, thereby reducing losses from the cells. The PEPcase activity increases among certain submersed plants with low CO_2 compensation points and results in elevated CO_2 concentrations around RuBPcase in the chloroplasts, which increases the CO_2/O_2 ratio and thus reduces photorespiration. The enzymes are separated intracellularly, even though submersed angiosperms do not exhibit anatomical differentiation,[2] as is common in C_4 plants (Hough and Wetzel, 1977).

In contrast, in the submersed macrophyte *Hydrilla*, a highly competitive, aggressive plant in the subtropics and tropics, no bundle sheath cells are evident. The PEPcase is located in the cytosol where bicarbonate is fixed, and four-carbon acids occur that are transported to the chloroplast in the same cell and decarboxylated to CO_2 and pyruvate (Bowes and Salvucci, 1984; Spencer *et al.*, 1996). This gas-exchange pattern, analogous to that of terrestrial C_4 plants, yields low rates of photorespiration, low CO_2 compensation points, and low O_2 sensitivity of photosynthesis. This plasticity of C_4-like photosynthetic metabolism in *Hydrilla* allows the plant to optimize carbon gain as the inorganic carbon availability in productive littoral areas changes rapidly over a daily period (Spencer *et al.*, 1994).

B. Water Movements, Boundary Layers, and Diffusion along Submersed Surfaces

When an aquatic plant attached to a substratum is exposed to the hydrodynamic forces of moving water flow, the net force exerted on the plant thallus is a vector resultant of two orthogonally opposed forces: (a) the lift force, which operates perpendicular to the direction of flow, and (b) two horizontal force components, the pressure force and the acceleration force (Nicklas, 1994). Most species of submersed plants cope with these forces by bending easily, thereby reducing drag. The flexure permits plants to absorb large amounts of energy without breaking. Submersed and emergent aquatic plants are both structurally flexible but employ different strategies. In submersed plants, structural simplicity and elasticity maximize flexibility, whereas in some emergent plants a twisted cantilevered beam structure allows severe bending without buckling (Rowlatt and Morshead, 1992; Biehle *et al.*, 1998).

Despite these adaptive mechanisms to the pressures of movement of a dense medium such as water against plant tissues, most aquatic plants cannot survive in habitats that are exposed to severe wind-generated waves. Most freely floating macrophytes are absent in such areas, and submersed species do not grow well, if at all, in shallow waters. Submersed plants are usually found at depths of greater than a meter or more, where the erosive actions on the sediments and stress on the plant morphology are ameliorated (cf. Chap. 7). Experimentally increased exposure to wave action commonly leads to reduced biomass production, tiller formation, and growth among even well-adapted emergent macrophytes (e.g., Coops *et al.*, 1994). Marked fluctuations in water level, as is common in reservoirs, can induce increases in wave disruption of the macrophytes directly as well as sediment accumulations and result in decreases in both production and biodiversity of littoral plants and associated biota (e.g., Memezes *et al.*, 1993).

Low-velocity currents impinging on leaf surfaces increase photosynthetic rates among submersed angiosperms by reducing the stagnant boundary layer and increasing diffusion rates (e.g., Barth, 1957; Westlake, 1967). Increasing flow rates to velocities above ca. 15 mm s^{-1}, however, can decrease photosynthetic rates precipitously (e.g., Madsen and Sondergaard, 1983). Although flows commonly affect river macrophytes, among most lake, pond, and many river habitats flows within submersed macrophyte beds are greatly attenuated within a few centimeters of the outer plant-bed boundaries (Losee and Wetzel, 1993; Sand-Jensen and Mebus, 1996; Stevens and Hurd, 1997). Laminar-flow boundary layer thickness at the surfaces of submersed leaves are very large (several mm to cm), often greater than macrophyte leaf thicknesses themselves. The presence of epiphytes and attached debris alters the flows and diffusion rates because of roughness and turbulence at the microlevel (cf. Riber and Wetzel, 1987;

[2] Kranz anatomy, where CO_2 is fixed in mesophyll cells with few or no chloroplasts with PEPcase and transferred in organic acids to chloroplasts located in bundle sheath cells surrounding vascular tissue.

Koch, 1994). The boundary layer is furthermore highly dynamic at times, such as when a passing wave temporarily increases water movement and decreases boundary layer thickness. Clearly, however, in lakes and many stream conditions, the acquisition of gases and dissolved substances from the water depends on diffusion, which is generally very slow.

C. Carbon Assimilation among Aquatic Macrophytes

Atmospheric carbon dioxide is clearly a significant source of inorganic carbon among emergent (Brix, 1990; Singer *et al.*, 1994) and floating macrophytes. Carbon dioxide in the internal spaces of the aerenchyma, however, is often highly concentrated despite convectional flowthrough mechanisms, discussed earlier, for the internal gases, particularly at night (e.g., Constable *et al.*, 1992; Li and Jones, 1995). For example, in the emergent papyrus wetland species with C_4 photosynthesis, it was estimated that about half of the CO_2 of the intercellular spaces emanates from respiration and is rapidly recycled by photosynthesis.

A few species of freely floating angiosperms, such as some duckweeds (*Lemna*), utilize both atmospheric and aqueous carbon sources (Wohler, 1966; Wetzel and Manny, 1972; Ultsch and Anthony, 1973; Filbin and Hough, 1985). Some data on sources of CO_2 fixation by floating-leaved but rooted macrophytes, such as the water lilies, indicate that atmospheric CO_2 comprised only about half of the total carbon fixed (Hough and Filbin, 1990). The remainder was obtained from the water. Heterophyllous aquatic macrophytes are similarly adapted to use both atmospheric CO_2 by the aerial foliage and aqueous CO_2–HCO_3 by the submersed foliage. Clearly, however, the utilization of atmospheric CO_2 is the predominant *external* source of inorganic carbon uptake under most circumstances among amphibious and emergent species (cf. discussion of Maberly and Spence, 1989; Sand-Jensen *et al.*, 1992; Constable and Longstreth, 1994; Frost-Christensen and Sand-Jensen, 1995).

The availability of free carbon dioxide is always low in water because rates of diffusion in water are 4 orders of magnitude slower than in air (cf. Chap. 11) and CO_2 is not very soluble in water. As a result, CO_2 from aqueous solution can be readily reduced or depleted in microzones near leaves or cells during intensive photosynthetic assimilation. Morphological adaptations that increase absorption among submersed leaves, stems, and some petioles include (a) thin tissues (1–3 cell layers), (b) reduced cuticle development, (c) extreme reduction or elimination of mesophyll, and (d) dense concentration of chloroplasts in epidermal cells. These adaptations all increase utilization and exchange of gases dissolved in water. Massive intercellular gas spaces in leaves, stems, and petioles facilitate rapid internal diffusion among plant parts, including the rooting tissues.

In contrast, concentrations of bicarbonate of natural hard waters can be several orders of magnitude greater than those of CO_2. Because of the slow rates of diffusion and relatively long diffusion pathways from the medium through the unstirred layer to sites of biochemical assimilation, the ability to assimilate bicarbonate ions can be regarded as an adaptive advantage to those plants that possess this capability. The transport of bicarbonate and the removal of the CO_2 from the HCO_3^- within cells, however, has an energetic cost (Raven and Lucas, 1985; Eighmy *et al.*, 1991).

The question of limitation of photosynthesis by the low solubility and slow diffusion of CO_2 in water has received much attention, especially in relation to the alternative utilization of the relatively abundant bicarbonate ions. In large submersed angiosperms and algae, the diffusion path through the cells of the thallus or leaf is long (up to 50 μm). In addition, an effective boundary layer gradient zone of at least 10 μm to several millimeters of unstirred water occurs at the cellular surfaces (Losee and Wetzel, 1993). Moreover, diffusion rates through the larger cells are much slower than among microalgae (Steemann Nielsen, 1947; Raven, 1970; Smith and Walker, 1980). Ions and gas molecules move only by diffusion through the boundary layer. Water movements over submersed surfaces reduce the boundary layer thickness but do not eliminate it, regardless of current velocities.

In algae, especially larger macroalgae, the ability to utilize bicarbonate ions in photosynthesis is widespread but not universal. The extensive work on this subject among mosses and submersed angiosperms by Steemann Nielsen (1944, 1947), Ruttner (1947, 1948, 1960), and others (e.g., Bain and Proctor, 1980) has shown that the freshwater red alga *Batrachospermum* and all assayed genera of freshwater submersed mosses utilize only free CO_2 and cannot assimilate bicarbonate. These latter plants are restricted almost universally to soft waters of relatively low pH or to streams in which CO_2 concentrations are relatively high.

Different strategies have evolved in submersed macrophytes that can be viewed as both physiological and exploitative mechanisms to ameliorate the constraints of limited carbon availability (cf. reviews of Maberly and Spence, 1983; Madsen and Sand-Jensen, 1991):

a. Many species utilize primarily or only CO_2 and necessarily are restricted to habitats with multiple sources of CO_2 (e.g., Wetzel, 1969; Brown

et al., 1974; Van *et al.*, 1976; Moeller, 1978; Winter, 1978; Kadono, 1980).

b. Utilization of HCO_3^- under natural conditions has been reported for a number of freshwater angiosperms (e.g., Raven, 1970; Helder and Zanstra, 1977; Lucas *et al.*, 1978; Browse *et al.*, 1979; Prins, *et al.*, 1980; Beer and Wetzel, 1981; Lucas, 1983).

No other area of aquatic plant physiology has received greater study than has the assimilation of inorganic carbon as CO_2 and bicarbonate ions by submersed plants. The ability of submersed macrophytes and algae to assimilate bicarbonate ions as a carbon source supplementary to carbon dioxide has been demonstrated in a number of investigations. Space does not permit detailed discussion of the long history of remarkable experimental studies as well as conflicting results of some of these studies (cf. Raven, 1970, 1984; Helder and Zanstra, 1977; Lucas *et al.*, 1978; Browse *et al.*, 1979; Helder *et al.*, 1980; Prins *et al.*, 1980; Lucas, 1983; Wetzel and Grace, 1983; Lucas and Berry, 1985; Bowes, 1987; Prins and Elzenga, 1989; Madsen and Sand-Jensen, 1991). Variations in physiological mechanisms of bicarbonate uptake are largely though not completely understood. Three general mechanisms exist:

1. A polar differential, established by spatial separation of HCO_3^- influx from resulting OH^- efflux, common in submersed angiosperms and Characeae that assimilate bicarbonate.
   a. Carbon dioxide assimilation occurs in all cell layers.
   b. Bicarbonate ions are utilized only by cells of the lower epidermis.
   c. Carbon dioxide (both as free CO_2 and as CO_2 derived from the dehydration of bicarbonate) is fixed, and hydroxyl ions equivalent to the amount of carbon dioxide derived from bicarbonate pass out through the adaxial (upper) leaf surface.
   d. Cations, primarily calcium, equivalent to the quantity of bicarbonate taken in through the abaxial (lower) leaf surface, are transported from the abaxial to the adaxial leaf surface, thereby achieving stoichiometry and charge balance in all compartments.
   e. The passage of calcium and hydroxyl ions to the adaxial leaf surface results in a high pH on this surface and usually results in precipitation of $CaCO_3$ on that surface. The carbonate deposits encrusting the upper surfaces of the submersed leaves of macrophytes in calcareous hard waters often exceed the weight of the plant material (Wetzel, 1960). Among emergent and floating macrophytes that utilize atmospheric carbon dioxide, encrustation on submersed plant portions was found to be highly variable and proportional to the extent of development of epiphytic algae. Deposits on submersed species were much heavier and were correlated directly with morphological variations in surface area and the ability to utilize bicarbonate ions.
2. HCO_3^-–H^+ cotransport with subsequent removal of CO_2, particularly among the Characeae macroalgae.
3. Extracellular conversion of HCO_3^- to CO_2 by the release of carbonic anhydrase.

Some plants, such as certain species of *Ranunculus*, combine conversion of bicarbonate to CO_2 with carbonic anhydrase as well as with a photodependent increase in plasma membrane H^+ release (Rascio *et al.*, 1999).

D. CAM Metabolism

Crassulacean acid metabolism (CAM) is a CO_2-concentrating mechanism in which carbon is incorporated into malate (a characteristic of C_4 plants) and stored temporarily as a stable product rather than as an intermediary carbon source. Because of the restricted availability of inorganic carbon in softwater environments, some submersed angiosperms accumulate malate in the light, which may function as an ion to balance excess cation uptake (Browse *et al.*, 1980). However, malate may also accumulate in the dark for subsequent decarboxylation and refixation of CO_2 in the light, complementary to fixation of exogenous carbon (Beer and Wetzel, 1981; Keeley, 1981, 1982, 1998; Madsen, 1987).

Aquatic CAM plants inhabit sites where photosynthesis is potentially limited by carbon. CAM submersed plants have been found in a number of common genera: *Isoëtes* (Lycophyta), *Sagittaria, Vallisneria, Crassula*, and *Littorella*. Some of these plants occupy fertile shallow temporary ponds that experience extreme diurnal fluctuations in carbon availability. Elevated nighttime CO_2 concentrations are assimilated and fixed into malate for use in the subsequent day period. Some of the CAM submersed plants live in oligotrophic softwater lakes were carbon limitation prevails. Where CAM is a dominant mechanism for acquisition of CO_2, as in some species of *Isoëtes* and *Littorella*, CAM can contribute to over half of the annual gain for plant photosynthesis (e.g., Boston and Adams, 1986).

E. Daily Rates of Photosynthesis among Submersed Macrophytes

Rates of photosynthetic carbon fixation in submersed macrophytes are generally correlated with the intensity of solar radiation on a daily basis. However, a midday and afternoon depression of carbon fixation is often observed, so those highest rates of photosynthesis are skewed toward morning (Wetzel, 1965b; Sculthorpe, 1967; Goulder, 1970; Hough, 1974, 1979). *In situ* experiments with the submergent *Najas* showed that the afternoon decrease in net photosynthesis was correlated with a proportional increase in photorespiration. The results of numerous studies suggest that photorespiration may increase through the day with increasing light intensity, with increasing oxygen tension of photosynthetic origin, increasing temperature, and possibly decreasing CO_2 availability (Fig. 18-3). Conditions conducive to accelerated photorespiration can develop in the littoral zone, particularly among dense macrophytic populations during calm weather with little turbulence. An increase in photorespiration would reduce net photosynthesis. Simultaneously, however, the concentrations of available inorganic carbon decrease, and certainly this reduced availability could contribute equally to the observed afternoon reduction in net photosynthesis (e.g., Jones *et al.*, 1996).

With cessation of photosynthesis during darkness, internal oxygen content decreases rapidly and carbon dioxide increases; then respiration is limited by the rate at which oxygen diffuses from the water to the cells. Dark respiration rates increase with rising temperatures and are generally, but not in all cases, enhanced by high concentrations of oxygen in the surrounding water, especially if the water is agitated slightly by low-velocity currents (Pannier, 1957, 1958; Owens and Maris, 1964; McIntire, 1966; Westlake, 1967; McDonnell, 1971; Hough and Wetzel, 1972; Stanley, 1972; Prins and Wolff, 1974). During the daytime, the effect of oxygen on photorespiration and dark respiration would further increase the release of CO_2.

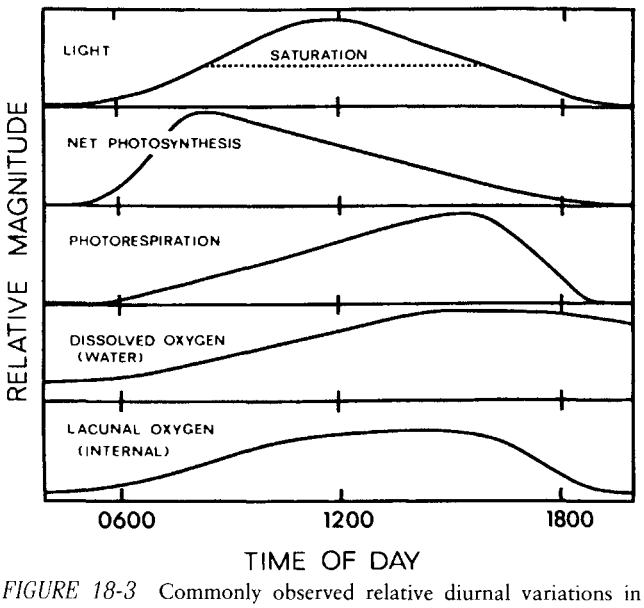

FIGURE 18-3 Commonly observed relative diurnal variations in light intensity, dissolved oxygen concentrations of the water and the internal lacunal spaces of submersed aquatic plants, net photosynthesis of submersed macrophyte (and some phytoplankton) populations, and proposed concurrent variations in photorespiration. (Modified from Hough, 1974.)

Physiological evidence indicates that most freshwater submersed angiosperms possess C_3–Calvin-type photosynthetic metabolism and high rates of photorespiration, which collectively reduce rates of net photosynthesis. Efficient internal recycling of respired CO_2, utilization of bicarbonate as well as dissolved CO_2, and augmentation of exogenous inorganic CO_2 by decarboxylation of malate formed during darkness are mechanisms by which certain submersed species adapt to the generally restricted availability of CO_2. There is no question that the evolution of an extensive internal lacunal gas system in submersed angiosperms constitutes an array of interrelated morphological adaptations related to (a) enhanced efficiency of carbon fixation, (b) flexibility to withstand water movements, and (c) positive buoyancy and positioning of leaves toward greater available light.

Little is known of the seasonal variations in respiration and photorespiration among submersed macrophytes. Photorespiration and dark respiration were found to be 10-fold greater during the fall than during summer as the annual submergent *Najas* was entering senescence following seed set in late summer (Hough, 1974). Photorespiration in the submersed perennial *Scirpus subterminalis* was relatively low during summer and increased under the ice in late winter.

Many submersed aquatic angiosperms of the temperate zone perennate beneath ice in lakes and ponds. Although some species lose their leaves and are dormant throughout the winter, many species retain leaf tissue and photosynthetic capacity beneath ice (Boylen and Sheldon, 1976; Best, 1986; Best and Visser, 1987). Submersed species that remain physiologically active beneath ice experience attenuated irradiance and cold nonfreezing temperatures. Analyses of submersed *Ceratophyllum demersum* found optimum temperatures for net photosynthesis of winter and summer plants were 5 and 30°C, respectively (Spencer and Wetzel, 1993). Dark respiration of winter plants was over 300% greater than that of summer plants. Reduced Rubisco carbon-fixing enzyme activity and increased dark respiration interacted to reduce net photosynthesis

and increase CO_2 and light compensation points of winter plants.

F. Secretion of Dissolved Organic Matter

The loss of recently synthesized organic carbon and nitrogen as secreted dissolved organic compounds has been demonstrated for a few submersed and freely floating angiosperms (Wetzel, 1969; Hough and Wetzel, 1972, 1975; Wetzel and Manny, 1972; Hough, 1979; Søndergaard, 1981, 1990; Nalewajko and Godmaire, 1993). The organic compounds released are largely of low molecular weight (ca. 200 D). Well known among the planktonic algae (see Chap. 15), this loss of organic carbon during active photosynthesis in submersed macrophytes can represent a significant reduction in photosynthetic efficiency. Secretion rates of dissolved organic carbon vary greatly (0.05 to over 100% of carbon photosynthetically fixed) under an array of experimental conditions of varying light and ionic composition of the medium. Most values, however, including those from *in situ* analyses, were between 1 to 10% of photosynthetically fixed carbon, increasing somewhat during the course of the daylight period, but the maximum secretion percentage of total carbon fixed occurred at the lowest rates of photosynthesis.

The secretion discussed here refers to that released extracellularly during active photosynthesis, rather than soluble organic compounds released during senescence and early stages of decomposition. The secretion may represent an incomplete adaptation of submersed macrophytes to a totally aqueous medium. Functionally, however, the secretion of labile organic compounds by submersed macrophytes enhances the development of a highly productive epiphytic community of microflora (Wetzel and Allen, 1970; Wetzel, 1993a). Nutrient interactions, both inorganic and organic, take place between the submersed macrophyte and epiphytic algal and bacterial populations (cf. Allen, 1971; Allanson, 1973; Wetzel, 1996; Chap. 19). These interactions are lacking or greatly reduced in the diluted planktonic regime. This apparent small decrease in photosynthetic efficiency by the loss of dissolved organic carbon could be viewed as a symbiotic interaction between the macrophyte and its epiphytic bacteria and algae.

The release of organic acids by roots for the solubilization and mobilization by complexation of nutrients from soils is widely known among terrestrial plants (e.g., Uren and Reisenauer, 1988). A similar mechanism has been demonstrated in rice (Saleque and Kirk, 1995) and is likely among many aquatic plants under natural conditions. Interstitial dissolved organic carbon was much higher in sediments with growing emergent macrophytes than in unvegetated sediments, and bacterial productivity was shown to be appreciably greater utilizing dissolved organic matter from the vegetated sediments (Mann and Wetzel, 1999b). Analogous enhanced bacterial communities have been found in the rhizosphere of marine angiosperms (Donnelly and Herbert, 1999).

G. Absorption of Ions and Nutrition in Aquatic Plants

The functional significance of the rooting systems in aquatic macrophytes, primarily angiosperms, has been a long-standing question in limnology (reviewed in Gessner, 1959; Wetzel, 1964; Sculthorpe, 1967; Bristow, 1975; Hutchinson, 1975; Agami and Waisel, 1986). Two views emerge, each with supporting evidence: (a) that the rooting systems function in the absorption of nutrients from the substratum, and (b) that the roots function merely as organs of attachment, particularly among submersed plants. An overwhelming accumulation of evidence now demonstrates that rooting tissues are essential for primary acquisition of nutrients for aquatic plants, including those that are submersed.

The roots of most aquatic plants, including certain submersed plants that have reduced rooting tissues, possess root hairs (Shannon, 1953) or lateral root projections (Cumbus and Robinson, 1977) that increase the absorptive capacities of nutrients from the interstitial water of sediments. In addition, a large number of emergent, floating-leaved and submersed aquatic macrophytes possess vesicular–arbuscular mycorrhizae (e.g., Søndergaard and Laegaard, 1977; Tanner and Clayton, 1985; Nakatsubo *et al.*, 1994; Stenlund and Charvat, 1994; Wetzel and van der Valk, 1996). Despite the anoxia of sediments, the release of oxygen from the intercellular spaces of the plant roots into the immediate microrhizosphere is presumably sufficient to allow reasonable infection and support of the mycorrhizae. Increases in symbiotic mycorrhizal infections are common under conditions of reduced nutrient availability or other stress factors (increased salinity and reduced pH). These root extensions likely also function in the enhanced release of extracellular enzymes to increase the availability of growth factors.

1. Rooted Emergent and Floating Aquatic Plants

Among emergent and floating-leaved angiosperms with active transpiration-mediated root-pressure systems, nutrient absorption and translocation from the roots to the foliage are clearly operational. Most, but not all, emergent plants are rooted in the sediments. Where emergent plants occur in large floating mats, nutrients are essentially all absorbed from the water through the rooting tissues.

Among emergent aquatic macrophytes, phosphorus requirements are met by uptake of inorganic and organic phosphorus compounds from the sediments (e.g., Islam *et al.*, 1979; Atwell *et al.*, 1980). Detailed studies of the growth and reproduction of the cattail (*Typha latifolia*) in marshes of differing successional maturity demonstrated that phosphorus limitations affect not only overall growth but also the allocation of photosynthate to sexual and vegetative reproduction, early spring mortality, and competitive success (Grace and Wetzel, 1981a). Elevated phosphorus concentrations of the hydrosoils is a primary factor influencing rapid cattail (*Typha* spp.) growth and invasive competition with native emergent macrophyte species in the Everglades of Florida (Newman *et al.*, 1998). In another example, about half of the ammonium assimilated by the roots of rice is rapidly translocated to the shoots (Wang *et al.*, 1993). Fertilization of sediments with nitrogen and phosphorus can result in major increases in the aboveground production (e.g., Granéli, 1985; Bornkamm and Raghi-Atri, 1986). For example, enhanced nitrogen as ammonia and phosphate of sediment interstitial water resulted in marked increases in net annual aboveground production of *Sparganium* (+57%) and *Typha* (+19%) (Neely and Davis, 1985).

Although aquatic plants must possess a well-developed aeration system of rooting tissues that are confluent with aerial leaves, anaerobic sediments of nearly all aquatic ecosystems are highly reducing and consequently contain relatively large quantities of nutrients in available form. Concentrations in sediments are usually several orders of magnitude greater than those in the overlying water. Clearly, the sediment and associated organic detritus (e.g., Morris and Lajtha, 1986) are the primary sources of nutrients for aquatic plants.

As occurs among terrestrial plants, much (often >90%) of the nutrients used, recycled during growth, and stored in aboveground tissues of aquatic plants is translocated back to and stored within rooting tissues below ground (e.g., Granéli *et al.*, 1992; DeLucia and Schlesinger, 1995). The release of ions during senescence and decay may be into the water or to the sediment (cf. Denny, 1987), but in both cases the vigorously growing attached microbial community sequesters most of the nutrients being released (Godshalk and Wetzel, 1978; cf. Chap. 19). Most of the aquatic plant detritus accumulates on the sediments and becomes incorporated into the sediments. As a consequence, the sediments effectively become a nutrient sink.

2. Floating Aquatic Plants

Floating vegetation occurs in many forms. Floating swamps of tropical regions and large river deltas, such as the delta of the Danube, can be very large mats of floating root and rhizome mats often many hectares in size. The mats or rafts of emergent vegetation may be attached to, and grow out from, beds of rooted vegetation along the shores of lakes and rivers or be freely floating (Denny, 1985, 1987). Emergent plants, such as *Cyperus papyrus, Phragmites,* and *Typha*, often occur with floating plants, such as the water hyacinth *Eichhornia.* The floating mats of dense aerial biomass overlie a lower heterotrophic zone of rhizomes and partially decomposed organic matter from the prolific photosynthetic productivity of the aquatic plants. The water under these mats is commonly shallow and often anoxic extending down to the sediments. Large amounts of nutrients are stored in the plant tissues and detrital organic matter, and a tight internal cycling occurs from the living foliage and the supporting organic matter and water beneath it (e.g., Gaudet, 1982).

Most of the nutrients in a bed of nonrooted, freely floating higher aquatic plants are acquired by roots from the water below and around the bed. Pendulant roots assimilate ions directly from the water. Translocation is mediated by active root-pressure kinetics via intense evapotranspiration. Macroalgae, liverworts, mosses, ferns, and other rootless macrophytes that float on the surface or in the water or are variously loosely attached to the substratum presumably obtain nutrients by foliar absorption rather than by rhizoidal structures. An exception is the rhizoid-bearing macroalga *Chara*, which absorbs phosphorus equally well in all parts; phosphorus absorbed by the rhizoids is translocated to other parts of the plant (Littlefield and Forsberg, 1965). In a floating-leaved water lily (*Nuphar luteum*), phosphorus absorption rates differed with the absorbing tissue (roots > submersed leaves > floating leaves) (Twilley *et al.*, 1977). About four times more phosphorus moved from the roots to leaves than from the leaves to the roots during summer.

Special mention should be made of the heterosporous aquatic fern *Azolla*, whose sporophytes float freely on the water surface in shallow quiet waters, wetlands, and particularly in rice fields. This small (1–3 cm in diameter), prolific fern contains throughout its life cycle a symbiont, a heterocyst-forming, nitrogen-fixing cyanobacterium *Anabaena azollae* (Lumpkin and Plucknett, 1980; Ito and Watanabe, 1983; Peters and Meeks, 1989; Wagner, 1997). The nitrogen-fixing symbiont can provide the total nitrogen requirements for the fern and continues to fix nitrogen regardless of assimilation of ammonium or nitrate by the fern from the water. The *Azolla–Anabaena* symbioses are used as a major nitrogen fertilizer in lowland rice cultivation in Asia and other regions. It has been estimated that as much as a quarter of the total human nitrogen

consumption is obtained from the *Azolla–Anabaena* source assimilated by rice.

3. Submersed Macrophytes

In rooted submersed plants, a positive absorptive capacity is present and guttation always occurs in small quantities, increasing from root tip to the basal portions of the plant and increasing from the apical parts to the base (reviewed by Stocking, 1956). Water exits via hydathodes on the upper portions of many submergents, and nutrients can enter apically through the numerous porous hydropoten. The extensive development of roots and root hairs among aquatic plants (>95% of 200 species of 105 genera and 54 families) emphasizes the dependency of these plants on roots for absorption of solutes as well as for anchorage (Shannon, 1953).

Submersed angiosperms have a reduced but well-structured vascular tissue containing xylem, phloem, and an endodermis with casparian strips important in the regulated flow of ions and water (Pedersen, 1993; Pedersen and Sand-Jensen, 1993). Acropetal water transport occurs from roots to leaves at low rates, but at rates markedly faster than is possible by passive diffusion. Transport depends upon light and presumably on photosynthetic products and energy. This transport clearly functions as a translocation system for nutrients taken up from the nutrient-rich sediments.

The absorption of phosphorus by roots of submersed plants both from the water and from the sediments is well known (cf. Chap. 13, and Gessner, 1959; Schwoerbel and Tillmanns, 1964a; Bristow, 1975; Denny, 1980; Vermaak *et al.*, 1982; Chambers *et al.*, 1989; Gunnison and Barko, 1989). Among most submersed macrophytes, phosphate absorption rates by foliage are proportional to and dependent upon the concentrations in the water. Very large quantities of several mg liter^{-1} are rapidly assimilated in excess of requirements until concentrations in the water are reduced to about 10 μg liter^{-1}. In most of these studies, however, discrimination between uptake and retention of phosphate by the attached periphyton is not differentiated from that taken into the macrophyte tissue itself. Where experiments are designed to specifically examine these pathways (e.g., Moeller *et al.*, 1988), clearly most of the phosphorus acquisition by the macrophyte was from roots, and uptake from the water was largely into epiphytic microorganisms and predominantly independently cycled in the epiphytic periphyton (cf. Chap. 19). Therefore, it is not clear in many of the older studies whether the nutrients from the water are being incorporated by the submersed plants or largely by the attached periphyton. The attached microorganisms are likely most important, particularly under conditions of low nutrient concentrations in the water.

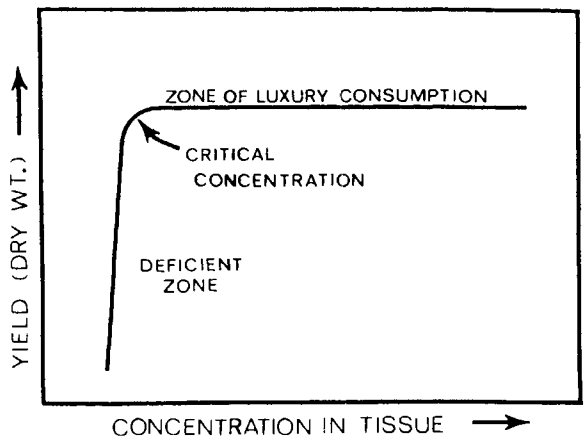

FIGURE 18-4 General relationship between aquatic plant biomass and the concentration of an essential element in plant tissue. (Modified from Gerloff, 1969.)

Luxury consumption of nutrients under high concentrations in the water, known especially for phosphorus but also for nitrogen, have led to the application of elemental analysis of tissues for evaluating nutrient supplies for algae and aquatic angiosperms, a technique long used in agriculture (Gerloff, 1969; Fitzgerald, 1972; Schmitt and Adams, 1981). Tissue analysis is based on the assumption that the concentration of an element in an organism varies over a wide range in response to the concentration in the environment and that over part of this range the yield (biomass) of the organisms is related to the tissue content of the element. Tissue analysis depends on establishing, for each species, the critical concentration for each element of interest, that concentration which is just adequate for maximum growth (Fig. 18-4). Below this point in the "deficient zone," plant yield is dependent on the supply of the element, but the elemental concentration in the organism changes little. Above this point, in the "zone of luxury consumption," the content of the element of the organism increases but plant growth does not. The method assumes that below a critical concentration, plant growth is being limited by the supply of that element. Such an assumption is true in a general way and is readily demonstrable in crop plants; some data additionally suggest a similar relationship among algae and aquatic plants grown hydroponically and axenically in completely aqueous media (e.g., Colman *et al.*, 1987). The correlation between nutrient concentration of the water and tissue content among submersed plants rooted in sediments, however, is less clear. When a macronutrient is distinctly limiting to growth of submersed macrophytes, however, the differences are conspicuously evident in tissue concentrations. For example, growth and biomass of submersed macrophytes

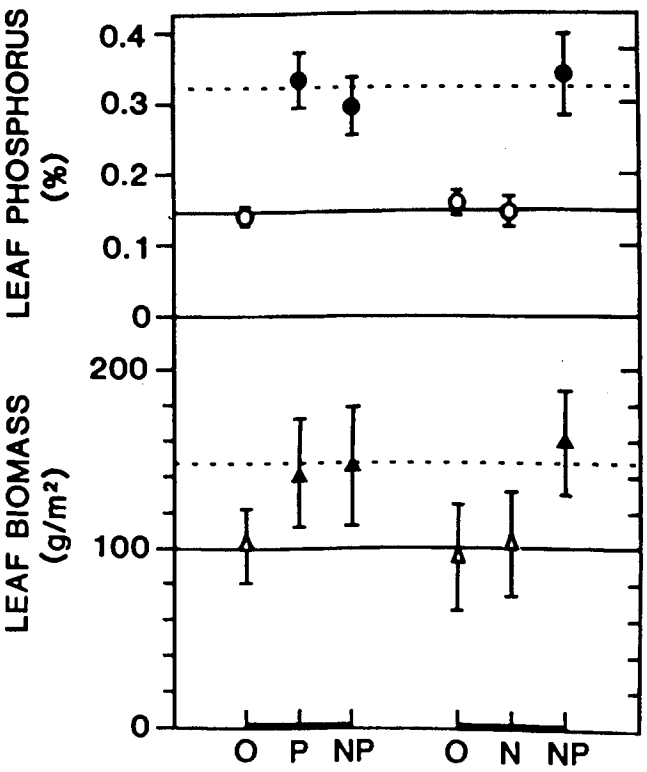

FIGURE 18-5 Response of the dominant submersed macrophyte *Scirpus subterminalis* to 1 year of inorganic phosphorus and nitrogen enrichments, separately and in combination, to sediments of hardwater Lawrence Lake, Michigan. *Upper*: P concentration in leaf tissue (% carbonate- and ash-free dry wt). *Lower*: Leaf biomass (g ash-free dry wt m^{-2}). Means with 95% confidence intervals are compared for three sites with a parallel P-alone enrichment and for two sites with N-alone enrichment (0 = control, NP = mixed fertilizer, N = +nitrogen, P = +phosphorus). (From data of Moeller *et al.*, 1998.)

increased significantly with enrichments of phosphate released experimentally in littoral sediments, but not with inorganic nitrogen, of an oligotrophic hardwater lake of southwestern Michigan (Fig. 18-5). The nutrient supply to the tissues, however, was from the sediment interstitial waters and not the overlying water. Root growth is directly enhanced in submersed *Myriophyllum* when nutrient concentrations of nitrogen and phosphorus in the water surrounding the foliage is reduced (Mantai and Newton, 1982).

Growth of the prolific nonrooted submersed angiosperm *Ceratophyllum demersum* is often limited by the ambient phosphorus concentration of lake water during summer. Winter-collected plants under the ice had 54 and 35% more phosphorus and nitrogen, respectively, than summer-collected plants (Spencer and Wetzel, 1993). Physiologically active perennation beneath ice enabled *C. demersum* to accumulate phosphorus during the winter when it was most abundant. Partial uncoupling of phosphorus acquisition from utilization may reduce phosphorus limitation upon growth during the summer when phosphorus concentration of the water is seasonally the lowest.

Experimental analyses have demonstrated that most rooted submersed angiosperms obtain most of their phosphorus from the interstitial water of the sediments (Bristow and Whitcombe, 1971; Schults and Malueg, 1971; DeMarte and Hartman, 1974; Bole and Allan, 1978; Welsh and Denny, 1979; Barko and Smart, 1980; Carignan and Kalff, 1980; Gabrielson *et al.*, 1984; Moeller *et al.*, 1988; Chambers *et al.*, 1989). Although some evidence is contradictory (e.g., Seadler and Alldridge, 1977; Swanepoel and Vermaak, 1977), most studies show an active absorption by the roots and translocation to the leaves. When concentrations of phosphate and sulfate of the water are low, absorption of these nutrients by the leaves of *Elodea* is limited by the rate of diffusion through the concentration gradient of the microlayer surrounding the leaves (Jeschke and Simonis, 1965). Absorption of phosphate is limited by the process of active uptake at intermediate exogenous concentrations and by the rate of diffusive influx into the leaves at high external concentrations (Grunsfelder and Simonis, 1973; Grunsfelder, 1974). Much of the phosphorus uptake from the water by the macrophyte–epiphyte community is utilized and recycled by the epiphytic algae (e.g., Howard-Williams, 1981; Pelton *et al.*, 1998). Detailed studies of the transport of phosphorus through the epiphytic algae and bacteria (Moeller *et al.*, 1988) have demonstrated that most of the phosphorus is actively recycled within the periphyton and that most of the phosphorus utilized by the submersed macrophytes is absorbed by the roots and translocated to the foliage. These studies indicate that many earlier studies that attributed high phosphorus uptake by the macrophytes from the water are in part simply a reflection of the inability to separate the uptake by epiphytic microbiota from the true assimilation from the water by the submersed angiosperm. High phosphorus concentrations in water frequently encourage the prolific development of epiphytic algae, to the detriment of submersed macrophytes by light attenuation (see Chap. 19).

Rates of nitrate assimilation by the foliage of several submersed macrophytes are considerably less than are rates of ammonia assimilation, especially at high pH values (Schwoerbel and Tillmanns, 1964b,c, 1977; Toetz, 1973b, 1974; Cole and Toetz, 1975; Nichols and Keeney, 1976; Holst and Yopp, 1979; Best, 1980; Madsen and Baattrup-Pedersen, 1995). High nitrogen concentrations are required by many submersed plants to maintain efficient carbon assimilation and carbon-concentrating mechanisms. Ammonium ions are readily absorbed by roots and translocated to apical tissues.

Furthermore, nitrogen from N_2-fixing bacteria of the sediments and plant rhizosphere can serve as a major nitrogen source for aquatic plants (e.g., Bristow, 1974a; Tjepkema and Evans, 1976; Purchase, 1977; Kana and Tjepkema, 1978; Ogan, 1979; Watanabe *et al.*, 1979; Blotnick *et al.*, 1980). Methanotrophic bacteria of anoxic sediments oxidize ammonium ions in the rhizosphere of aquatic plants and the nitrate is utilized by the macrophytes (Bodelier and Frenzel, 1999).

Among shallow lakes, phosphorus tends to be in abundance and is largely actively recycled to the sediments from aquatic plants and attached microflora. Under conditions of high production of organic matter and abundant anaerobic sediments and detritus, however, denitrification can result in major losses of nitrogen and contribute to nitrogen limitation (e.g., Lijklema, 1994). Such low levels of nitrogen can be correlated with lower productivity of submersed and emergent aquatic plants and with greater biodiversity than occurs at higher concentrations of nutrients (e.g., Gough and Grace, 1998; Moss, 1998).

Considerable information exists on the inorganic chemical composition of aquatic plants (cf. review of Hutchinson, 1975; Cowgill, 1989). There are large variations in chemical composition, even among closely related species and from site to site in the same species. Metals and alkalis are absorbed from the water by leaves and the interstitial water of sediment by roots (e.g., DeMarte and Hartman, 1974; Marquenie-van der Werff and Ernst, 1979), and many elements are concentrated in the macrophytes in great excess of metabolic requirements. As a result, submersed and emergent plants are often suggested to be scavengers of contaminants in surface waters (e.g., Wolverton and McDonald, 1978, 1979)

In summary, ion absorption in submersed macrophytes occurs both from the water by foliage and from the sediments by root and rhizoid systems. Under most circumstances, even in nutrient-rich waters, roots are the dominant sites of nutrient uptake and assimilation for aquatic plants. Translocation occurs in both directions, with the dominant acropetal translocation from the roots to the leaves. Because roots serve as a primary site of nutrient absorption from the sediments, the value of tissue analyses of element concentrations in aquatic macrophytes is suspect as an index of the fertility of the lake or river water. Nutrient content of the water can be quite unrelated to plant growth of those species having ready access to the abundant nutrient supply in the sediments. The method is, however, applicable to analyses of nutrient availability from the sediments or rootless submersed macrophytes. Also, as was indicated earlier (Chap. 13), the rooted plants can function as a "pump" of nutrients from the sediments; some of those nutrients can then be lost to the water during both active growth and decomposition. Most of the nutrients released from senescing tissues, however, is sequestered by attached microbial communities, intensively retained, and recycled (cf. Chap. 19).

IV. RATES OF PHOTOSYNTHESIS AND DEPTH DISTRIBUTION OF MACROPHYTES

A. Light and Temperature

Emergent macrophytes are among the most productive natural plant communities in the biosphere. The high rates of emergent macrophyte production have been attributed, among many factors, to a constant water supply and high nutrient concentrations of sediment interstitial waters. The leaf and growth morphology and minimal development of canopy structure of emergent macrophytes minimize shading and maximizes inception of light. In general, emergent and floating-leaved macrophytes exhibit sun plant characteristics and are capable of utilizing full sun with minimal photoinhibition at high irradiance levels.

Although macrophyte productivity varies with seasonal changes in temperature and irradiance within natural environments, the efficiency of photosynthetic carbon fixation and respiration/photorespiration vary markedly with light and temperature. For example, the overall photosynthetic efficiency of an emergent rush, *Juncus*, determined over a wide range of *in situ* irradiance and temperature levels, was 1.43 ± 0.03% (± SE, $n = 3974$) (Mann and Wetzel, 1999). Average photosynthetic efficiency was highest (4.5%) at the lowest irradiance and decreased with increasing irradiance levels (Fig. 18-6). Light saturation occurred at relatively low light levels (ca. 750 μmol quanta m^{-2} s^{-1}) and efficiency of light utilization decreased to about 0.5% at full sunlight without any apparent photoinhibition. The optimal temperature range for maximum average net photosynthesis was between 35 to 40°C for this species, but the photosynthetic efficiency decreased markedly at the higher temperatures (Fig. 18-6) as rates of respiration and photorespiration increased. Similar temperature optima have been found with other emergent and freely floating plant species (e.g., Wedge and Burris, 1982; Sale and Orr, 1987). Distinct photoinhibition by normal midsummer insolation has been found, however, among littoral bryophytes, such as *Sphagnum* mosses (Murray *et al.*, 1993). Transpirational cooling of the leaves and vertical orientation can reduce the temperature of the leaves several degrees below ambient temperature and improve efficiencies of photosynthesis (e.g., Pearcy *et al.*, 1974).

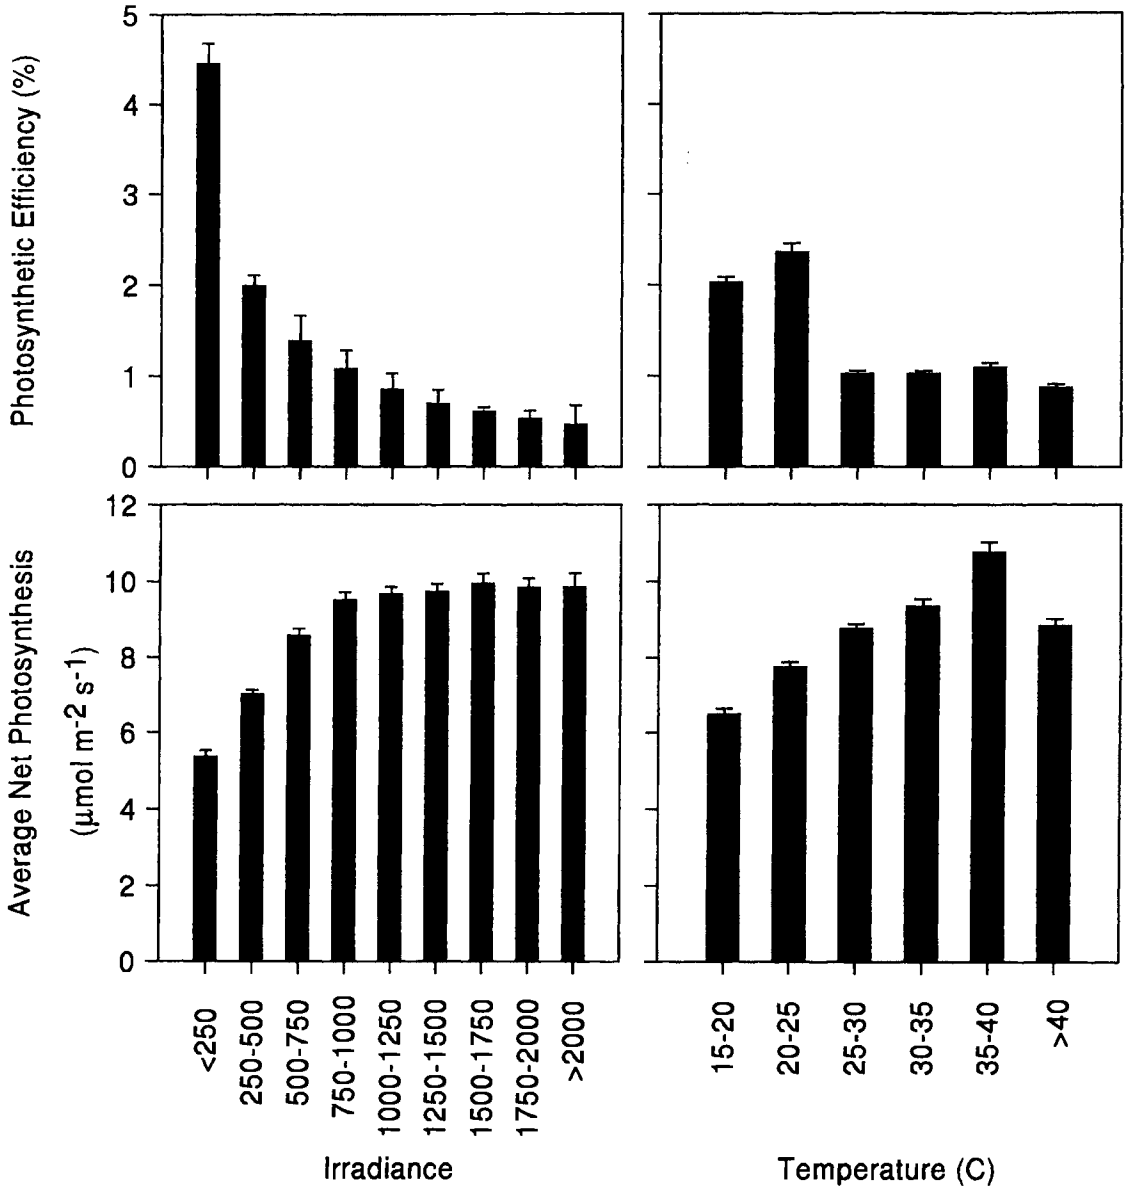

FIGURE 18-6 Average *in situ* net photosynthesis (± SE) and apparent photosynthetic efficiency (± SE) of the emergent aquatic plant *Juncus effusus* over a range of irradiance and temperature. (From Mann and Wetzel, 1999.)

All submersed species of higher aquatic plants are physiologically shade plants where photosynthesis is saturated by a fraction of full sun irradiance. Light saturation for leaf photosynthesis of submersed plants ranges from 10 to 50% of full sunlight (ca. 2000 μmol quanta m^{-2} s^{-1}) (Spencer and Bowes, 1990). The inhibitory effects of high light intensities in the surface waters, commonly observed among planktonic algae, are not generally observed among submersed macrophytes. Results from the few studies on *in situ* rates of photosynthesis in relation to light indicate a tendency toward increased photosynthesis at 1–2 m below the surface on bright, clear days, where surface light intensities are reduced from 25 to 50 percent. On the other hand, exposure of some submergents to extremely high light intensities (>1500 μmol quanta m^{-2} s^{-1}) did not significantly alter rates of photosynthesis; other species are clearly adapted to growth at low light levels as low as 20 μmol quanta m^{-2} s^{-1} or less (Gessner, 1955; Bowes *et al.*, 1977; Barko *et al.*, 1982; Wetzel *et al.*, 1984; Sand-Jensen and Madsen, 1991; Blanch *et al.*, 1998).

Many submersed macrophytes exhibit distinct morphological variations in relation to light intensity. Shade-adapted leaves are finely divided, whereas on the same plant growing at higher light intensities (shal-

lower depths) leaves can be larger and much more lobate. Photosynthetic rates can be significantly higher near the surface in cases where overlying foliage of dense populations shades the lower leaves. Shade-adapted plants have also been shown to be sensitive to ultraviolet light, which is rapidly removed below the first meter of water, whereas photosynthetic rates of plants adapted to high light intensities were unaffected by ultraviolet light that is found in surface layers of water.

Gessner (1955) attempted to clarify the many physiological reactions of submersed macrophytes to light by grouping the plants into adaptation types either genetically fixed or phenotypically plastic. (a) A strictly shade-adapted form, such as the fenestrated tropical *Aponogeton*, is physiologically active only at low light intensities. (b) Numerous submergents are strictly light-adapted and require high light intensities for optimal metabolism. (c) Some submersed macrophytes exhibit a broad adaptation to light intensities, including some (d) that adapt to light or shade conditions depending on the area of development, (e) others that are generally tolerant of high light but develop best in weak light, and (f) still others that are shade-adapted but photosynthesize optimally at intermediate littoral light intensities. While such a scheme does not explain the physiological and morphological bases underlying such adaptations, it does demonstrate the extreme plasticity and adaptability of submersed macrophytes to the highly variable underwater light conditions.

Some insight into the mechanisms of photosynthetic adaptation of submersed macrophytes has been gained by the investigations of Spence and Chrystal (1970a) on two species of *Potamogeton*. The rates of net oxygen production at various irradiances, dark respiratory oxygen uptake, chlorophyll content, specific leaf area (cm^2 leaf area per mg leaf dry weight), and leaf thickness were measured for a shallowwater, "sun-adapted" species (*P. polygonifolius*) and a deepwater, "shade-adapted" species (*P. obtusifolius*). From estimates of relative rates of photosynthesis and respiration per leaf area and per pigment content of the species, and sun and shade leaves of each species, it was concluded that (a) surface leaf area increases and respiration and leaf thickness decrease with depth and with light reduction, and (b) higher net photosynthetic capacity per unit area of shade-adapted leaves and shade species of *Potamogeton* at low irradiances (approximately 1% of summer daylight) is achieved by lowered respiration per area. The latter may result from a reduction in leaf weight per unit area. Potential complications introduced by photorespiration, discussed earlier, were not considered in these studies.

Other studies on the photosynthetic capacities and compensation points of submersed plants growing at low light intensities indicate marked variability. Compensation points commonly occur at 1–3% of full sunlight (Wilkinson, 1963; Spence, 1976, 1982; Bowes *et al.*, 1977; Agami *et al.*, 1980; Moeller, 1980). However, considerable metabolic adaptation is found. For example, in an oligotrophic Danish lake, *Littorella* occurred between 0 and 2 m, and *Isoëtes* grew at between 2- and 4.5-m depths (Sand-Jensen, 1978). Light-saturated photosynthesis of *Littorella* was higher than that of *Isoëtes*, and the difference increased with rising temperatures within the range of 5–20°C. At low irradiance, photosynthetic rates of *Isoëtes* were similar to those of *Littorella*, despite greater chlorophyll content per unit biomass in *Isoëtes*. Respiration rates were lower in *Isoëtes* than in *Littorella*.

Two other common competing submersed angiosperms, *Myriophyllum spicatum* and *Vallisneria americana*, exhibit different growth forms; most of the biomass of *Myriophyllum* is near the water surface, whereas most of the leaf biomass of *Vallisneria* is near the sediment (Titus and Adams, 1979). *Vallisneria* was shade-adapted, and photosynthetic fixation rates were much more efficient than those of *Myriophyllum* at low light intensities. Optimum temperatures for photosynthesis (33°C) were nearly identical for the two species, but at 10°C, the photosynthetic rates of *Myriophyllum* were nearly twice those of *Vallisneria*. Similar light and temperature interactions have been found among several other submersed angiosperms (Barko and Smart, 1981).

The heat capacity of water buffers the water temperatures to which submersed plants are exposed, usually within a range of ca. 2–40°C. Active growth can occur at low temperatures near zero, including under ice cover, although growth is slow and near maintenance levels (e.g., Hough and Wetzel, 1975; Boylen and Sheldon, 1976; Spencer and Wetzel, 1993). Net photosynthetic rates of submersed plants under ice are 50% greater than those of summer-grown plants measured at similar low temperatures. For example, optimum temperatures for net photosynthesis of winter-adapted plants of the submersed nonrooted *Ceratophyllum* that remained physiologically active under ice were 5°C and for summer-adapted plants 30°C. Dark respiration rates of winter plants were many times greater (to >300%) than those of summer plants, which contributed to reduced net photosynthesis.

Temperature optima among summer-adapted submersed macrophytes are in the range of 25–37°C (Spencer and Bowes, 1990). Photosynthesis-to-respiration ratios decline with increasing temperatures, particularly above 20°C, although significant species variations occur (Barko and Smart, 1981). Some prolific,

invasive, and highly competitive species, such as *Hydrilla*, have a greater capacity for growth at higher temperatures than most other submersed species.

The metalimnion of stratified lakes varies in depth and thickness but commonly in small lakes begins at a depth of 3–4 m and extends to 6–8 m. Water temperatures at the depths of the lower metalimnion and upper hypolimnion are commonly in the range of 5–12°C throughout the year in the temperate zone (e.g., Dale, 1986). As a result, if light adequate to support net photosynthesis of submersed macrophytes reaches these depths, as it does in many lakes of low-to-modest productivity, the cold temperatures suppress maximum rates of photosynthesis and limit the maximum depth distribution of aquatic macrophytes.

Any additional factors that influence attenuation of light under water can influence the growth, survival, and distribution of submersed vegetation. Floating macrophytes can form dense surface canopies that severely shade underlying submersed vegetation (e.g., Janes *et al.*, 1996). Growth of epiphytic microorganisms on the surfaces of submersed macrophytes can severely shade and even kill the macrophytes (e.g., Sand-Jensen, 1990), a subject discussed at length in the ensuing chapter (Chap. 19).

B. Hydrostatic Pressure

Normal growth can be abruptly inhibited when certain submersed angiosperms are exposed to moderate increases in hydrostatic pressure (Fig. 18-7). Leaves become shorter, stems are much thinner and possess greatly reduced lacunal intercellular spaces, and growth of adventitious roots is inhibited (Ferling, 1957; Gessner, 1961; Hutchinson, 1975). Increased pressure of as little as 0.5 atm above air pressure at the surface of the lake, equivalent to about 5-m depth, also induces increased growth of internodes, similar to the effects of low light intensities. Increased pressure also can inhibit flower formation; most submersed angiosperms produce aerial flowers that are wind or insect pollinated.

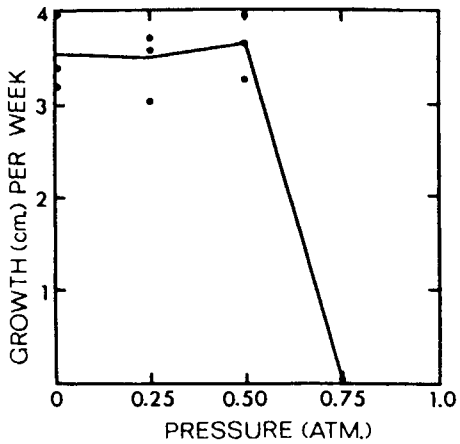

FIGURE 18-7 Average growth (cm) per week of *Hippurus* in relation to hydrostatic pressure. (Modified from Gessner, 1955.)

Growth inhibition is not usually proportional to pressure, and many species exhibit an irreversible "all-or-none" effect at an increase of about 1 atm of hydrostatic pressure above surface atmospheric pressure (approximately 10-m depth equivalency). Little can be said about the physiological effects of increased pressure. One effect is the inhibition of movement of intercellular gases to the root system. Short-term effects include increased secretion of soluble organic matter by excessive hydrostatic pressure. Such increased cellular permeability may lead to losses of nutrients and hormonal growth substances. Golubić (1963) demonstrated in a very clear, transparent lake that a hydrostatic pressure of 0.8 atm limited photosynthesis of submersed angiosperms. The macroalgae *Chara* and *Nitella*, lacking intercellular gas systems, are unaffected by pressure differences.

Growth inhibition by hydrostatic pressure is apparently not universal among all submersed angiosperms. For example, marine angiosperms grow commonly at depths of several atmospheres of hydrostatic pressure in clear waters, and rates of photosynthesis are unaffected in these plants by pressure changes (Payne, Beer, Wetzel, and Iverson, unpublished). Pressure effects (to 2.3 atm, corresponding to a depth of 13.3 m) on growth of the freshwater angiosperm *Hippuris* could be overcome by warm temperatures (>15°C) and high light intensities (>100 μmol quanta m^{-2} s^{-1}; Bodkin *et al.*, 1980). The physiological ramifications of various pressures remain obscure, but it is likely that hydrostatic pressure interacts, if at all, with other parameters, especially light, to restrict the distribution of freshwater angiosperms to depths of less than 10 m.[3] Shoots of *Myriophyllum spicatum* and other species are not affected by increased hydrostatic pressure (Dale, 1981, 1984; Payne 1982). Payne (1982) demonstrated that a lacunar arch system in stems of *Myriophyllum* expands the lacunae against external pressure by increasing cellular turgor pressure.

[3] *Potamogeton strictus* has been reported to a depth of 11 m in Lake Titicaca, Peru–Bolivia (Hutchinson, 1975). However, at an altitude of 3815 m, pressure at 11 m would be equivalent to a depth of 7.5 m in a lake at sea level. *Elodea canadensis* has been reported at a depth of 12 m in Lake George, New York (elevation approximately 100 m) (Sheldon and Boylen, 1977), although the range of this species in this lake is predominantly between 1 and 7 m.

Older stems and roots were weaker and were limited by low hydrostatic pressures.

C. Senescence

Most aquatic plant species grow more or less continuously, with losses of members of the population or parts of the same plant through senescence and death. A majority of aquatic plants grow perennially, with a constant turnover of population members that are senescing as new cohorts are emerging and growing. Some submersed plants grow actively at the apical tip and lower leaves senesce and slough off of the stem or petiole.

Although cell death is programmed genetically, the control agents and mechanisms for suppression homologs among aquatic plants are essentially unknown. Clearly, restricted light availability is involved in senescence induction along spatial dimensions in lakes (e.g., Rorslett, 1985) but the physiological mechanisms are unclear. During senescence, chlorophyll loss accelerates along with proteolysis and lipid oxidation, and carboxylation enzyme activities decrease (Jana and Choudhuri, 1982; Philosoph-Hadas *et al.*, 1994). Production of ethylene increases during senescence, which can enhance certain senescence-associated processes. Cell membrane integrity collapses during senescence with major losses of soluble cellular constituents. This released dissolved organic matter, including important organic nitrogen and phosphorus compounds, can be readily assimilated by attached microbial communities (Chap. 19).

V. PRIMARY PRODUCTIVITY OF MACROPHYTES

A. Changes in Biomass and Cohort Structure and Their Dynamics

Macrophyte productivity is most commonly evaluated by measuring changes in biomass (Westlake, 1965b). The initial biomass of seeds of annual macrophytes is negligible. The biomass of macrophytes typically increases in a sigmoid fashion during the growing season (Fig. 18-8). In this idealized example, gross productivity reaches a plateau and later declines in older tissues; net productivity decreases and becomes negative because respiration continues to increase. Maximum biomass, the maximum cumulative net production, is reached when the current daily net productivity becomes zero. Subsequently, both the biomass and cumulative net production decrease, and terminal net production is equal to the quantity of material that has not been respired by the time the whole plant is dead. Although numerous variations are found among natural populations, this general pattern of growth and metabolism prevails among *annual* (growth beginning from germinating seeds) macrophyte species in temperate and subtropical communities.

If the initial biomass (e.g., seeds of an annual plant) is negligible, or if the plant dies before the seasonal maximum is reached, and losses other than respiration are negligible, as is commonly the case, the seasonal maximum biomass is equal to the maximum annual net

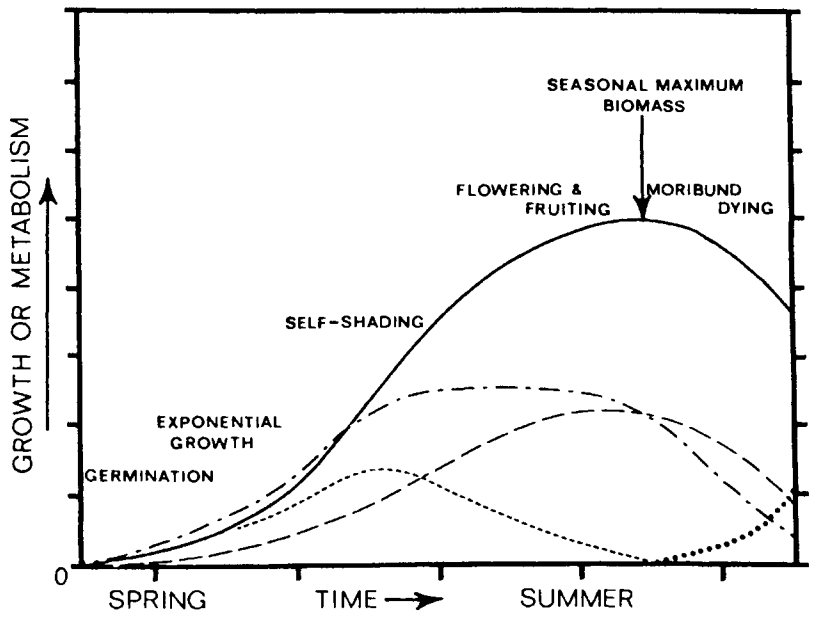

FIGURE 18-8 Generalized growth and metabolic patterns for a typical annual aquatic macrophyte. —— = total biomass;- - - - - - = current gross productivity; - - - - - = current net productivity; — — — = current respiration rate; ..... = death losses. (After Westlake, 1965b.)

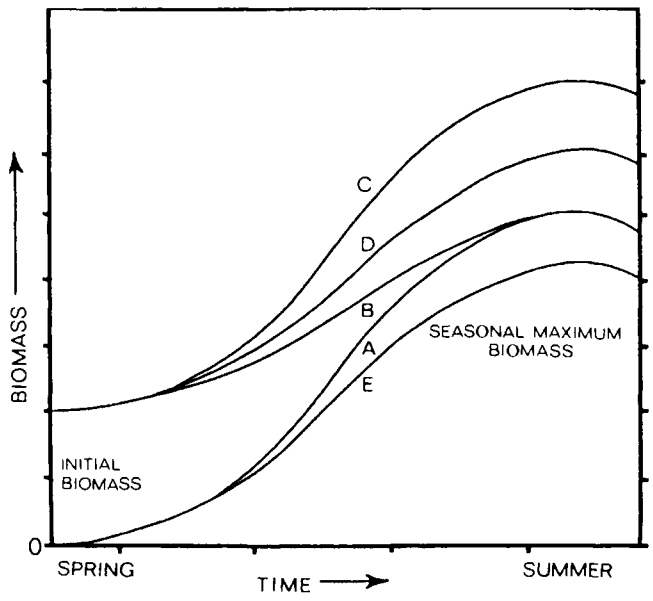

FIGURE 18-9 Types of growth curves among aquatic macrophytes. (*a*) True annual or a plant with manifest annual regrowth; (*b*) plant with obscured annual regrowth; (*c*) plant with spring biomass persisting until seasonal maximum; (*d*) plant with only part of spring biomass persisting until seasonal maximum; (*e*) plant with annual regrowth and losses from current year's biomass before seasonal maximum. (After Westlake, 1965b.)

production (Fig. 18-9, curves A and B) (Westlake, 1965b). This annual regrowth is characteristic of many plants that die down to a small quantity of perennating organs, but the extent of regrowth becomes less obvious when much of the plant survives until the next spring growing season. If the initial biomass persists without appreciable losses until after the seasonal maximum, the annual net production may be obtained as the difference between the final and initial biomass values for curve C (Fig. 18-9).

Most wetland and aquatic macrophytes are herbaceous perennials with massive carryover of perennating rooting tissues from one cohort of emergent foliage to the next. Most commonly, a variable proportion of the initial biomass is lost with senescence and decay (curve D). The maximum seasonal biomass in the latter case, as seen, for example, in populations of the macroalga *Chara*, is commonly only a few and highly variable percent (10–80%) of the annual net production. When losses of the current season's production are appreciable, the estimation of production from changes in biomass is complicated (Fig. 18-9, curve E), and can only be evaluated by detailed analyses of changes in the population demographics and biomass. Plant biomass remains more or less constant in extreme cases, such as in subtemperate and tropical communities, despite continuous growth. Very large amounts (50–90%) of the annual productivity would be missed by analyzing only maximum biomass at any given time.

Cohorts of a species population are constantly growing, senescing, and decaying back and being replaced simultaneously by new cohorts. In populations with a high plant mortality (e.g., in some reedswamp-emergent macrophytes or among populations with a high turnover of leaves) (Westlake, 1966; Bernard and Solsky, 1977; Dickerman and Wetzel, 1985; Dickerman *et al.*, 1986; Tsuchiya *et al.*, 1993; Wetzel and Howe, 1999), much of the production does not survive to be measured as terminal maximum biomass of the population. It is extraordinarily difficult to measure the productivity of these constantly emerging cohorts of new populations and to evaluate the losses occurring with senescing cohorts of shoots and roots in order to evaluate the composite population productivity. For example, continuous changes in the population dynamics, above- and belowground biomass, growth rates, and production of the emergent rush *Juncus effusus* were evaluated over an annual period in a subtemperate riparian littoral area (Wetzel and Howe, 1999). Shoots emerged continuously at all times of the year, and the number of ramets (shoots) increased four times from summer to winter (12,000 to >30,000 shoots m^{-2}) (Fig. 18-10). Individual culms (leaves) in November–December, however, were generally smaller (41–52%) than those in summer. Maximum growth of individual new culms ranged from a maximum of 6.4 mg day^{-1} in June (40–50 days to maximum biomass) to 1.1 mg day^{-1} in November (70–110 days to maximum biomass in winter). Continuous recruitment and gradual culm senescence resulted in numerous multiple cohorts on an annual basis. Annual root production was about 42% of shoot production. Average annual production estimates of combined above- and belowground components of this ubiquitous emergent species were nearly 10-g ash-free dry mass m^{-2} per year (Table 18-4). The extremely high production rates of this species result from the continuous growth, while simultaneously shoot densities changed seasonally as the inverse of biomass. These processes maximized photosynthetic carbon fixation under the mild climatic conditions of the winter and spring seasons. This dynamic growth strategy is likely common among herbaceous perennial emergent aquatic plants in mild climate regions.

These studies indicate the major importance of evaluating what percentage of total production is allocated to belowground tissues. For example, in the common sedge *Carex rostrata*, 88% of the total annual production was allocated to belowground tissues (Saarinen, 1996). Among total plant production allocated to rhizomes, coarse roots, and fine roots, 79% was directed to fine-root production (cf. Table 18-8).

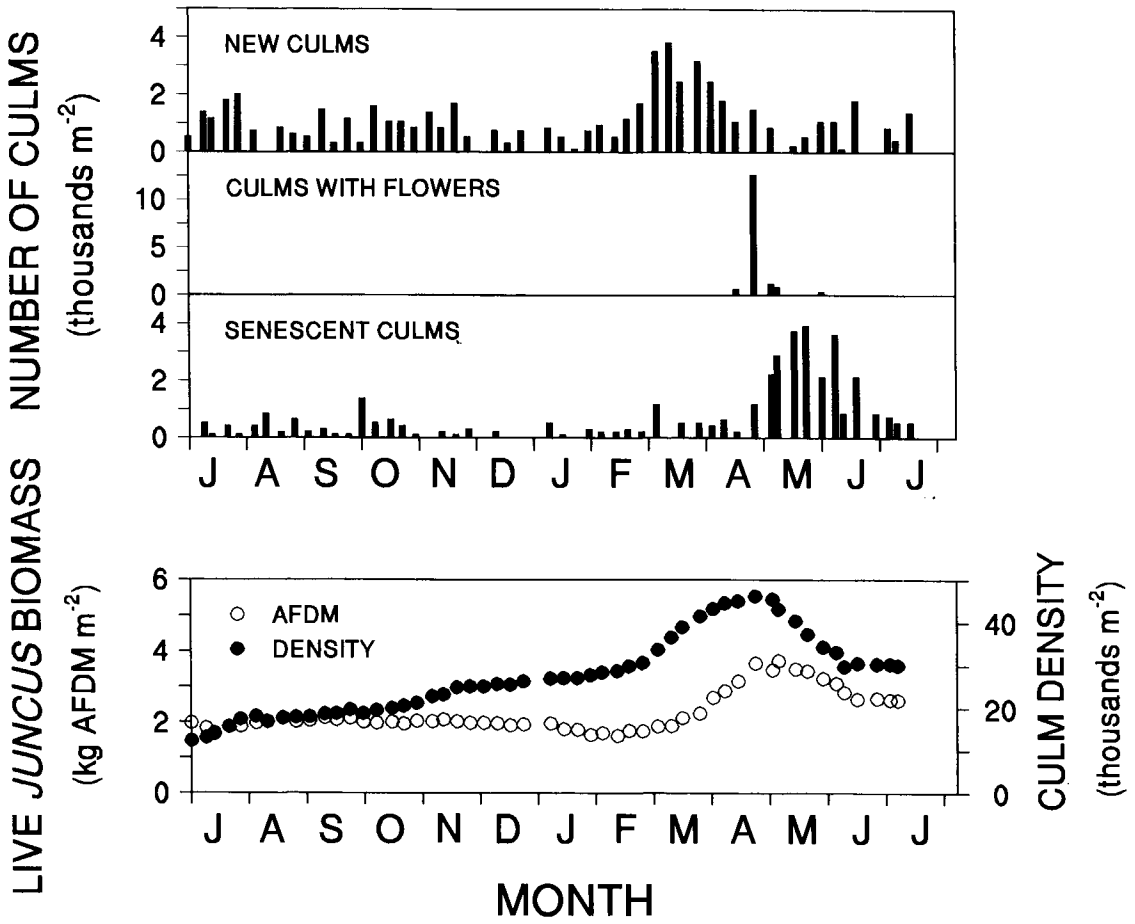

FIGURE 18-10 Example of number of new photosynthetically active culms, culms with flowers, and senescent culms of *Juncus effusus* formed each week per square meter over an annual period (*upper*) and total culm density (thousands m^{-2}) and biomass of photosynthetically active plants (kg AFDM m^{-2}) in Talladega Wetland Ecosystem, Alabama (*lower*). (Extracted from Wetzel and Howe, 1999.)

In more temperate regions with shorter growing seasons, the same multiple cohort strategy occurs among these plants but with reduced cohort turnover numbers. In a cattail (*Typha latifolia*) population in southern Michigan, 19% of the shoots had completely senesced prior to maximum aboveground biomass, and 95% of these "prematurely" senesced shoots had entirely disappeared from the population before the maximum biomass occurred (Fig. 18-11) (Dickerman and Wetzel, 1985). Other significant biomass losses resulted from high leaf turnover. On the average, 50 percent of the total number of leaves produced by a cattail shoot

[a] From Wetzel and Howe (1999).

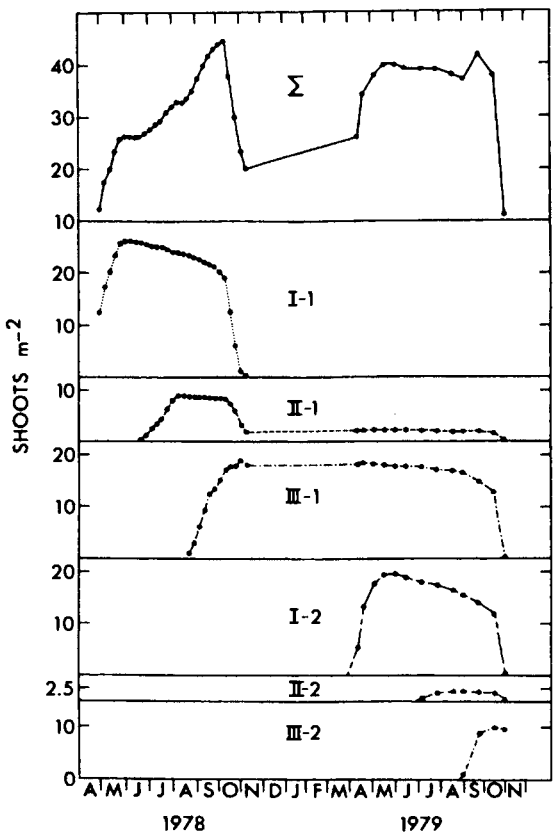

FIGURE 18-11 Shoot density of the composite population (Σ) and individual cohorts (roman numerals) during the first (1) and second (2) years of analysis of the common cattail (*Typha latifolia*), Lawrence Lake, Michigan. (After Dickerman and Wetzel, 1985.)

had undergone senescence and abscission by the time maximum aboveground biomass had been attained. As a result, the composite population experiences continual senescence after the first cohort reaches maturity and starts to decline. Further, early shoot mortality can also account for a significant loss of population biomass.

Emergence of cohorts throughout the growing season (Fig. 18-11) frequently more than offsets shoot mortality; a constant or increasing shoot density may help exclude potential competitor species. Density decreases with increasing accumulations of litter, increases when the area is flooded by rising water levels and increased inorganic nutrients, and decreases with grazing of buds and moderate increases in salinity (Rudescu *et al.*, 1965; Björk, 1967; Haslam, 1971a; Rodewald-Rudescu, 1974). High light, warmer temperatures, and higher water levels promote growth in dense, monospecific stands. Among mixed stands of emergents, the final balance of dominance is determined by a combination of (a) physical factors and inherent properties of the plants, such as soil and water régime, growth form, size, and abundance of sexual and vegetative organs, (b) physiological characteristics of the species, such as shade tolerance, requirements for germination and establishment, survival in relation to temperature, water availability, and litter cover, and (c) physical events, such as opening of the litter mats, grazing, and diseases (Haslam, 1971b, 1973).

Floating-leaved rooted macrophytes, particularly the water lilies, also exhibit numerous cohorts on an annual basis in which new cohorts are emerging and senescing rapidly, with an average turnover rate of aboveground foliage of 4–8 times a year (Table 18-5). Leaf longevity averages about 30 days and increases to about 50 days during cooler seasons. Senescence and sinking of leaves are essentially continuous throughout the growing season and, for example, averaged an annual loss rate of 5.2 leaves m^{-2} day^{-1} in a wetland pond at a latitude of 33°N (Carter *et al.*, 2000). True aboveground production rates require summation of the cohort production rates. That integration yields annual values nearly an order of magnitude higher than would be obtained from aerial instantaneous biomass estimates during the growing season (Table 18-5).

Similar situations have been found among most submersed macrophytes that have been examined in detail (Borutskii, 1950; Rich *et al.*, 1971; Best and Dassen, 1987). In the nonrooted submersed *Ceratophyllum demersum*, for example, production was over three times higher than that estimated from the difference between seasonal maximum and minimum biomass. Demographic methods developed for analyses of fish benthic invertebrate populations subject to high mortality have been applied successfully to dense macrophyte populations, in which, for example among *Glyceria* and *Typha* populations, net production was some 3–4 times greater than seasonal maximum biomass (Mathews and Westlake, 1969; Wetzel and Pickard, 1996; cf. Dickerman *et al.*, 1986).

B. Disease, Herbivory, and Other Mortality of Aquatic Plants

Pathogenic decimation of entire macrophyte populations is rare; natural diseases usually only cause gaps in existing populations, which result in a more heterogeneous distribution of individuals (see, e.g., Klötzli, 1971; cf. Zettler and Freeman, 1972; Freeman, 1977). Losses of plant biomass from damage from water movement is generally not severe in lakes and ponds, but can be a major mortality loss factor in streams and rivers. The few macrophytes growing in running waters are well adapted to moderate to even torrential river flows (cf. Gessner, 1955; Haslam, 1978). Many macrophyte fragments and seeds can be moved downstream

TABLE 18-5 Aboveground Production and Turnover Rates of Rooted Floating-Leaved Macrophytes from Various Sources

Floating-leaved macrophyte	*Location*	*Habitat*	*Biomass*[a]	*Annual production*[a]	*Turnover rate* (yr^{-1})	*Leaf longevity (days)*	*Reference*
Nymphaea tetragona	Japan	Pond	133–173.2 g DM m^{-2} (leaf and petiole)	515–559 g DM m^{-2}	6.7	31	Kunii and Aramaki (1992)

[a] AFDM = ash-free dry mass; DM = dry mass.

during normal and spate river flows (Sand-Jensen *et al.*, 1999). The drifting shoots in particular can become caught on projections and serve as a means of recruitment and expansion of new colonies. Marginal bank and floodplain vegetation, however, can be vulnerable to strong spates and flood conditions, and large quantities of particulate organic matter is often moved downstream and heterogeneously distributed within the river channels as well as laterally on the flood plain (e.g., Furch and Junk, 1997). Most of the subsequent decomposition of the plant organic matter is microbial, particularly after the flood waters recede and conditions shift back to semiterrestrial phases.

Herbivory of aquatic plants is very poorly studied. Losses from grazing before the seasonal maximum biomass are generally considered small among temperate annual macrophytes (Westlake, 1965b; Sculthorpe, 1967). Although many animals, especially immature insects, eat live aquatic macrophytes, few cause extensive damage (see especially the extensive review of Gaevskaya, 1966). Although the percentage loss by animal ingestion or destructive maceration is set in the range of 25% for the *aboveground instantaneous biomass* of freshwater vascular macrophytes, and somewhat higher among nonvascular macrophytes (Lodge *et al.*, 1998), the percentage of loss of *total above- and belowground production* of aquatic plants by animal herbivory is nearly always unknown and certainly is lower.

Nearly all studies examine the losses to aboveground biomass, often during episodic events (e.g., intensive feeding during bird migrations), without evaluations of the recovery of subsequent cohort production of the plants or the impacts of herbivory on an annual basis. In the few cases where this evaluation is done correctly, herbivory of the total annual net production of the aquatic plants is usually low (<5%; e.g., Carter *et al.*, 2000). As a result, many of the quantitative values in the literature are certainly overestimates of true loss of organic matter by herbivory. Nonetheless, these data place in perspective some of the relative losses than can occur by animal herbivory.

Earlier assumptions that herbivory on aquatic plants was unimportant evolved because many plant tissues are difficult to ingest and of low nutritional quality; such assumptions are not valid (cf. reviews of Lodge 1991; Newman, 1991; Lodge *et al.*, 1998). Herbivore consumption of aboveground freshwater macrophyte biomass is similar to that among terrestrial vascular plants. About 25% of aboveground tissue of freshwater macrophytes is lost on the average to all animal herbivory, and this would be reduced by at least half or more of that value when one considers that aboveground production is about half of the total production. Moreover, total aquatic plant production is often made up of multiple cohorts, some of which may not be preyed upon as severely at certain times of the year. Certainly, consumption by herbivory of aboveground biomass of freshwater vascular plants is less than that of the attached microalgae of periphyton and of macroalgae growing on submersed portions. A distinction is needs to be made consumption of organic matter production and secondary effects that partial consumption of tissues can have on the plant biology. For example, damage to internal vascular tissues may affect plant metabolism severely even though the consumption of plant tissue is low.

Herbivory of aboveground vascular plant tissues by aquatic insects and snails is low in comparison to potential losses to crayfish crustaceans (e.g., Bolser and Hay, 1998; Bolser *et al.*, 1998), herbivorous fish specialists, mammals, and aquatic birds under certain conditions. Snails and many immature aquatic insects feed largely on detritus and periphyton rather than the macrophyte tissue (e.g., Kolodziejczyk, 1984). Mammals, particularly the muskrat (*Ondatra*) and nutria (*Myocastor*) commonly impact aboveground macrophyte biomass at levels intermediate between insects and the other vertebrates, birds and specialized fish. Herbivory of the leaf surface area of submersed plants ranged from 0% to nearly 100% in a variety of different studies (Lodge, 1991) but was usually at the low portion of that range and somewhat higher in streams (ca. 5%) than in lakes (ca. 2%) for a species of *Potamogeton* (Jacobsen and Sand-Jensen, 1995). Great seasonal and interannual variability in herbivory on submersed species was found (Jacobsen and Sand-Jensen, 1994). In vast areas of wetlands and littoral areas, however, reductions of total biomass by herbivory of these animals is much lower, particularly of the most productive emergent macrophytes.

Many classes of plant compounds are known to function as plant deterrents for herbivory (Otto, 1983; Ostrofsky and Zettler, 1986; Suren and Lake, 1989; Lodge, 1991; Newman, 1991; Bolser *et al.*, 1998). Direct chemical interactions are poorly known among aquatic plants. For example, when the high nitrogen-containing leaves of watercress (*Nasturtium officinale*) are damaged by feeding by caddisfly larvae, snails, or amphipods, myrosinase-mediated hydrolysis of phenylethyl glucosinolate forms a toxic end product, phenylethyl isothiocyanate, that inhibits further herbivory (Newman *et al.*, 1992, 1996). Components of the glucosinolate–myrosinase defensive system have been shown to be induced by the ubiquitous defensive signaling molecule jasmonic acid (Farmer *et al.*, 1998). Herbivores then shift to low nitrogen-containing senescent leaf tissues that also contain much less of the toxic

compound. The freshwater orchid *Habenaria* synthesizes a defensive compound, habenariol, that is a significant deterrent against herbivory by the crayfish *Procambarus* (Wilson *et al.*, 1999). Similar mechanisms to suppress herbivory are likely common among the higher aquatic plants (Bolser *et al.*, 1998; Amudhan *et al.*, 1999). The metabolic costs of such chemical antiherbivore defenses versus potential gains in reproductive fitness are very poorly understood among freshwater aquatic plants.

Fish, birds, and a few mammals can, under exceptional circumstances, cause extensive damage or consume significant portions of the annual production of macrophytes. Some herbivorous fish, such as the grass carp (*Ctenopharyngodon idella*), can decimate submersed and floating macrophytes (e.g., Sutton, 1977; van der Zweerde, 1990). These fish have been used as a management tool to control aquatic macrophytes in semitropical and tropical fresh waters. Under natural conditions, values of grazing loss, however, usually range from about 0.5–8% of the total. Under most circumstances, most of macrophyte production is consumed by bacteria and fungi when the plants undergo senescence (see Chap. 21). Moreover, it must be recalled from an ecosystem perspective that even if the organic matter of the macrophytes is ingested, assimilation efficiencies are modest, usually much <50% in the animal digestive system, and much of the plant material is returned to the aquatic ecosystem as detrital particulate and dissolved organic matter. Most of the detrital particulate organic matter and all of the dissolved organic matter is largely metabolized subsequently by microbiota.

C. Belowground Biomass and Growth

The roots or rhizoids of submersed freshwater macrophytes generally constitute a small but significant proportion of the total plant biomass (Table 18-6). Among floating-leaved and emergent macrophytes, however, the extensive system of roots, rootstocks, and rhizomes constitutes a major, often dominating, portion of the total biomass. Not only are the respiratory demands on organic carbon and energy of the rooting tissues very high but these demands change under different growth and environmental conditions. For example, rhizome respiration rates of the reed *Phragmites* were found to be inversely related to rhizome age but directly related to temperature change seasonally (Cízková and Bauer, 1998). In another example, much greater amounts of the total aquatic plant productivity are often devoted to root growth under conditions of nutrient stress or limitation (e.g., Grace and Wetzel, 1981a). In general, allocation to root and rhizome production is lower under more reducing conditions (Day and Megonigal, 1993). Rates of decomposition of rooting tissues are similarly markedly reduced under more reducing conditions of saturated sediments.

Clearly, accurate analyses of productivity must include an evaluation of the dynamics of growth of the rooting system. Measurements of only the aboveground foliage ("standing crop," see definitions in Chap. 8) are inadequate and can be quite misleading

when evaluating true ecosystem constructs. The biomass of underground organs is difficult to measusre but can be estimated by randomized coring and quadrat excavation (Fiala *et al.*, 1968; Westlake, 1968; Fiala, 1971, 1973, 1978). A continuing problem is differentiating between living and moribund rooting tissues. Growth patterns and discrimination of annual growth among perennial root systems can be determined using a combination of tagging and growth experiments in which biomass increments of different age classes are analyzed (e.g., Ervin and Wetzel, 1998). The ratio of biomass of underground parts to above-sediment parts is relatively constant among certain species at maturity in a particular habitat (e.g., Szczepański, 1969) but usually increases markedly as the growing season progresses (e.g., Fiala, 1976, 1978; Szczepański, 1976; Granéli *et al.*, 1992; Ervin and Wetzel, 1998). Photosynthetic allocation to above- and belowground tissues can also be evaluated by *in situ* pulse labeling of photosynthetic tissue with radioactive CO_2 and determination of the allocation to above- and belowground plant parts over time (Grace and Wetzel, 1981a; cf. also Tietema, 1980).

D. Organic Chemical Composition of Aquatic Macrophytes

An extensive collation of existing data on the general organic chemical composition of aquatic macrophytes (Straškraba, 1968; Hutchinson, 1975; Muztar *et al.*, 1978a,b) provides useful information on the relative potential contribution of these plants to production and decomposition processes in aquatic ecosystems. Morphological and physiological differences among the different plant types are reflected in a higher content of water, ash, and protein and a lower content of fiber in submersed as compared to emergent macrophytes (Table 18-7). Carbohydrate and fat content is similar within the two groups. Floating-leaved macrophytes exhibit approximately intermediate composition values but contain significantly more lipids, which is reflected in somewhat higher average caloric values. The caloric values of aquatic macrophytes (Table 18-7) are approximately 20% lower than the mean for phytoplankton (approximately 6000 cal g^{-1} organic matter).

E. Comparative Macrophyte Productivity among Habitats

A comparison of productivity of any biotic group among freshwater ecosystems is difficult because of large variations in analytical and sampling techniques employed and frequency of sampling. Variability is especially great for evaluations of macrophyte productivity. Sampling of total biomass, including the rooting systems, has been done seriously only in recent years. Species distribution and production depend on an array of physical and chemical characteristics of both the water and the sediment. The result is extreme heterogeneity in distribution and productivity, both spatially and temporally. Further, results are commonly biased toward the growing season, which is often much shorter than a year. The annual time period is the only meaningful interval for quantitative comparisons of material and energy fluxes at population, community, and ecosystem levels (cf. Wetzel, 1995). Despite these difficulties, approximate comparisons of macrophyte productivity are possible (see especially Westlake, 1963, 1982; Sculthorpe, 1967; Květ, 1971). The few exemplary figures given in Table 18-8 indicate the general range of aboveground maximum annual biomass and productivity among macrophyte communities. Submersed macrophytes generally exhibit conspicuously lower productivity than plants of floating or emergent

communities. Table 18-9 attempts to summarize many data that include both the above- and belowground production rates. Clearly, production is much higher, nearly double among the emergent plants, than is indicated by the aboveground production rates alone.

Annual net primary productivity (usually only aboveground) of submersed macrophytes ranges from 5 to 10 metric tons (mt) per hectare (500–1000 g m^{-2} yr^{-1}), the lower values being more common in oligotrophic and moderately fertile waters and the higher values in fertile lakes (Table 18-10). Greater macrophyte productivity occurs among submersed communities in subtropical regions, from 10 to as high as 60 mt ha^{-1} yr^{-1} in the marine *Thalassia* community of Puerto Rico. Few accurate data are available for productivities of floating or floating-leaved macrophytes, although it is apparent that this community reaches levels of 11–33 mt ha^{-1} yr^{-1} in warmer climates and can easily achieve greater productivity under tropical conditions (Westlake, 1963).

Numerous investigations of the productivity of emergent macrophytes of fertile reedswamps and marshes indicate very high values, even though the range is quite large. Temperate-zone emergents can attain productivity levels of 20–45 mt ha^{-1} yr^{-1} and, in subtropical and tropical regions, can reach 40 to at least 90 mt ha^{-1} yr^{-1}. Inspection of the annual net productivity of the plant communities (Tables 18-9 and 18-10) shows that the emergent reed communities are as productive as terrestrial communities. Under fertile conditions with a continuous growing season, emergent aquatic macrophyte communities can be more productive than terrestrial communities. In the temperate zones, the organic productivity of emergent communities is comparable to that of perennial agricultural crops and coniferous forests and appreciably greater than that of deciduous forests. In tropical zones, emergent communities are among the most productive of all plant communities.

By comparison, the submersed macrophytes, with the possible exception of tropical marine angiosperms, are relatively unproductive and are only slightly above the composite areal productivity of the least productive component, the phytoplankton. In spite of the number

of adaptations to aqueous conditions found among submersed macrophytes, the severe reductions in rates of diffusion and spectrally selective attenuation of light by the water preclude intensive productivity. In certain respects, the submersed habitat is less severe than the terrestrial (e.g., in terms of water availability and thermal stability). These ameliorated parameters permit some growth of perennial populations of submersed macrophytes to continue all year (Rich *et al.*, 1971; Hough and Wetzel, 1975; Boylen and Sheldon, 1976; Stickey *et al.*, 1978). However, these advantages are not sufficient to offset the strictures of being totally submersed (Table 18-11).

It should be emphasized in comparative analyses of productivity of macrophyte communities, as done briefly here (Table 18-11) and by others (e.g., Keefe, 1972), that geographically diverse ecosystems are not fully distinguished. The importance of geographic and genetic differences within a species may be reflected in their productivity and other growth characteristics, which vary in a given environment from population to population as well as among populations from one environment to another. These multidimensional variations among ecotypes of the same species are well characterized in detailed studies of *Typha* populations in which phenotypic adaptations to numerous environmental parameters, especially temperature, photoperiod, light availability, and nutrients, are seen reflected in marked differences in productivity (McNaughton, 1966b, 1970; Grace and Wetzel, 1981a–c, 1982a,b).

F. Productivity and Competition among Aquatic Macrophytes within Habitats

Competition with plant communities of a particular habitat can occur by indirect, exploitative competition for resources, such as light or nutrients, or direct interference among competing individuals (Tilman, 1988). The latter interference usually occurs from allelochemical interactions and suppression. Rarely have both exploitative and interference competition been studied simultaneously among aquatic plants. The literature on the qualitative phytosociological composition of aquatic macrophyte communities is prodigious (e.g., Hejný, 1960; Hutchinson, 1975). Although these analyses of changes in dominance yield much information on

TABLE 18-11 Comparative Characteristics of Larger Aquatic Plant Communities among River, Reservoir, and Natural Lake Ecosystems[a]

Characteristic	*Rivers*	*Reservoirs*	*Natural lakes*
Littoral zone/wetland	Major land–water floodplain interface of rivers, particularly lowland rivers of low gradient	Irregular and limited by severe water level fluctuations	Major land–water interface component of most lakes, particularly the dominant small and shallow lakes
Macrophyte community structure	Dominated by wetland macrophytes of flood plains and temporary islands of braided river channels and floating and emergent plants of large rivers; submersed macrophytes generally limited to specialized forms and to backwater areas	Wetland macrophytes often limited to riverine portions of reservoir; submersed macrophytes often limited to shallow embayments; massive development of floating macrophytes common under eutrophic conditions	A three-community gradient from emergent to floating-leaved but rooted to submersed macrophytes is common in littoral areas; macro- and microalgae often occur in the littoriprofundal zone below the lower submersed plant zone
Nutrient acquisition	Largely by rooting tissues in wetland and littoral areas; some nutrient acquisition from water by in-stream macrophytes	Mostly from sediments by rooting tissues	Nearly all from sediment if rooted; in competition with epiphytic periphyton from the water
Light acquisition	Low and restrictive in low-order streams in forested regions and by turbidity in large-order rivers	Commonly restricted to shallow areas by high and irregular turbidity	Not restricted in wetland emergent and floating-leaved macrophytes; along depth gradient among submersed macrophytes; restrictive by epiphytic periphyton and by dense phytoplankton in eutrophic lakes
Macrophyte biomass and production	High in floodplain areas; low in low-order canopied streams, increasing in mid-order (3–5) streams, and low to very low within large rivers	Low to moderate, largely in riverine wetland areas; floating-leaved macrophytes and floating islands can be very productive	High to extremely high, particularly by emergent macrophytes and some floating-leaved communities; submersed plant productivity reduced by limitations of light and gaseous exchange rates

[a] Adopted from the syntheses on rivers by Wetzel and Ward (1992) and on reservoirs and lakes by Wetzel (1990a,b).

the floristic structure of the communities, the criteria used (e.g., percentage areal cover) do not yield much insight into the causal mechanisms underlying competitive interactions.

Clonal growth is common among higher aquatic plants, and such vegetative growth is relied upon heavily for maintaining large populations. Clonal growth and other types of vegetative dispersion and expansion allow rapid, relatively complete expansion into favorable habitats. Seasonal changes in species dominance (e.g., percentage areal cover) are commonly observed among submersed, floating-leaved, and emergent communities, but a clear tendency to form extensive monospecific populations is also commonly observed.

An example of competitive interactions has been observed between two emergent reeds, *Glyceria* and *Phragmites* (Buttery *et al.*, 1965a,b). *Glyceria* grows rapidly in the spring, and and under optimal growing conditions it can completely suppress *Phragmites* by producing dense foliage that effectively shades its slower-growing competitor. When sediments are water-saturated and anaerobic, however, *Glyceria* growth is reduced and *Phragmites*, with taller and more erect foliage that absorbs more incident light, can increase effectively and eventually exclude *Glyceria*. Experimental manipulation of nutrient supply had no effect on this competitive interaction.

Two species of cattail, *Typha latifolia* and *T. angustifolia*, commonly segregate along a gradient of increasing water depth, with *T. latifolia* restricted to depths of <80 cm and *T. angustifolia* to depths >15 cm (Grace and Wetzel, 1981b,c). In these two species, habitat partitioning resulted from differences in morphology; *T. latifolia* was prevented from growing in deep water because of the higher metabolic cost of producing broader leaves but was able to outcompete *T. angustifolia* for light in shallow water owing to its greater leaf surface area. This competitive separation can persist for long periods of time (decades) in the same habitat (Grace and Wetzel, 1998).

Among submersed macrophytes of calcareous hardwater lakes, the ratio of organic matter to calcium carbonate of the sediments has been implicated in the competition between the macroalga *Chara* and rooted angiosperms (Wohlschlag, 1950). Higher organic matter content of manipulated lake plots favored the production of rooted angiosperms. Other experimental and correlational *in situ* studies indicate that, in general, growth and productivity of both submersed and emergent macrophytes increase on organic-rich sediments (Szczepańska and Szczepański, 1976; Barko and Smart, 1979; Sand-Jensen and Søndergaard, 1979b; Aiken and Picard, 1980; Grace and Wetzel, 1981a, 1982a).

The seasonal growth patterns of aquatic macrophytes can be exemplified by the common emergents *Phragmites* and *Typha*, a submersed annual *Myriophyllum*, and submersed perennial macrophytes in a hardwater lake. Many other examples exist and variations from these typical temperate zone patterns can be found. Growth and production analyses of emergent macrophyte communities are commonly based on measurements of total plant biomass, biomass of component species (or plant parts), or leaf area index. The leaf area index (LAI) is simply the ratio of leaf area per unit ground area (Květ, 1971). The reedswamp plants exemplified in Figure 18-12 demonstrate the marked differences in growth rates found among perennial emergent plant species during a summer growth season. In *Phragmites*, maximum biomass (W) occurred in midsummer, whereas the maximum biomass of *Typha*

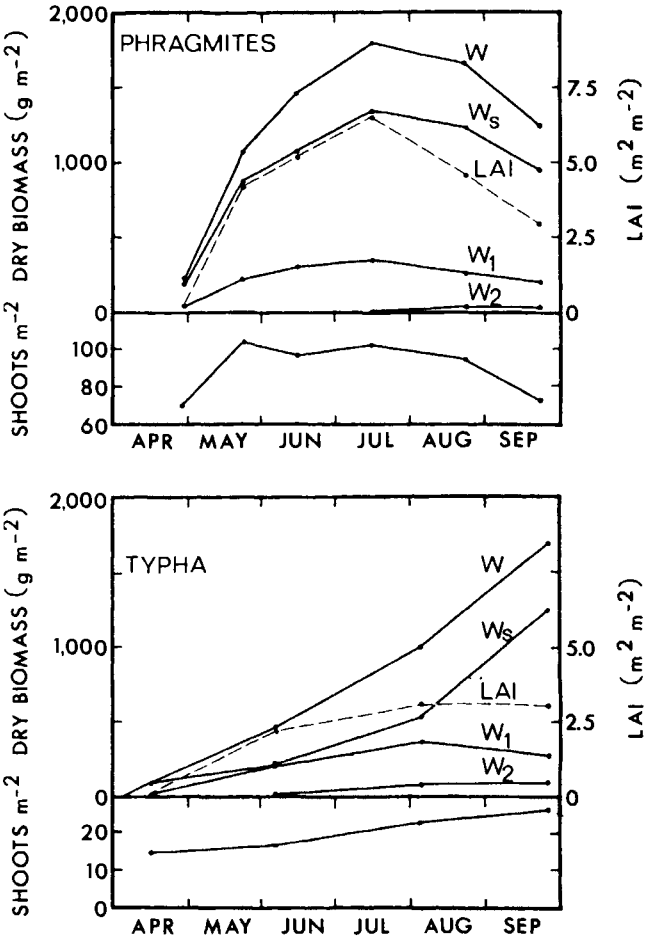

FIGURE 18-12 Changes in total plant biomass (dry, W); stem, sheaths, and stubble (W_s); leaf laminae (W_1); inflorescence (W_2); leaf area index (LAI); and the stand densities (shoot m^{-2}) of *Phragmites communis* and *Typha latifolia*, southern Czechoslovakia. (Modified from Květ, Svoboda, and Fiala, 1969.)

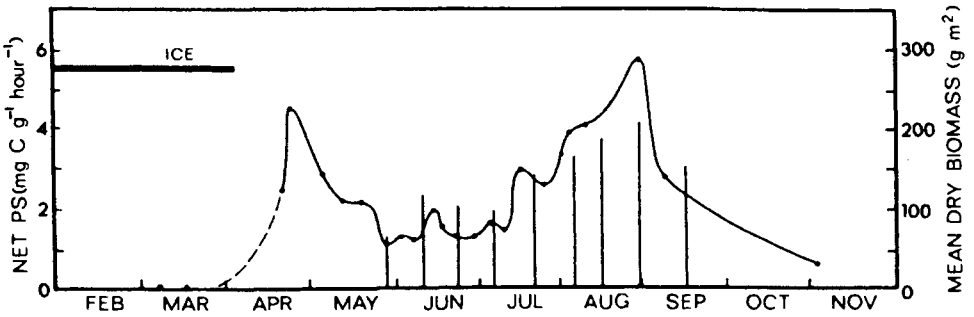

FIGURE 18-13 Rates of net photosynthesis (mg C gram dry weight^{-1} h^{-1}) of 15-cm tip sections of *Myriophyllum spicatum* (curved line) and mean ash-free organic weight (g m^{-2}) (vertical bars) in eutrophic Lake Wingra, Wisconsin, 1971. (From data of Adams and McCracken, 1974.)

increased over the entire growing season with little difference between the maximum values (1810 and 1620 g m^{-2}, respectively) for these two species. The average rate of increase in shoot biomass was 9.4 g m^{-2} day^{-1} in the cattail population and nearly 20 g m^{-2} day^{-1} in the *Phragmites* population. In both species, stem biomass (W_s) formed an increasingly greater proportion of the total (W), with a concomitant decrease in the proportion of leaf biomass (W_l). In *Phragmites*, however, both stem and leaf biomass decreased in the latter half of the growing season, whereas they continued to increase in *Typha*. It must be recalled, however, that these plant species experience constant turnover of cohorts of new shoots as well as senescence of portions of the earlier cohorts. As a result, the observed biomass maxima seasonally are generally marked underestimates of plant productivity. The leaf area index followed the changes in leaf biomass, and, coupled with changes in shoot density, it is clear that shoots of *Typha* that emerged later in the growing season had a better chance to survive in sparse stands than in the dense *Phragmites* stand. In the dense *Phragmites* stand, shorter shoots of *Typha* were handicapped by competition for light. Monodominant stands of emergent macrophytes (e.g., *Phragmites* and *Typha*) are common; invasion by other species can be resisted for long periods of time.

The seasonal succession of macrophyte communities on the flood plains of very large tropical river ecosystems is strongly coupled to the extent (water depth) and duration of seasonal flooding. A pronounced seasonal succession occurs with an alternation between aquatic and terrestrial conditions over large wetland areas of the flood plains (e.g., Prado *et al.*, 1994). On sites temporarily inundated for a period of several months, a succession occurred from purely terrestrial species to rapidly growing, short-lived annual aquatic species and perennial species that are able to tolerate periods of dryness by dormancy.

The littoral community of eutrophic Lake Wingra, Wisconsin, is dominated by the submersed annual macrophyte *Myriophyllum* (Adams and McCracken, 1974; Adams and Prentki, 1982). *In situ* measurements of photosynthetic rates demonstrated a rapidly formed spring maximum, followed by a marked summer reduction and subsequent maximum in late summer (Fig. 18-13). The spring maximum of photosynthetic rates did not coincide with the rates of biomass accumulation, a phenomenon similarly observed for the single submergent (*Ruppia maritima)* of a saline lake (Wetzel, 1964, and other studies). The biomass maxima occurred at the time of flowering in late summer (see review of *Myriophyllum* by Grace and Wetzel, 1978). A cumulative amount of organic matter approximately equal to 1.6 times the maximum biomass of *Myriophyllum* was lost by nighttime respiration and sloughing of leaves. Within the *Myriophyllum* community, most of the total biomass, leaf surface area, and photosynthetic activity occurred in the upper portion of the water column. Light reduction is definitely a major factor in the marked decrease in photosynthetic rates with depth observed by many investigators. Surface photoinhibition, so frequently found in phytoplankton photosynthesis, is seen only rarely among submersed macrophytes. Other factors, such as temperature and light reduction, greater age of tissue, and encrustations of epiphytic algae and carbonates on older leaf surfaces, contribute to lower rates of photosynthesis in deeper strata.

The importance of light to submersed macrophytes is further indicated by the depth distribution of biomass of the dominating perennial macrophyte *Scirpus subterminalis* (76% of total biomass) in oligotrophic Lawrence Lake, Michigan (Fig. 18-14). Two annual maxima are evident from two peaks at different depths. The larger fall maximum consisted of a major peak at 2 m in September, and an additional peak occurred at 4 m in midsummer when insolation was greatest. A fall

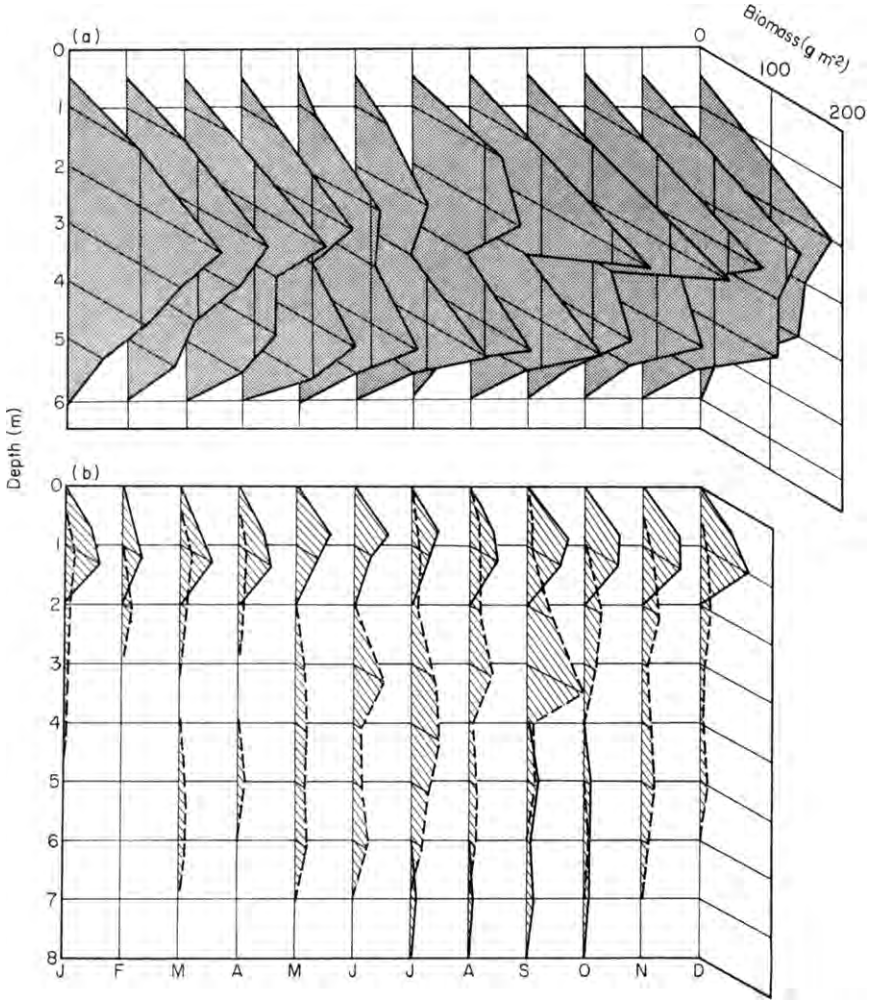

FIGURE 18-14 Annual biomass (g m^{-2} ash-free dry organic weight) depth distribution of (a) *Scirpus subterminalis*, and (b) Characeae (——) and annual macrophytes (- - - - -), Lawrence Lake, Michigan. (After Rich, P. H., Wetzel, R. G., and Thuy, N. V.: Distribution, production and role of aquatic macrophytes in a southern Michigan marl lake. *Freshwater Biol.* 1:3–21, 1971.)

maximum of the macroalgae of the Characeae (16% of total biomass) was evident even though its seasonal biomass was relatively constant; the Characeae of this lake is similarly best described as a perennial population (Figs. 18-14 and 18-15). The submersed annual macrophytes (8% of total macrophytic biomass) of Lawrence Lake were dominated by two species of *Potamogeton*. These macrophytes exhibited two maxima and died back to perenniating rooting tissues in the autumn (Figs. 18-14 and 18-15).

The relatively constant biomass of perennial macrophytes throughout the year presented in this example is probably a much more common characteristic of lakes than is generally recognized. Turnover rates (ratio of production to biomass) of emergent and submergent *annual* plants are relatively low (1.02–2 times maximum biomass on an annual basis). Among perennial populations, turnover rates are much higher (range, 1.5–8 times the maximum biomass). Even among oligotrophic lakes, the productivity of perennial populations of submersed macrophytes can approach or exceed that of the commonly more productive annual macrophytes (Table 18-12). Comparisons of the relative contribution of the macrophytes to the primary productivity of attached algae and phytoplankton of lakes will be deferred until the conclusion of the discussion of littoral microalgae (Chap. 19).

The fate of organic matter produced by aquatic macrophytes as they undergo senescence, death, and decomposition is treated separately with a discussion of the metabolic processes in sediments (cf. Chaps. 21 and 23). From the perspective of the ecosystem, the

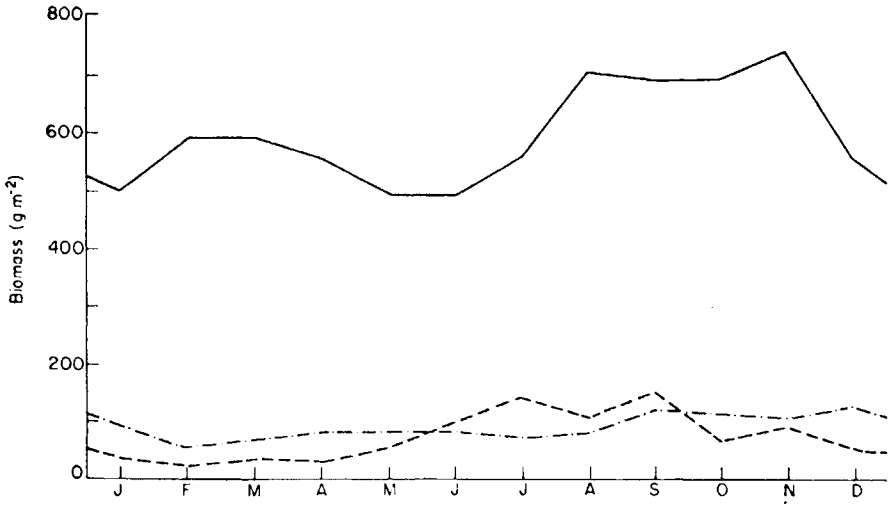

FIGURE 18-15 Annual biomass (g m^{-2} ash-free dry organic weight) of the important submersed macrophytic groups summed with respect to depth, Lawrence Lake, Michigan. —— = *Scirpus subterminalis* - - - - - = Characeae, - - - - = annuals. (After Rich, P. H., Wetzel, R. G., and Thuy, N.V.: Distribution, production and role of aquatic macrophytes in a southern Michigan marl lake. *Freshwater Biol.* 1:3–21, 1971.)

productivity of the wetland and littoral interface regions between the land and the water usually exceeds the losses by decomposition. The factors that impede the decomposition of the accumulated organic matter, such as anoxia and labile organic nutrient availability (e.g., Wetzel, 1979; Ostendorp, 1992; Xiong and Nilsson, 1997), are simultaneously those that enhance the growth of macrophytes, particularly emergent macrophytes. Particulate organic matter tends to remain in and near sites of production in the land–water interface zones. What moves and is transported is colloidal and dissolved organic matter, from which more labile, readily decomposable organic compounds are degraded by attached microbial communities on the living and detrital particulate matter (Wetzel, 1992). The more recalcitrant dissolved organic compounds pass downgradient to the open waters of the stream or lake (cf. Chap. 23).

G. Interference Competition among Aquatic Plants

Allelochemical interactions and interspecific competition occur when an organism releases a chemical compound into the environment and this compound impacts, either positively or more commonly negatively, another organism (Rice, 1987; Einhellig, 1995). Extracts from live or dead tissues of a large number of aquatic plants have been found to inhibit growth or affect in some way the development of other species of aquatic macrophytes (Schröder, 1987; Gopal and Goel, 1993; Elakovich and Wooten, 1995; Inderjit, 1996). Of the many functional groups of allelochemicals, alkaloids, fatty acids, flavonoids, phenolic compounds, quinones, and terpenoids are most common. Many of the allelochemical compounds found in nature are secondary metabolites that are released during or after decomposition of structural plant tissues. Responses in

TABLE 18-12 Comparison of Annual Primary Productivity of Submersed Macrophytes in Several Lake Systems

Lake	*g C m^{-2} (of lake) yr^{-1}*	*Remarks*
Wingra, WI	117	*Myriophyllum*; eutrophic lake (Adams and McCracken, 1974)
Lawrence, MI	87.9	Perennials; oligotrophic lake (Rich, Wetzel, and Thuy, 1971)
Narock, Russia	59.4	Largely perennial charophytes; mesotrophic lake (Winberg *et al.*, 1972)
Marion, British Columbia	50.8	Annuals; mesotrophic lake (Davies, 1970)
Kalgaard, Denmark	21.0	Perennial isoetids; oligotrophic, softwater lake (Søndergaard and Sand-Jensen, 1978)
Mirror, NH	1.4	Perennials; oligotrophic, softwater lake (Moeller, 1975)
Borax, CA	1.2	Single annual plant *Ruppia*; saline lake (Wetzel, 1964)

affected species vary markedly. For example, certain phenolic compounds inhibit seed germination, while others complex proteins and enzymes and alter nutrient uptake rates (e.g., Blum, 1993; Wetzel, 1993; Lemke *et al.*, 1995; Inderjit, 1996). Allelochemicals can impact several processes of target organisms: cell division and elongation, cell membrane permeability, respiratory metabolism, organic synthesis, and complexation with hormones or enzymes. In some cases, allelochemicals released from aquatic plant tissues exhibit autotoxicity on the same plant at certain stages of its life history. For example, organic compounds released from the emergent rush *Juncus effusus* did not affect growth of several sympatric aquatic plant species or its own seed germination (Ervin and Wetzel, 1999). *Juncus* seedling development, however, was strongly suppressed by exudates in the nearby vicinity (<0.5 m) of the clonally reproducing mother plants.

H. Inhibition of Phytoplankton, Attached Algae, and Zooplankton by Submersed Macrophytes

A number of investigations have demonstrated a distinct inhibition of phytoplankton in the littoral zones containing heavy stands of emergent and submersed macrophytes (e.g., Schreiter, 1928; Hasler and Jones, 1949; Hogetsu *et al.*, 1960; Stangenberg, 1968; Goulder, 1969; Dokulil, 1973). Circumstantially, these investigations implied that organic compounds excreted by the macrophytes inhibited the growth of phytoplankton. However, competitive reduction of nutrients, light, and other substances by the macrophytes as factors inhibiting phytoplanktonic growth was not satisfactorily ruled out in these studies.

A detailed study of the influence of four species of submersed macrophytes on phytoplankton within the stands showed that decreases in rates of phytoplankton photosynthesis were caused by shading (Brandl *et al.*, 1970). Average reductions over three years in the rates of phytoplankton production among the plant stands as compared to rates in the open water were *Potamogeton pectinatus*, 60%; *P. lucens*, 46%; *Batrachium aquatile*, 40%; and *Elodea canadensis*, 12%. Phytoplankton production was markedly reduced when the phytoplankton were taken from the pelagic zone and incubated among the macrophytes and increased greatly when littoral phytoplanktonic algae were incubated at the same depth in the open water (Table 18-13).

The presence of membrane-filterable (1.2-μm pore size) organic substances capable of inhibiting the photosynthesis of phytoplankton could not be confirmed. However, increasing the pH of the water, as occurs with a reduction in available free CO_2 in dense stands of actively photosynthesizing submersed macrophytes (Fig. 18-16), reduced the rates of phytoplankton productivity. This decrease could be reversed completely by small additions of CO_2. Brammer (1979) similarly found that the submersed macrophyte *Stratiotes* inhibited the growth of contiguous populations of phytoplankton. Competition for nutrients and reductions in the concentrations of ions in the littoral water by the macrophytes were likely responsible for the decline of the phytoplankton.

TABLE 18-13 Changes in Rates of Primary Production of Phytoplankton from the Pelagic Zone Incubated among Submerged Macrophyte Stands of the Littoral and Littoral Phytoplankton Incubated in the Pelagic Zone, Czechoslovakian Shallow Lakes[a]

Submersed macrophyte species dominating littoral area	*Percentage reduction in littoral zone*	*Percentage increase in pelagic zone*
Potamogeton pectinatus	56	250
Potamogeton lucens	46	270
Batrachium aquatile	39	230
Elodea canadensis	27	500

[a] From data of Brandl, Brandlová, and Poštolková (1970)

Dense stands of macrophytes can markedly alter other immediate environmental conditions in comparison to those of the open water. Under floating macrophytes (e.g., duckweed and hyacinths), water temperature increases, pH values decline with increased CO_2 levels, and oxygen concentrations decrease (Ultsch, 1973; Dale and Gillespie, 1976; Rai and Munshi, 1979; Schreiner, 1980). In reed *(Phragmites)* stands, conductance and calcium and bicarbonate concentra-

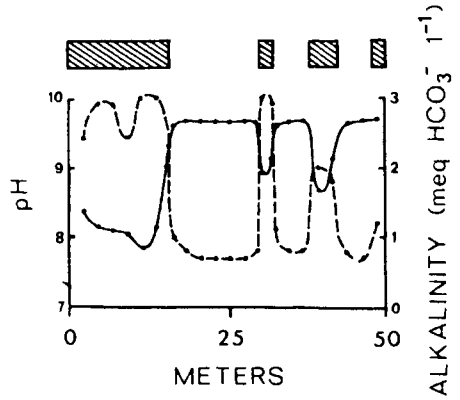

FIGURE 18-16 Changes in the pH (- - -) and alkalinity (——) in the surface water along a transect across Sangwin Pond, in the afternoon (June) through intermittent areas of dense cover of the submersed macrophyte *Ceratophyllum demersum* (indicated by hatching). (Modified from Goulder, 1969.)

tions can be higher than in the open water (Planter, 1970). In all cases, light is severely and selectively attenuated by the macrovegetation (Gessner, 1955; Dykyjová and Květ, 1978) and can result in the nearly complete removal of light and suppression of attached algal photosynthesis at the base of dense emergent macrophyte stands (Grimshaw *et al.*, 1997).

Extracts from several species of the submersed plant *Myriophyllum* were found to strongly inhibit cyanobacteria and to a lesser extent algae. Detailed chemical analyses indicated that the substances released were a number of phenolic compounds, including a potent ester, galloyl glycoside (Saito *et al.*, 1989; Gross and Sütfeld, 1994; Gross *et al.*, 1996). This polyphenolic compound, found to occur in concentrations as high as 1.5% dry weight of *Myriophyllum*, complexes with and inactivates extracellular enzymes. A large number of humic acids and other humic substances released from decaying higher aquatic plants were demonstrated similarly to noncompetitively inhibit extracellular and membrane-bound enzymes (Wetzel, 1991, 1993; Kim and Wetzel, 1993; Boavida and Wetzel, 1998). Other phenolic compounds with antialgal activity are also released from the freely floating water lettuce *Pistia* and seedlings of the water lily *Nuphar lutea* (Sütfeld, 1993; Dellagreca *et al.*, 1998). Several sulfur-releasing and related compounds (methylthio dithiolane and trithiane) occur in and are likely released by several species of the macroalgae *Chara* and the submersed angiosperm *Ceratophyllum* (Wium-Andersen, 1987). These compounds distinctly suppress microbial and insect activities.

Although much of the apparent inhibition of phytoplankton growth among dense stands of macrophytes is likely related to competition for light and nutrients, the production of biotically inhibitory or stimulatory organic substances cannot be totally excluded. For example, the presence of macrophytes favors the dominance of some cyanobacteria (Guseva and Goncharova, 1965) but is inhibitory to algal groups (Kogan and Chinnova, 1972). Macrophytes may influence the competition of cyanobacteria with algal groups by cyanobacterial heterotrophic utilization of certain excreted organic compounds. Zooplankton of many groups are inhibited strongly or repelled by substances secreted into the water by submersed angiosperms and macroalgae (much of the scattered literature is reviewed by Pennak, 1973, and Dorgelo and Koning, 1980). For example, *Daphnia* is strongly repelled by water containing *Elodea*, *Myriophyllum*, or *Nitella*. The magnitude of the negative responses varied with the plant species and was more pronounced at higher temperatures. Sexually mature *Daphnia* responded more rapidly than immature instars. The inhibitory or insecticidal effects of organic compounds secreted by macrophytes, especially the macroalgae Characeae, on mosquito larvae have been reported widely (and critically reviewed by Hutchinson, 1975). The active compounds are probably of the general allyl sulfide group, analogous to those derived enzymatically from garlic oil.

Despite the abundant evidence for intensive competition for light and nutrients among the macrophytes, attached microflora, and phytoplankton and the potential for release of organic suppressants from the larger aquatic plants, phytoplankton production can still be appreciable in nutrient-rich littoral and wetland areas (e.g., Robarts *et al.*, 1995). Clearly, phytoplankton production of shallow water bodies can constitute a significant part of the collective primary production.

I. Retention and Release of Nutrients

The surface area of wetland and littoral plants and associated detrital particulate organic matter increases greatly in the transition from emergent to submersed macrophytes. As a result, colonization of surfaces by epiphytic algae and bacteria increases along the littoral gradient from emergent to submersed macrophytes (Chap. 19). Both the macrophytes and epiphytic microflora utilize and release inorganic nutrients and dissolved organic compounds (Wetzel and Allen, 1970; Allanson, 1973; Mickle and Wetzel, 1978a,b, 1979; Wetzel, 1990, 1996). The photosynthetic productivity of epiphytic algae can be very high, often exceeding that of the submersed macrophytes (Chap. 19).

As water of the drainage basin containing inorganic nutrients and organic compounds passes through the complex vegetation and their epiphytes, marked alterations can occur in the chemical composition of the influent water. Submersed vegetation–epiphytic complexes can be extremely effective in removing such inorganic nutrients as Ca, K, combined N, and P of inflowing water, either by direct assimilation or via adsorption onto inorganic precipitates (such as $CaCO_3$) induced by photosynthetic activity (Mickle and Wetzel, 1978a). Labile organic compounds of low molecular weight (<1000 D) can be effectively removed by the epiphytic microflora. The fate of high-molecular-weight compounds (>1000–30,000 D), which dominate from terrestrial and wetland sources, is variable; they may be selectively removed or, alternately, pass through relatively unaffected, and their concentration may increase owing to release from the macrophytes themselves (Mickle and Wetzel, 1978b, 1979; Murray and Hodson, 1986; Wetzel *et al.*, 1995; Wetzel, 2000d).

During senescence of macrophytes, particularly emergent macrophytes, marked translocation of

nutrients occurs from the dying tissues. Nutrient enrichment of plants tends to accelerate translocation to rooting tissues and retention within the plants (e.g., Davis, 1991). Accompanying senescence and after the death of the macrophytes, large releases of inorganic nutrients and dissolved organic matter can occur (Chap. 21). The release rates are governed by the population growth dynamics of the macrophytes, their mortality during and following the growth period, and the conditions prevailing at the time of death and decomposition. Release rates are also influenced by the type of vegetation; decomposition and release of nutrients and organic compounds are much faster from submersed and floating-leaved macrophytes than from emergent macrophytes (Chap. 21). Some of the release is from immediate autolysis of cells during senescence in addition to simple physical leaching. For example, dissolved organic matter releases are high during early stages of decomposition, and the loss rates of elements are commonly K > Na > P > Mg > C > N > Ca > Fe among submersed and floating-leaved macrophytes (Brock, 1984; Brock *et al.*, 1985; Ochiai and Nakajima, 1994). Depending upon when these nutrients and organic compounds enter the influent water, and how their concentrations are selectively modified and reduced by the metabolic sieve of the submersed macrophyte–epiphyte complex, the inputs can have marked influence on phytoplanktonic growth in the recipient stream or lake (Chap. 15) as well as the bacterioplankton (e.g., Murray and Hodson, 1986). For example, large, decaying stands of the submersed macrophyte *Myriophyllum* in a reservoir in Indiana contributed about 2% of the annual nitrogen and perhaps 18% of the potential phosphorus loading in comparison to allochthonous loadings (Landers, 1982). It should be recalled from earlier discussions that phytoplanktonic responses may be stimulated or inhibited by the inorganic–organic loadings, since the stimulatory effects of some inorganic nutrients can be counteracted by the inhibitory effects of certain organic compounds of macrophyte origin.

The release of dissolved organic matter and nutrients tends to be greatest per unit of macrophyte biomass immediately at senescence and during the early stages (initial few hours) of decomposition (e.g., Helbing *et al.*, 1986; Howard-Williams *et al.*, 1988; Moran and Hodson, 1989; Menéndez and Forés, 1998). The efficiency of bacterial utilization of these organic and inorganic compounds by bacterioplankton is high (30 to >50%) (e.g., Findlay *et al.*, 1986b; Kairesalo *et al.*, 1992; Mann and Wetzel, 1996), but under natural conditions most of such release is utilized directly by the epiphytic microbial community attached to the surfaces of the plants and its detritus (cf. Chap. 19). The dissolved organic matter released from living macrophyte leaves was used much more efficiently than that released from senescent leaves (Mann and Wetzel, 1996), but the humic substances are nonetheless utilized with moderate efficiency (Kairesalo *et al.*, 1992; Bicudo *et al.*, 1998).

VI. SUMMARY

1. The size of the littoral zone of lakes varies greatly in relation to the size of the open-water pelagic region. Similarly, the floodplain–littoral regions of streams and rivers are very dynamic and constantly changing in relation to hydrograph variations. Since most lakes of the world are small in area and shallow, and the floodplain-saturated bank littoral areas of streams are very large in relation to water of the channels, the wetland and littoral flora and its epiphytes are commonly a dominant source of synthesized organic matter to recipient waters.
2. Four groups of aquatic macrophytes can be distinguished on the basis of morphology and physiology; each of the groups dominates a major region of the littoral zone (Fig. 8-2):
   a. *Emergent* macrophytes grow on water-saturated or submersed soils from where the water table is about 0.5 m below the soil surface (supralittoral) to where the sediment is covered with approximately 1.5 m of water (upper littoral).
   b. *Floating-leaved* macrophytes are rooted in submersed sediments in the middle littoral zone (water depths of approximately 0.5–3 m) and possess either floating or slightly aerial leaves.
   c. *Submersed* macrophytes occur at all depths within the photic zone. Vascular angiosperms occur only to about 10 m (1 atm hydrostatic pressure) within the lower littoral (infralittoral), and nonvascular macrophytes (e.g., macroalgae) occur to the lower limit of the photic zone (deepest boundary of the littoriprofundal).
   d. *Freely floating* macrophytes are not rooted to the substratum; they float freely on or in the water and are usually restricted to nonturbulent, protected areas.
3. Emergent macrophytes produce erect, linear leaves from an extensive rhizome/root base and are physiologically similar to terrestrial plants.
   a. Rooting tissues grow in a water-saturated, anaerobic substratum and must obtain oxygen for respiration from aerial organs. The plants develop extensive intercellular gas lacunae that permit internal gas movement and exchange.

b. Rates of transpiration by emergent and floating macrophytes are often extremely high and result in water losses to the atmosphere that are greater than evaporation from an equivalent area of water. Vegetative evapotranspiratory losses of water can be sufficiently large to appreciably reduce water levels of the fresh waters and surrounding terrestrial areas.

4. Submersed angiosperms possess numerous morphological and physiological adaptations to their aqueous environments.
   a. Leaves are only a few cells in thickness, and photosynthetic pigments are concentrated in epidermal tissue. Leaves tend to be much more divided, with greater surface-to-volume ratios, than are leaves of other aquatic or terrestrial plants. Leaf morphology maximizes exposure of cellular surfaces to reduced light, gas, and nutrient availability under water.
   b. Many submersed angiosperms exhibit extreme vegetative polymorphism *(heterophylly)* in leaf structure, often on the same stem or petiole. Morphology commonly shifts from finely divided submersed leaves to more coalesced, entire shapes in surface-floating or aerial leaves. Heterophyllous growth is regulated by interactions of temperature, CO_2, and hormonal action mediated by ethylene concentrations and light.
5. Vegetative and clonal reproduction is a major mechanism for population growth and dispersal. Although sexual reproduction and genetic recombination has been retained, it is commonly subordinate to vegetative reproduction.
   a. Vegetative, clonal growth occurs by (i) fragmentation and dispersal of aboveground tissues, (ii) winter buds (turions), and (iii) horizontal expansion by rhizomes, tubers, corms, and bulbs.
   b. Many of the most effectively competitive aquatic plants combine continuous clonal growth with production of seeds for long-distance dispersal.
   c. Aerial flowering dominates among even submersed aquatic plants; pollination occurs by insect or wind vectors.
6. Movement of gases within and through plant parts are essential to alleviate toxicity effects of fermentation products (e.g., volatile fatty acids and hydrogen sulfide) in anaerobic sediments and to maintain active respiratory and photosynthetic metabolism.
   a. Oxygen, carbon dioxide, and other gases move within and through interconnecting aerenchymatous and intercellular cortical gas spaces of shoots and roots.
   b. Gas flux mechanisms among aquatic plants with aerial leaves include:
      i. Diffusion-dependent throughflow convections based on pressurization differentials
      ii. Nonthroughflow convections based on differential gas concentrations from metabolic uptake or release of gases
      iii. Venturi-induced throughflow convections from wind pressure differentials
      iv. Very large amounts of carbon dioxide and methane pass from sediments through rooting tissues into the intercellular gas system and to the atmosphere
   c. Within intercellular lacunae of submersed plants, oxygen from photosynthesis diffuses to sites of respiration, particularly to rooting tissues. Some oxygen diffuses into the microrhizosphere and reacts chemically and is utilized by microaerophyllic bacteria. Carbon dioxide from respiration diffuses to photosynthetic tissues and can augment CO_2 and bicarbonate sources from the water for photosynthesis.
7. Carbon assimilation is more difficult in submersed macrophytes than in emergent and floating-leaved plants that have access to atmospheric CO_2, primarily because rates of diffusion of gases are several orders of magnitude slower in water than in air. Nearly all submersed species possess C_3-type photosynthetic metabolism with relatively high rates of photorespiration. Because of chronic potential for inorganic carbon limitations to photosynthesis and growth, numerous mechanisms have evolved for conservation and recycling of CO_2:
   a. The cuticle of submersed angiosperms is reduced or absent, photosynthetic tissue is thin (1–3 cells thick), and chloroplasts are densely distributed in outer epidermal cells—all enhance exchange of gases and nutrients that are dissolved in the water.
   b. Extensive intercellular gas lacunae (often >70% of plant volume) in leaves, stems, petioles, and roots facilitate rapid diffusion of internal gases. Microzones at the cellular surface of leaves rapidly develop in quiescent littoral waters; these microzones set up gradients of reduced gas availability.
   c. Certain species of submersed macrophytes assimilate and subsequently decarboxylate bicarbonate ions. This assimilation represents a physiological adaptation to limited availability of free CO_2.
   d. Most submersed angiosperms possess C_3–Calvin-type photosynthetic metabolism with high rates of photorespiration. CO_2 from

mitochondrial respiration of foliage and rooting tissue, photorespiration, and, in a few softwater plants, CO_2 from sediments, augment CO_2 and/or HCO_3^- assimilated from the water. Some CO_2 from respiration is efficiently recycled in the internal gas lacunae of leaves.

e. Certain submersed macrophytes assimilate CO_2 in periods of darkness and relative abundance, store it as malate, and utilize the carbon in the subsequent daylight period of photosynthesis.
f. Many submersed macrophytes have low CO_2 compensation points and relatively high photosynthetic efficiency.

8. Nutrients are assimilated from the sediments by emergent and rooted floating-leaved macrophytes and translocated to their shoots and from the water in freely floating macrophytes.
   a. Most submersed rooted macrophytes obtain most of their nutrients from the interstitial water of sediments, where concentrations are much greater than in the overlying water. When nutrient concentrations of the water are high, a greater proportion is assimilated from the water.
   b. Some nutrients are released to the water by submersed macrophytes during active growth; large amounts can be released upon senescence and death, although most are immediately sequestered by attached microbial communities.
   c. Translocation of nutrients occurs in both directions with dominant acropetal translocation from the roots to the leaves.
9. Light availability is a major factor regulating the growth and competitive interactions of aquatic macrophytes.
   a. Light saturation occurs at relatively modest irradiances (ca. 750 μmol quanta m^{-2} s^{-1}) with efficiencies of light utilization at about 0.5% at full sunlight without apparent photoinhibition among emergent macrophytes. Photosynthetic efficiencies decrease markedly at higher temperatures as rates of respiration and photorespiration increase.
   b. Submersed macrophytes are distinctly shade-adapted with high concentrations of pigments and low-light compensation points of photosynthesis, commonly at 1–3% of full sunlight. Considerable photosynthetic and respiratory adaptation to low light and differing temperatures is found among submersed species.
   c. Among submersed macrophytes, light attenuation rapidly limits the vertical distribution of plant growth. Light availability and interspecific shading can be major factors influencing the competitive success of one species over another.
   d. Hydrostatic pressure likely interacts with low light intensities to limit the distribution of freshwater angiosperms to depths of <10 m.
10. The productivity of aquatic macrophytes has been evaluated from changes in biomass over time and, in a few cases, by *in situ* determinations of rates of photosynthesis.
   a. Most aquatic macrophytes are perennial, with varying degrees of biomass turnover during growth. As a result of continuous partial mortality and populations with high turnover of leaves, much of the annual production does not survive to be measured as seasonal maximum biomass. Multiple cohorts or continuous replacement growth and senescence prevail among most emergent, floating-leaved, and submersed macrophytes. In many cases, cohort longevity is in the range of 30–40 days.
   b. Roots and rhizomes of submersed macrophytes make up a lesser portion (1–40%) of total plant biomass than is the case for floating-leaved (30–70%) or emergent (30–95%) macrophytes.
   c. Emergent macrophytes contain a much higher content of structural tissue than do submersed or floating-leaved macrophytes. This structural tissue is of a chemical composition that is relatively recalcitrant to rapid microbial decomposition.
   d. Growth of aquatic macrophytes is generally higher on organic-rich sediments than it is on sandy sediments.
   e. On a unit-area basis, the net primary productivity of aquatic macrophytes is among the highest of any community in the biosphere (Table 18-10). Emergent macrophyte productivity is the highest (1000–10,000 g AFDW m^{-2} yr^{-1}); freely floating macrophytes is intermediate (300–5000 g m^{-2} yr^{-1}), floating-leaved rooted macrophyte productivity is modest (100–500 g m^{-2} yr^{-1}), and submersed macrophytic productivity is considerably less (5–1500 g m^{-2} yr^{-1}). Nearly all of the macrophyte productivities exceed those of phytoplankton (25–200 g AFDW or 50–450 g C m^{-2} yr^{-1}).
   f. Seasonal variations in aquatic macrophyte productivity are great. In the temperate zone, productivity of aquatic macrophytes commonly follows increasing insolation and temperature; some submergents persist under ice cover, although net productivity is low or zero. In the tropics, growth can be nearly continuous.
11. In addition to natural, genetically programmed senescence and death, cued by environmental

parameters, mortality can occur by disease, herbivory, and other factors.

a. Pathogenic decimation of entire macrophyte populations is rare; disease usually increases gaps and community heterogeneity.
b. Herbivory of aboveground vascular plant tissues by aquatic insects and snails is low in comparison to potential losses to crayfish crustaceans, herbivorous fish specialists, mammals, and aquatic birds under certain conditions. The percentage loss by animal ingestion or maceration is in the range of 25% for the *aboveground instantaneous biomass* of freshwater vascular macrophytes and somewhat higher among nonvascular macrophytes. However, the percentage loss of *total* above- and belowground *production* of aquatic plants by animal herbivory is usually unknown and certainly is lower (5–10%).
c. Many classes of plant compounds function as plant deterrents for herbivory and are known to be operational in many aquatic plants.
d. Losses of plant biomass by damage from water movement are often severe, particularly periodically in rivers and streams.

12. Interspecific competition among macrophyte species is poorly understood. Compounds released from living or dead tissues of many aquatic plants can inhibit growth and development of other aquatic macrophytes or attached microbiota.
13. Phytoplankton productivity is generally lower in littoral zones containing stands of aquatic macrophytes. Experimental evidence indicates that this phenomenon results largely from a competition for nutrients (including carbon) by submersed macrophytes and by a reduction of light by macrophyte foliage.
14. Wetland and littoral regions of freshwater ecosystems are commonly intensely metabolically active owing to the presence of aquatic macrophytes.
    a. The macrophytes are frequently the primary source of organic matter to both lakes and rivers.
    b. The synthesis of organic matter by emergent vegetation and its decomposition in and on wetland sediments result in high loading of dissolved organic matter and inorganic nutrients to recipient lakes. The timing of loading is strongly influenced by the stages of wetland plant growth, senescence, and decomposition.
    c. As water laden with nutrients and dissolved organic compounds passes to the lake, the chemical loading is greatly modified by the metabolic activity of littoral submersed macrophytes and their epiphytic microbiota. The littoral macrophyte–epiphyte complex can function as a selective metabolic sieve.

VI. Summary

Microbiota grow upon and attach to any surface immersed or growing in water. The succession of microorganisms upon a surface is complex and involves adsorption of organic substances to the surfaces and attachment of microorganisms in sequence. Usually bacteria attach first followed by algae, cyanobacteria, and protists. Extracellular mucilaginous materials, also referred to as exopolysaccharides or exopolymer secretions (EPS), often occur as coatings around individual microbial cells or projections from cells. Ultimately this material forms a matrix inhabited by a variety of microorganisms, particularly bacteria, algae, protists, and fungi (e.g., Fletcher and Marshall, 1982).

Excretion of exopolymer fibrils by bacteria is an important initial phase of attachment of microbes to surfaces (Fletcher and Floodgate, 1973; van Loosdrecht *et al.*, 1990; Brading *et al.*, 1995). A substantial portion of any attached aquatic microbial community will be composed of nonliving, mucilaginous materials. Most of this material is believed to be mucopolysaccharide, although the exact composition and texture of it varies with environmental conditions as well as the nature and condition of the organisms that secrete it (e.g., Sutherland, 1985; Hoagland *et al.*, 1993).

Much excellent study has been directed to biofilms attached to surfaces of technical devices (e.g., pipes,

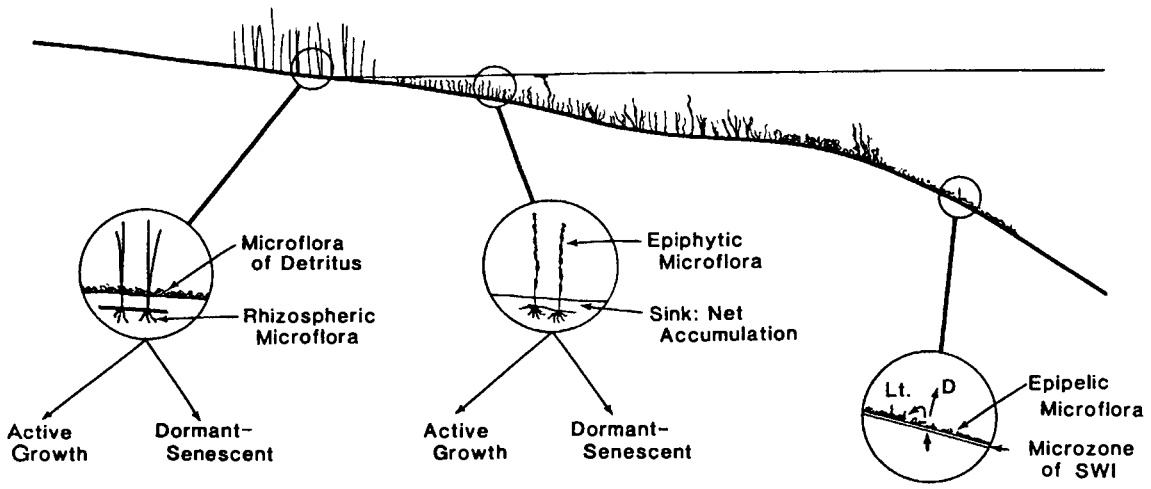

FIGURE 19-1 Primary habitat and attached algal community components along a wetland–littoral gradient of standing waters and backwater areas of river ecosystems. *SWI* = sediment–water interface; *D* = dark; *Lt* = light. (Modified slightly from Wetzel, 1990a.)

ship hulls, and teeth) that convey or are immersed in water (e.g., Characklis and Wilderer, 1989; Characklis and Marshall, 1990). These studies correctly focus largely on heterotrophic attached microorganisms, especially bacteria, because growth occurs on most of these anthropogenic surfaces in darkness. In natural ecosystems, however, algal photosynthesis is irrevocably coupled to heterotrophic attached microbial metabolism. As a result, mixed autotrophic–heterotrophic assemblages form much more complex and metabolically dynamic communities than those that are only heterotrophic.

1. ATTACHED MICROBES AND ALGAE OF LITTORAL REGIONS

A. General Habitat Characteristics

Benthic algae and other autotrophic microbes, such as the cyanobacteria, are generally associated with or attached to substrata. These substrata are living or dead, organic or inorganic, and in various combinations. Because photosynthesis is the only significant process for synthesis of organic matter among these organisms, light is mandatory within both the macrohabitats and the microhabitats of the communities in sufficient quantities to allow net synthesis of ATP. The land–water interface zone is a gradient that extends from detrital masses in hydrosoils and pools of wetlands through littoral zone regions of emergent, floating-leaved, and submersed macrophyte communities to sediments extending into deeper waters well beyond the vascular macrophytes (littoriprofundal). Available light shifts from abundant in wetland and shallow nontree-canopied littoral areas to low and highly variable seasonally in deeper areas as the densities of seston change in the overlying waters. Within this zone of adequate light, substrata diversity is highly variable but can be organized into general zones in relation to potential substratum nutrient and other environmental characteristics (Fig. 19-1).

1. Emergent Plant Zones

These zones consist of saturated hydrosoils and pools of upland wetlands and flood plains among emergent macrophytes that are made up of largely of standing and collapsed dead macrophytes and dense aggregations of particulate detritus among the understory. Although many critical plant nutrients are retained within living plant tissues and translocated to rooting tissues at the end of growth periods of individual plant cohorts, soluble organic matter and organic nutrients, particularly organic phosphorus, are released from the highly productive emergent macrophytes during and following active growth, senescence, and decomposition (Chaps. 18 and 21). Many of these herbaceous perennials have more or less continuous leaf or culm turnover of many cohorts per year in both northern and southern regions. As a consequence, relatively constant partial senescence of leaves and decomposition occur among macrophytes with release of cellular organic matter and nutrients.

The high production of the emergent macrophytes in excess of decomposition results in high detrital organic matter accumulation at the sediment–water

interface. This loading, which contains relatively high proportions of moderately recalcitrant structural tissues from emergent plants, shrubs, and trees contributes to high substrata surface area for microbial colonization in relatively shallow water of high light and temperatures. The high loading of organic matter results in predominantly anaerobic conditions with increased solubility of critical nutrients, particularly P and N, in the interstitial waters near and at the sediment–water interface (cf. Chaps. 12 and 13). Much of the combined nitrogen as nitrate is commonly denitrified by facultative anaerobic bacteria in such detrital–sediment masses and released to the atmosphere as N_2 (Triska and Oremland, 1981; Bowden, 1987).

2. Submersed Plant Zones

As we have summarized in the Chap. 18, submersed macrophytes of lakes, ponds, rivers, and floodplain pools generally possess morphology of thin, finely divided, and reticulated leaves. The resulting increased surface area of leaves markedly enhances interceptions of light and the exchange of gases with those of the water. This greatly increased ratio of surface area to volume results in enormously increased substrata for colonization by epiphytic algae, cyanobacteria, and other microbes and protists. For example, the leaf surface area available for colonization by epiphytic algae on the submersed linear-leaved macrophyte *Scirpus subterminalis* averaged 24 m^2 of leaf area projecting upward three-dimensionally above every square meter of bottom in the moderately developed littoral zone of a lake in southwestern Michigan (Burkholder and Wetzel, 1989). The extensive area of these macrophytic surfaces projects myriad diverse microhabitats with attendant attached algal communities upward into littoral environments. In this spatial habitat in the water column, relative abundance occurs of light, dissolved gases from photosynthesis (O_2) and decomposition and respiration (CO_2), and nutrients diffusing from the high decomposition in interstitial waters of detritus and sediments and imported from upland allochthonous sources. Related to the very large diversity of microhabitats in this dynamic and highly productive region, most (>80%) of freshwater species of algae and cyanobacteria are attached, sessile forms (Round, 1981; Wetzel, 1999b).

3. Sediment Substrata

The benthic habitat in both standing and running fresh waters can be a physically hostile yet nutritionally advantageous environment. Epilithic and epipsammic microbes, attached to rocks and sand grains, respectively, are common in streams and wave-turbulent areas of lakes. Active water movements offer advantages for nutrient and gas exchanges but also expose the communities to molar action by particles such as sand and potential burial by sediments with reduction or removal of light (Meadows and Anderson, 1966; Moss and Round, 1967). Most lakes and ponds are small with modest fetch and wind-induced water movements. Water turbulence also decreases rapidly with increasing depth (cf. Chap. 7; also Imberger and Patterson, 1990), and submersed macrophyte communities greatly attenuate flows in both lakes and streams (cf. Chap. 18). As a result, even loosely aggregated organic-rich sediments can serve as substrata for algae and cyanobacteria attached to the surface of these sediments (epipelic) when they receive adequate light. The unstable nature of such sediments and frequently high rates of deposition from settling seston increase the risk of epipelic algal burial and light reduction. The high nutrient availability from interstitial waters of sediments, however, is a distinct advantage. Many epipelic algal species migrate, often in rhythmic fashion, to compensate for shifting light attenuation by sediment (cf. Round, 1981).

Algae growing adnate to unconsolidated, shifting sediments are constantly in danger of being removed from light, which is attenuated to zero in a few millimeters.[1] Whether epipelic algae supplement photosynthetic growth by heterotrophic utilization of organic substrates is unclear. Circumstantial evidence of the high concentrations of organic substrates in the interstitial waters of organic-rich sediments and many epipelic algae growing under very low light conditions is pervasive that facultative heterotrophy may occur among some benthic algae (e.g., Gaines and Elbrächter, 1987; Tuchman, 1996). In spite of this physiological potential, an important adaptation to the rigors of this habitat is an ability to move vertically within the sediments in response to light availability.

Persistent diurnal vertical migration rhythms have been shown in epipelic diatoms, flagellates, and cyanobacteria from flowing waters and shallow lakes (Round and Happey, 1965; Round and Eaton, 1966). Cell numbers on the sediment surface start to increase before dawn and reach a maximum about midmorning. Thereafter, surface cell numbers decrease and reach a minimum before the onset of darkness. This rhythm persists for a limited time in continuous darkness or continuous light, although the synchrony is lost more rapidly under continuous light conditions.

[1] The attenuation of light by sediments is highly dependent upon the type of sediment. Highly organic sediments attenuate light much more rapidly than does sand. For example, Palmer and Round (1965) found that radiation was reduced to about 1% of the incident value under about 3 mm of organic-rich sediment. Similar results were found by Wasmund and Kowalczewski (1982).

Studies of the diurnal rhythms of freshwater epipelic algae have shown that the maxima of cell emergence in the surface sediment layers and photosynthetic capacity coincide, although the increase in photosynthesis preceded cell emergence (Brown *et al.*, 1972). The photosynthetic rhythm persisted at light intensities well below saturation; minimum photosynthetic values were found in midafternoon, after which the rate increased again, a rise that preceded the reemergence of cells. The maximum photosynthetic rate occurred when maximum cell numbers were present on the sediment surface.

4. Metaphyton

Loosely aggregated algae and cyanobacteria, the metaphyton, in inundated water of wetlands and littoral areas of many lakes, ponds, and floodplain areas of rivers are neither strictly attached to substrata nor truly suspended. Metaphyton communities originate from fragmentation of dense epiphytic communities that aggregate and become clumped and loosely attached in littoral areas by wind-induced water movements and then can form dense microbial accumulations with intense internal nutrient recycling. The productivity and collective metabolism of metaphyton can be very high and radically alter the nutrient cycling of littoral areas.

In contrast to the immense amount of study on the systematics, physiology, and ecology of the phytoplanktonic algae of aquatic systems, there is a dearth of information on the algae attached to substrata or loosely aggregated in the littoral regions of lakes or shallow zones of streams and rivers. Although the taxa of these largely sessile algae are somewhat better understood, information is sparse on their geographical distribution, seasonal population dynamics, utilization of microhabitats, responses to parameters of water movement or water and substratum chemistry, or on their interactions with other organisms.

The extreme heterogeneity in distribution of the algae across an exceptionally variegated spectrum of microhabitats subjects attached organisms to much more variable environmental physicochemical and biotic parameters than usually occur in the open water. Spatial and temporal heterogeneity of phytoplankton in pelagic habitats is minor in comparison to that of the attached algae. Nonetheless, despite the numerous problems associated with obtaining quantitative information, indications are that the algal populations specialized to these habitats sustain high rates of productivity. Our poor understanding of the complex interactions between the sessile flora and their substrata, and the contributions of the attached microorganisms to the total system productivity, represents a major void in contemporary limnology that warrants intensified study.

B. Terminology and Zonation

The limnological terminology applied to attached algae is complex. These terms and the general zonation of littoral algae have been introduced earlier (Chap. 8; Fig 8-3, pp. 131–133).

C. General Distribution of Littoral Algae

Floristic surveys of the distribution of algae among subcommunities of the littoral zone result in long lists of species. Observed different associations reflect acute heterogeneity in parameters of light, temperature, nutrient availability, water movement, substratum, grazing pressure, and other factors. Detailed floristic analyses indicate specific characteristics of dominant taxa and designate the range of probable interactions among species, thereby providing a foundation upon which experimental approaches can be designed (Round, 1964a; Biggs, 1996; Stevenson, 1996a). The initial evaluations often lead to recognition of algal associations in various habitats, thereby enabling quantitative sampling and the separation of dominant and casual species. These evaluations are difficult to perform, especially among algae of the sediments, but have been done in a number detailed analyses of littoral communities.

The attached algae often dominate algal biomass in small streams and shallow lakes. Probably >90% of all algal species grow attached to a substratum; these species include practically all of the pennate diatoms and a majority of the Conjugales, Cyanophyta, Euglenophyta, Xanthophyceae, and Chrysophaceae (Round, 1964a; Biggs, 1996; Lowe, 1996).

Epilithic and epiphytic communities have many algal species in common, but there is relatively little interchange of species between those of the mud-living epipelic habitat and the other substrata types. Epipelic algae are largely motile; their motility is essential to enable them to move to the surface after any disturbance of the sediments. Algal species adnate to sediments of streams and rivers with moderate to fast flow are almost exclusively motile.

Epipsammic algae, consisting largely of small diatoms and cyanobacteria attached more or less firmly to crevices in the surface of sand grains and rock surfaces, exhibit an extremely variegated, heterogeneous distribution (Fig. 19-2). These algae tend to be less motile than epipelic algae, which usually grow on finer, organic sediments (Round, 1965a; Meadows and Anderson, 1966, 1968; Miller *et al.*, 1987). In the

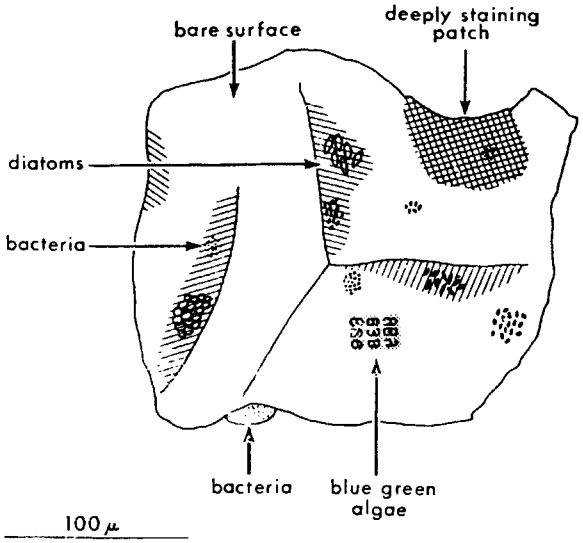

FIGURE 19-2 Diagrammatic representation of typical localized distribution of microorganisms and staining (carbol fuchsin) patches of organic materials on the surface of a sand grain. (From Meadows, P. S., and Anderson, J. G.: Micro-organisms attached to marine and freshwater sand grains. *Nature (London) 212*:1059–1060, 1966.)

shallows of a temperate English lake, Moss and Round (1967) found that both epipelic and epipsammic algae showed marked population maxima during the spring. The biomass of the epipsammic algae of the surface 5 cm of sediments was consistently greater than that of the epipelic algae. Algal populations in interstitial water of a sandy beach in a southern Michigan lake were also large and exhibited a spring maximum (Davies, 1971). Percentage water content in sand sediments was an important determinant of algal composition between the saturated zone of the water's edge and higher sand beaches subject to periods of desiccation. Within the sand, light is attenuated rapidly and is essentially extinguished within half a centimeter. Yet viable epipsammic algae have been found attached to sand grains as deep as 20 cm in sandy beach zones exposed to heavy wave action. It is believed that wave action is adequate to mix the sand grains and return attached algae to a lighted zone sufficiently often to permit active, although low, photosynthesis (Steele and Baird, 1968).

1. Attached Lichens of the Eulittoral

Lakes and streams with rocky shores and moderately stable water levels may have an abundant and diverse eulittoral crustose lichen flora. Largely studied among waters of northern Europe, a characteristic stratified zonation is commonly observed (Santesson, 1939; Hutchinson, 1975). Just above the lowest summer water level, grey–black *Verrucaria* spp. occur epilithically, being submersed some 80–90% of the year. Above this zone, some 20–30 cm above the lowest water level, several lichens, dominated by blackish-brown *Staurothele*, occur and are submersed well over half of the year, mostly in winter. A higher association, covered by water for 25–50% of the year, is dominated by light-brown or grey *Lecanora* spp. Above this zone at about the highest water level, the lichens shift to foliose species and associations. This distinct community demarcation, called the *lichen line* (*Flechten linie*; Naumann, 1931), represents the most probable highest water level in the immediate historic past.

Distribution of species within streams can be delimited into four distinct zones in the British Isles (James *et al.*, 1977; Gilbert, 1996): (1) The fluvial submersed zone involves about 15, mainly pyrenocarpous, species; (2) the fluvial mesic zone contains the richest aquatic lichen flora, with about 20 species and approximately 60% cover; (3) the fluvial xeric zone is lichen-depauperate, being scoured by spates about once a month; and (4) the lichen flora of the fluvial terrestrial zone is influenced only by nutrient loading from the stream water through the substrata. Along a stream gradient, the lichen flora varies from species-rich headwater flow with a cover of 80% of exposed rock to more erosive areas subjected to scour and substrata instability where species diversity was low and cover of bedrock was <1%.

Very little is known about the physiological characteristics and constraints of these semiaquatic lichens, although some of the ecophysiological factors that account for the delimited distribution of them have been investigated (Ried, 1960a,b). Practically no species tolerates continuous submersion. A notable exception is *Hydrothyria venosa*, a submersed species of the Collemataceae characterized by hyphae that ramify among the gelatinous matrix of single cells of the phycobiont *Nostoc* (Russell, 1856). This rheobiont lichen is rather commonly distributed on stones in relatively quiescent mountain streams with its thallus often in dense tufts to 10 cm or more in height. As in terrestrial environments, semiaquatic and submersed lichens generally occupy harsh, austere habitats that are physically stable and relatively free of nutrient enrichments and siltation (Gilbert, 1996). Stable springheads of small streams are common habitats in which interspecific competition of lichens is low. It is suspected that aquatic lichens usually possess slow growth rates and contribute relatively small percentages to overall material and energy fluxes of freshwater ecosystems.

The mineral content and pH of the water influence the lichen flora as instanced by impoverishment of communities on siliceous rocks on lakesides where inflow streams are basic in composition. Lake and stream lichens are also vulnerable to contamination by

inorganic fertilizers in runoff and seepage. Hypereutrophication encourages cyanobacteria and green algae that can outcompete lichen communities. Long-term studies of aquatic lichen communities are of value in monitoring lowering or rising water levels that result from human-induced alterations and diversions of water (Seaward, 1996). River channel capacity can also be determined by lichen zonation (Gregory, 1976).

D. General Structure of Periphyton Communities

Problems of exchange of nutrients, gases, and metabolic products from within the periphyton communities and the overlying water involve problems of diffusion across the periphyton community boundaries and the external medium. Slow diffusion into attached microbial communities is particularly acute in relatively thick communities, where high productivity is maintained by intensive internal recycling of nutrients, including carbon, among mutualistic microbiota (Wetzel, 1992, 1993a). Abiotic adsorption of particulate and dissolved organic compounds, as well as incorporation of inorganic nutrients and metals into the mucilaginous matrix, can provide a concentration mechanism (Lock, 1981, 1982; Lock *et al.,* 1984; Roemer *et al.,* 1984; Beveridge and Graham, 1991; Freeman and Lock, 1995). Such concentration could enhance diffusion within the community matrix to the organisms. This mechanism likely not only stimulates the metabolism of the community but in the case of certain cations, such as calcium, magnesium, iron, and manganese, affect the physical properties of the mucilage matrix, such as hydrophobicity (e.g., Freeman *et al.,* 1995; Lemke *et al.,* 1995) and possibly texture. The extracellular matrix can also provide sites for attachment for extracellular enzymes, such as phosphatases and proteases, that are critical in rendering nutrients and carbon available to microorganisms (Wetzel, 1990a, 1991a).

Developing periphyton is three-dimensionally enmeshed with hydrated glycocalyx and other mucopolysaccharide materials, secreted by bacteria and algae, that both sequester ions and isolate the microorganisms from the water column (Wetzel and Allen, 1970; Allen, 1971; cf. review of Burkholder, 1996). Accumulated detrital particles and precipitated calcium carbonate crystals, as well as the glycocalyx materials, enhance nutrient enrichment by adsorbing phosphorus, ammonium, and various organic substances (Fig. 19-3). Nutrients may be assimilated, sometimes with the aid of excreted enzymes such as phosphatases (*), utilized, and released via leaching, excretions, secretions, or cell lysis by the benthic algae (A) (Fig. 19-3). Epiphytic microfauna and macrofauna can release phosphatases and nutrients during feeding

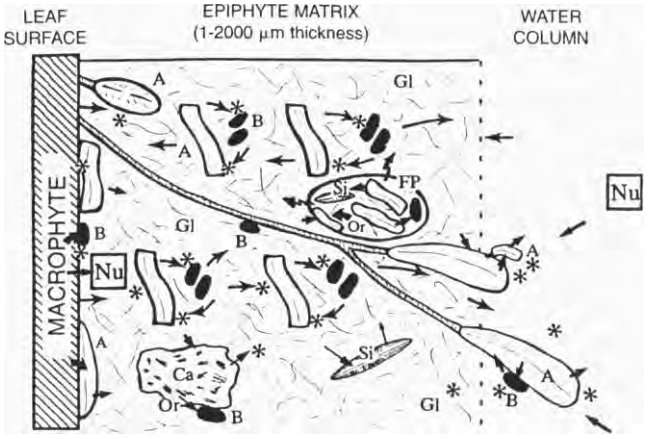

FIGURE 19-3 Diagram of the supply of nutrients (*Nu*, such as organic and inorganic forms of carbon, phosphorus, and nitrogen) to benthic algae and other microbes within a periphyton matrix on a substratum, in this case a submersed macrophyte leaf. Arrows indicate routes of nutrient cycling form the substratum and the water column, which represent the two major external sources of nutrient supply to the periphytic matrix. (See text for explanation of relationships and symbols.) (From Burkholder, 1996.)

and excretion (e.g., fecal pellets (FP) with viable algae and bacteria that have become nutrient-enriched during passage through the animal gut, nutrient waste products, and dead microflora and other organic detrital particles).

Other nutrient-sequestering or -releasing materials include inorganic calcium carbonate (Ca) that is precipitated by photosynthetic processes and siliceous frustules of dead diatoms (Si), organic debris (e.g., recently dead algae and animals, Or), and microbially derived hydrated glycocalyx/mucopolysaccharides (Gl) (Fig. 19-3). The microflora and fauna can also be colonized and attacked by fungi, especially when moribund, and this process would result in nutrient remineralization or release. Some algae and bacteria are directly adnate to and in contact with the leaf or other substratum surface. Other microflora are loosely attached in the overstory matrix, and some have stalks or other attachment structures to the substratum (Fig. 19-4).

Insight into the community structure of epiphytic microflora of submersed macrophytes can be gained from electron photomicrographs[2] of a typical association (Fig. 19-4). The surface structure of the epiphytic community (Fig. 19-4A) indicates the manner in which the loosely woven diatomaceous component is held in place by a stranded matrix formed largely from gelatinous stalks of mucoid substances (Fig. 19-4B), which

[2]The scanning electron photomicrograraphs were kindly provided by Dr. B. R. Allanson University, South Africa; some are from his investigations reported in Allanson (1973).

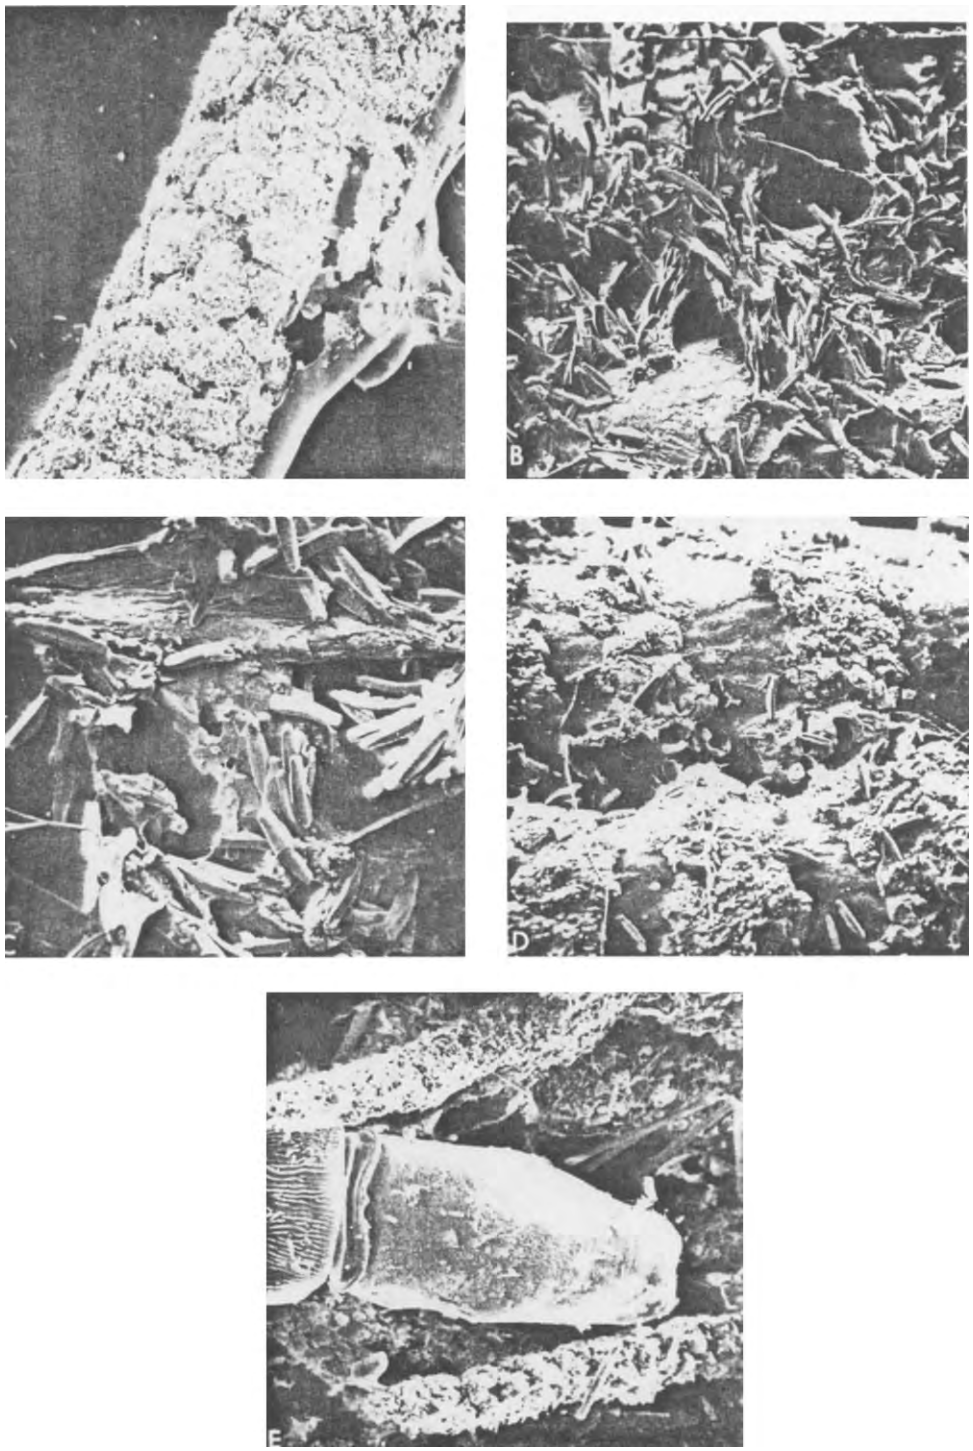

FIGURE 19-4 The structure of a microfloral community upon the macroalga *Chara* from Wytham Pond, Oxford, England. R.: Fine structure of the periphyton of *Chara* sp. and *Potamogeton natans* from Wytham Pond, Oxford, and its significance to the macrophyte periphyton metabolic model of R. G. Wetzel and H. L. Allen. *Freshwater Biol.* 3:535–541, 1973.)

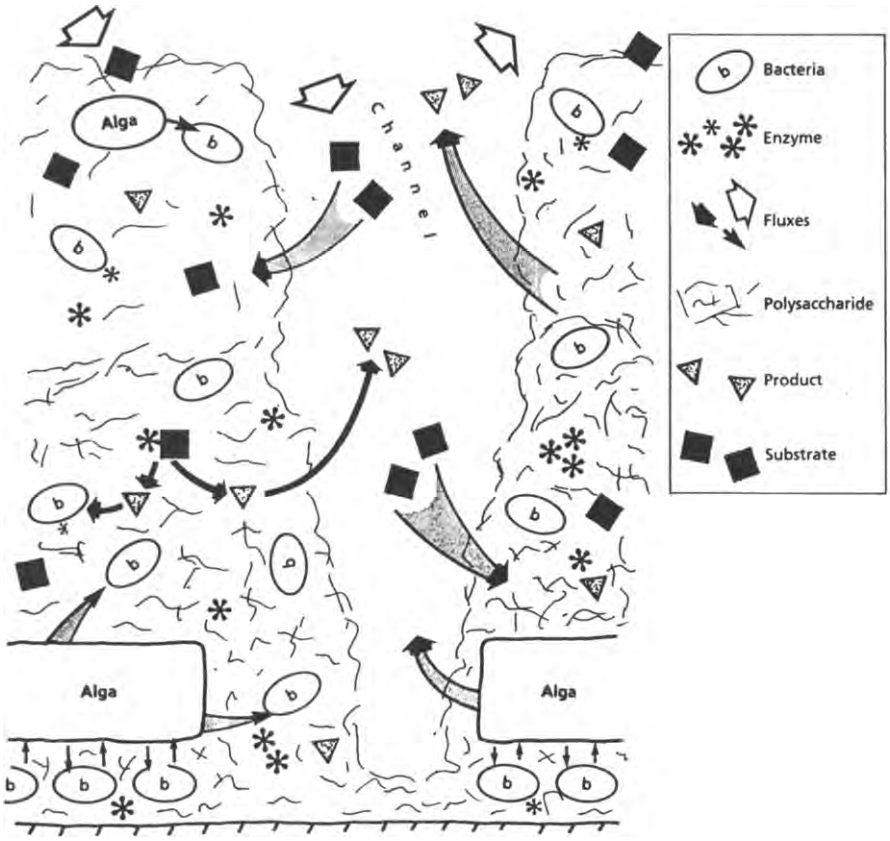

FIGURE 19-5 Conceptual model of the structure and metabolic fluxes within periphyton communities and from or into microchannels of the polysaccharide matrix and the overlying water. (See text; modified slightly from Lock, 1993.)

in places extends as a fragmented membrane above the deposits of calcium carbonate covering the cell wall (Allanson, 1973; Roos *et al.*, 1981). While some algae (diatoms and cyanobacteria) and heterotrophic bacteria are loosely associated within and on the calcite and mucoid complex, others penetrate through the complex to the macrophyte itself and attach themselves directly along its entire surface or by means of simple or branched mucilagenous stalks. Much of the matrix is associated with the mucopeptide cell walls of the epiphytic bacteria, algae, and cyanobacteria, an association that is lost in the techniques used to prepare these scanning electron photographs; this matrix can be seen, however, in transmission electron microscopy.

Most of this relatively rich community of microflora epiphytic upon macrophytes is destined to become detritus. Massive accumulation rates on the supporting plants *Chara* and *Potamogeton* (Allanson, 1973) and differences seen in the fine structure of the epiphytic-carbonate-mucoid complex between parts of the plant as it grows and provides new surfaces for colonization indicate that little of the community is utilized by grazing animals. In places, however, evidence for grazing occurs (Fig. 19-4 D,E).

Periphyton structure is envisaged to consist of microbes embedded within the polysaccharide matrix made from material secreted by bacteria and algae (Fig. 19-5). The polysaccharide matrix is potentially permeated by microchannels that may act as conduits in which diffusion of organic and inorganic nutrients is faster than through the polysaccharide matrix (Lock, 1993; Costerton *et al.*, 1994; DeBeer *et al.*, 1994; Wimpenny and Colasanti, 1997). The size of these microchannels varies greatly but is commonly in the range of 5–50 μm, and they permeate the microbiota and matrix in a dendritic, likely fractal pattern (Fig. 19-6). The amount of the polysaccharide matrix and likely the size of these microchannels is influenced by external factors. For example, microchannel size is increased in the presence of high dissolved humic substances and ultraviolet irradiance (Wetzel *et al.*, 1997, unpublished).

Fluxes of nutrients and dissolved gases from and to the overlying water and among microbial components within the periphyton would be faster in the liquid of

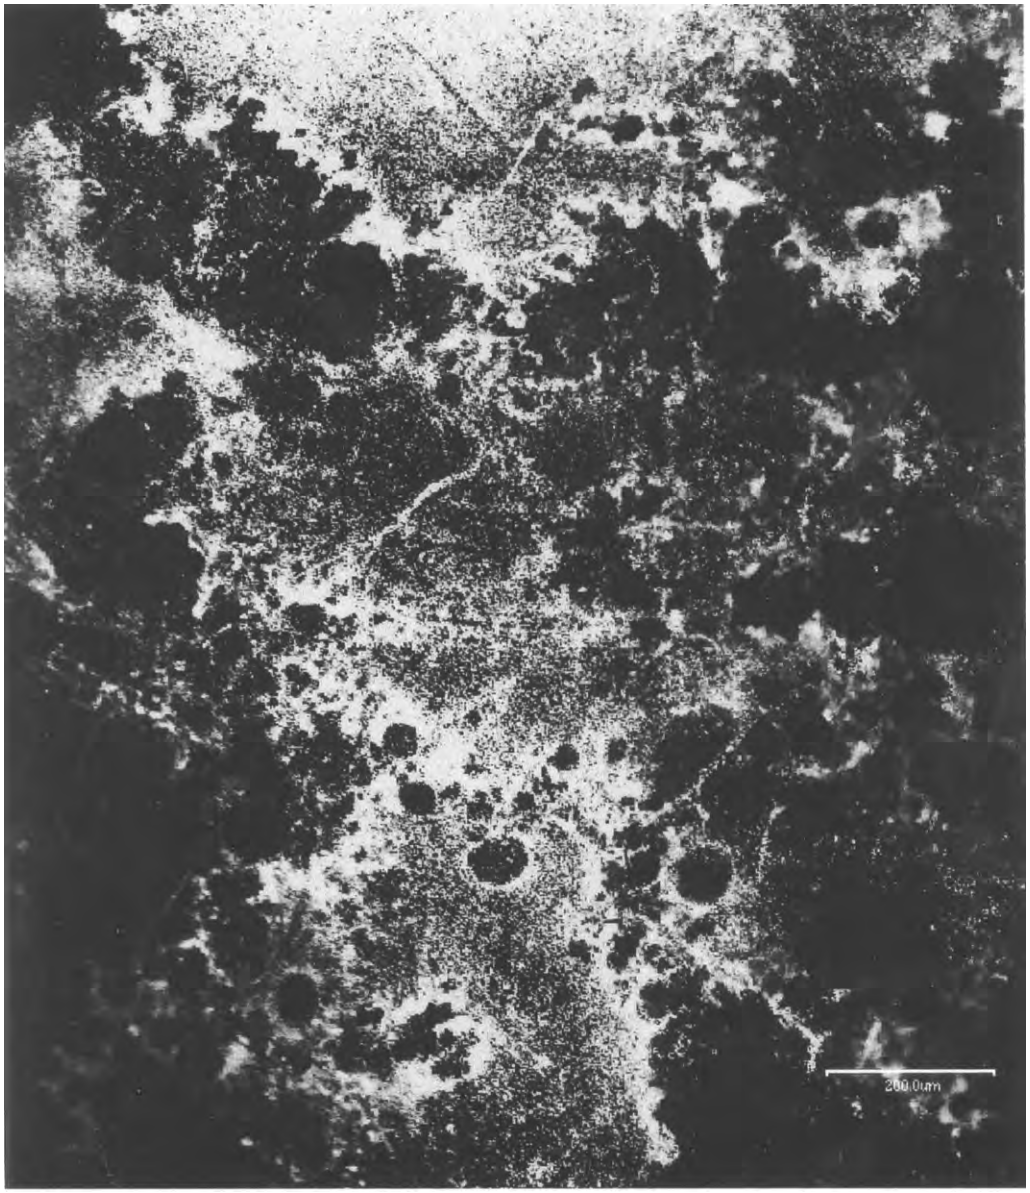

FIGURE 19-6 Fluorescent microspheres dispersed within microchannels of a lentic periphyton community at one focal plane about 75 μm below the surface–overlying water boundary. Black areas are bacterial and algal cell clusters within extracellular polysaccharide matrix. (E. Espeland and R. G. Wetzel, unpublished.)

the microchannels than through the matrix itself. Photosynthetic products of algae released intercellularly can be used by bacteria or may diffuse into the channels and to the overlying water. Reciprocally, bacteria secrete organic micronutrients (e.g., vitamins), CO_2, and enzymes intercellularly that may persist in the matrix for some time before being assimilated by algae or other microbes or diffusing from the matrix. Membrane-bound or -released extracellular enzymes may hydrolyze dissolved organic matter (DOM) released from other microbes, especially algae, or from DOM or particulate organic matter (POM) adsorbed from the overlying water. These hydrolyzed products can then be assimilated by microbes, adsorbed by the polysaccharide matrix, or be diffused into the microchannels or overlying water.

The polysaccharide matrix permeated with microchannels forms a physical medium in which diffusion is much slower than in the overlying water. A conceptual model, depicted in Figure 19-7, indicates the periphyton matrix attached to and overlying the substratum (Riber and Wetzel, 1987). In the interstitial water of the matrix, the concentration of a nutrient (C_m) will be the net effect of numerous factors,

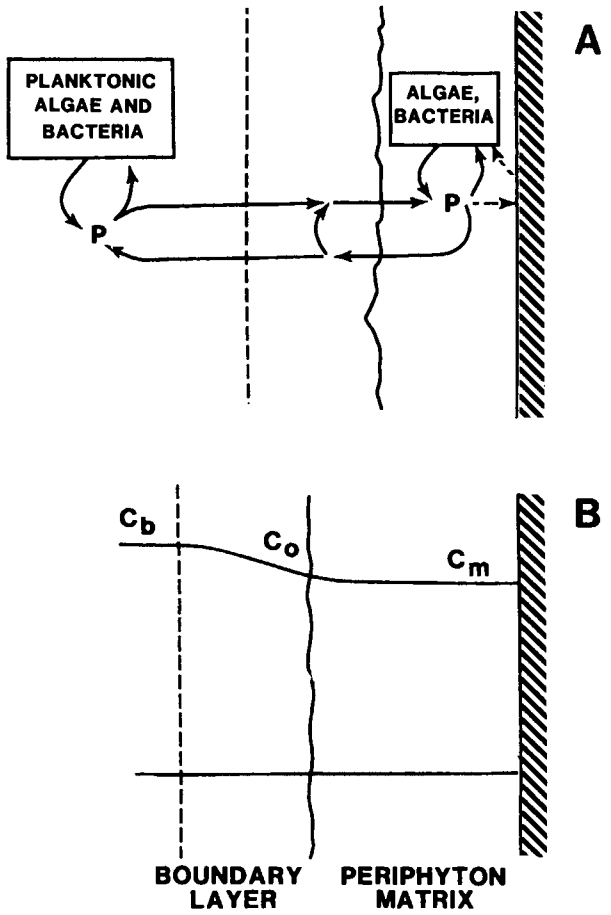

FIGURE 19-7 A conceptual model of nutrient (*P*) exchange between the organism in a periphyton matrix, the boundary layer, and the bulk water in which the nutrient availability is affected by exchange with planktonic organisms (*a, upper*). Nutrient concentration gradient (——) between the bulk-water concentration (C_b) and the periphyton matrix concentration (C_m). The concentration at the matrix surface is C_o (*b, lower*). (Modified from Riber and Wetzel, 1987.)

including uptake and release by algae and bacteria and adsorption by particles. C_m will vary somewhat as a function of periphyton depth due to biological stratification and exchange processes. The concentration at the matrix surface is denoted C_o. In the bulk water, the nutrient or gas concentration (C_b) is correspondingly determined by the activity of the plankton. The exchange of nutrient or gas between the two systems will be through the diffusive boundary layer. The mass flux through the boundary layer, N, is given by the general equation

$$N = h(C_b - C_o)$$

where h is the boundary-layer mass transfer coefficient, which depends on hydrodynamic conditions, including currents and turbulence in the bulk water (Chap. 7), and the geometry of the substratum and periphyton community structure. In some cases, h can be estimated by hydrodynamic calculations (Skelland, 1974). Since the net flux depends on the difference between bulk water and matrix concentrations, flux may go in either direction and can change rapidly with differences in metabolic conditions. When both systems are limited by nutrients and the concentrations are low, the net flux will be small or even zero.

The structure of the periphyton community can also influence transfer flux rates. Because of the uneven development and distribution of periphytic microbiota, some groups of organisms project upward and contain valleys in between. This increased roughness can theoretically increase turbulence as water flow velocities increase over the communities (e.g., Nikora *et al.*, 1997). However, at low flow rates, much of the water mass passes over the community with little turbulence between the high and low points of the community (Riber and Wetzel, 1987).

E. Growth-Regulating Resources

A number of consumable resource requirements influence the metabolism, growth, production, and exploitative competition among periphytic communities. Important distinctions are needed among (a) external resources in the overlying and surrounding medium, such as light and nutrients, (b) internal resources that are obtained from abiotic or biotic sources within the substrata on which the periphyton communities are attached, and (c) internal recycling within periphyton among algae and associated microbiota, as summarized later (pp. 593–594). All of these parameters are summarized in a comparative manner in Table 19-1.

1. Habitat Space

The availability of space for colonization is essential and markedly affects the composite productivity of the periphytic communities. As will be emphasized in the discussion on microspatial community structure and on comparative productivity later, the periphytic communities attached to surfaces (e.g., rock, and sediments) that are relatively fixed in area available for colonization and development can rapidly be limited by space when other growing conditions are good. Although these communities can project somewhat above the surface, and certain stalked and filamentous algal forms do so (e.g., Hoagland *et al.*, 1982), the communities readily become compacted and stratified with steep gradients of light attenuation, redox, and accumulated products of fermentation (Wetzel, 1993a). In contrast, periphyton growing epiphytically on submersed macrophytes have manifold increased surface

TABLE 19-1 Summary of Common Responses of Epilithic, Epipelic, and Epiphytic Autotrophic Microbiota to Dominant Physical, Chemical, and Biotic Resource Parameters[a]

Environmental parameter	*Epilithic*	*Epipelic*	*Epiphytic*
Physical			
Water movement	High in rivers and upper littoral areas; molar abrasion high	High → low in depth gradient; decreasing with depth	High exchange in water column; low exchange within dense submersed macrophtye stands
Substrata	Stable at low-to-moderate water velocities	Unstable; subject to frequent disturbance	Stable in position, but changing with growth and senescence; often increasing seasonally
Temperature	Often, marked seasonal and diurnal fluctuations	Decreasing with increasing depth; higher and variable in epilimnion, low and more stable in metalimnion	Commonly high in shallow areas and changing widely seasonally
Light			
a. Quantity	Steep seasonal changes, especially low in canopied streams; steep exponential declines with depth	High → low in depth gradient; rapid decrease within sediments	Moderate to high; decreasing with depth but often increasing seasonally as submersed macrophytes develop upward into water column
b. Quality	Selective attenuation by water column	Steep selective attenuation of red and blue spectra within periphyton and within sediments	Selective attenuation in water column and by pigments within periphyton communities
Habitat available	Moderate; sorting by wave action and flowing water; sets particle size and surface area	Low; essentially two-dimensional	High, particularly among submersed macrophytes; projection into water column, three-dimensional
Chemical-biotic			
General conditions	Usually oxic; low nutrients	Reducing but diurnal oxic; high nutrients	Oxic, with diurnal variations
Inorganic nutrients			
a. Phosphorus	Low, often restrictive	Very high from interstitial waters	Low, variable; some from macrophyte
b. Nitrogen	Low, often restrictive	Very high from interstitial waters	Low, variable; some from macrophyte
c. CO_2 (HCO_3^-)	Usually adequate to high	Very high from sediment metabolism	Low to high; much internal recycling
d. Others	Usually adequate	High	Low; likely much internal recycling
Organic substrates/nutrients			
a. Organic micronutrients	Low, but variable with season in lakes and floodplain inundation in rivers	Very high from sediment metabolism	Low, high microbial competition, much internal recycling
b. Heterotrophy	Algal heterotrophy low or absent; bacterial heterotrophy low to moderate	Algal heterotrophy potentially moderate, likely low; bacterial heterotrophy very high	Algal heterotrophy low; bacterial heterotrophy high
Primary productivity	Low to moderate	Low	High
Symbiotic interactions among microbes and substrata	Low	Moderate to high	High to very high

[a] Greatly modified from Wetzel (1983b).

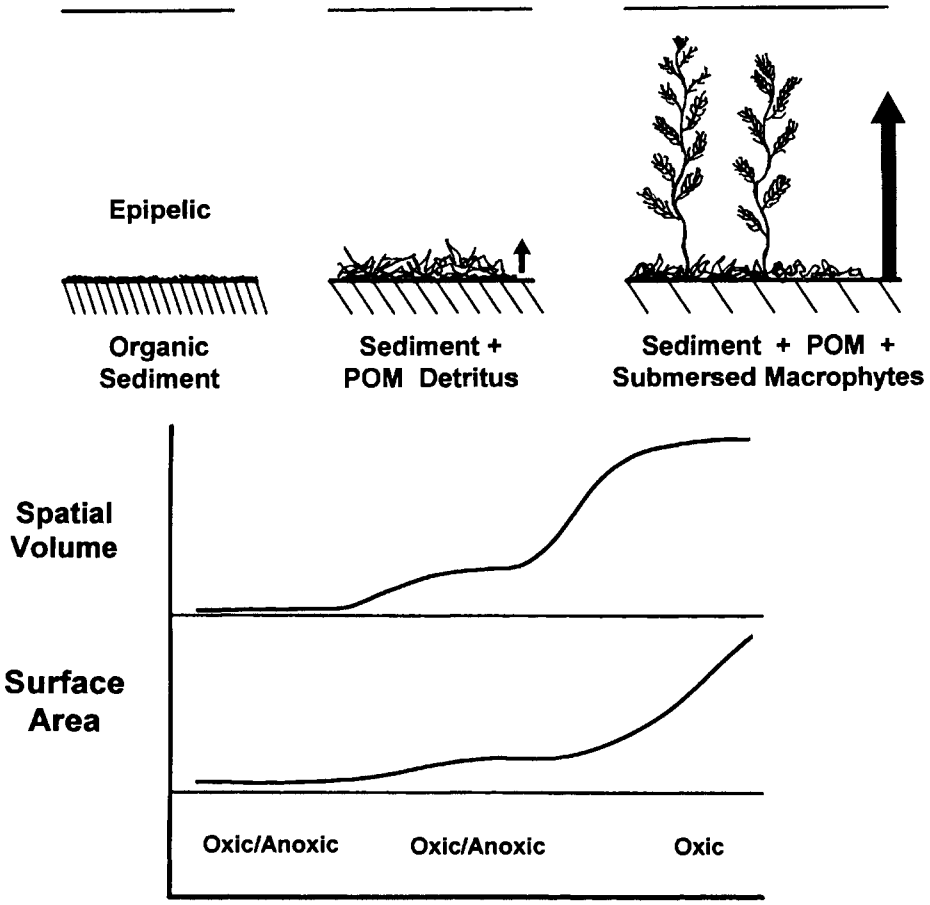

FIGURE 19-8 Transition of substrata surface area for attachment of periphyton from a predominantly two-dimensional spatial habitat through increasing surface area of particulate organic matter (POM) detritus to a fully three-dimensional spatial habitat of surface area of submersed aquatic plants.

area as the substrata becomes three-dimensional and projects upward into the water column and enhanced light field (Fig. 19-8). Not only does the surface area available for colonization increase exponentially but the spatial volume increases greatly with much greater exposure of the communities to largely oxic water column conditions (Fig. 19-8).

Analogous conditions occur in running waters. Although submersed macrophytes are much less well developed in streams and rivers (cf. Chap. 18), large woody debris often constitutes significant particulate organic debris (cf. Chap. 21) and can provide appreciable surface area for colonization by periphyton. Large woody debris tends to be moved downstream during flooding events considerably less than does fine particulate matter. In addition, stones and other particles tend to organize in clusters during high water velocity events and flooding in streams where a large anchoring stone (an obstacle clast) and smaller stones lying against the upstream face of the clast (the stoss) provide a hydraulic shelter for accumulation of smaller particles behind in the wake tail (Fig. 19-9). The surface area of the smaller rocks is increased considerably in comparison to large rock surfaces and shifts upward in a modest three-dimensional manner. Although the abrasive and export actions of flooding events often greatly reduce the abundance of attached algae, these microform bed clusters of hydraulic refuges can provide increased substrata area and support appreciably greater algal periphyton (e.g., Biggs *et al.*, 1997; Francoeur *et al.*, 1998). Among epipelic algal communities on organic sediments, however, a very small size of sediment grains, particularly below 125 μm, reduces the sites for microalgal community development (Cahoon *et al.*, 1999). With the shift toward a two-dimensional configuration, algal biomass is reduced and declines with the increasing percentage of very fine particles.

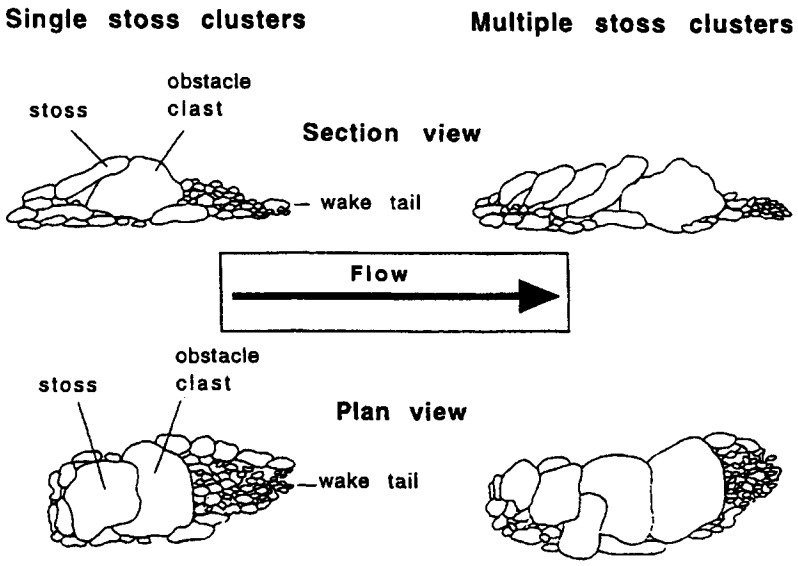

FIGURE 19-9 Microform bed clusters of sediment particles downstream of a large anchoring obstacle clast and smaller stones (the stoss) lying against the upstream face of the clast. (From Francoeur *et al.*, 1998.)

2. Nutrient Availability and Utilization from the Overlying Water

The physiological requirements and growth responses of attached algae are similar to those of phytoplankton, already discussed at length (cf. Chap. 15). Nutrients can be obtained by diffusion into the communities from the overlying water or from below from the substratum, which may be living or senescing (e.g., macrophytes), dead (organic detritus), or relatively inert, such as rock. Nutrient availability is determined by hydraulic conditions at the boundary layer that influence the thickness of the diffusive layer, the concentrations of compounds dissolved in the bulk environment of the surrounding water, and the metabolic activity of the attached organisms for utilization or production of the compounds.

At the macrogradient level of influence of nutrient concentrations of the overlying water on the development and production of periphyton communities, numerous studies have demonstrated that enrichments of nutrients, particularly P and N, in the overlying water commonly result in enhanced growth of attached algae on many different substrata. Examples are many. Growth responses of natural epiphytic communities of submersed macrophytes of an oligotrophic lake of Michigan were compared to that of another area of the littoral in which nutrients were administered to simulate release from macrophyte tissue (Moeller *et al.*, 1998). Epiphytic growth increased immediately where phosphate was released above the sediment, and after 10 weeks a 40-fold increase of epiphytic algal biomass occurred at the center of the plot as compared to biomass immediately outside of the m^2-plots. Whole-lake fertilization experiments with P and N in a shallow, subarctic Swedish lake resulted in massive increases in phytoplankton (Björk-Ramberg and Ånell, 1985). The resulting competition for light resulted in precipitous declines to less than half of the periphyton primary production to the total lake photosynthetic production. In unfertilized lakes, high periphyton productivity was maintained and contributed 70–83% of the total lake primary production. In habitats with relatively abundant nutrient concentrations, dense phytoplankton can shade periphyton development severely as the attached communities shift from nutrient to light limitations (e.g., Hansson, 1992).

Nutrient enrichment of the overlying water can also lead to marked changes in species composition of periphyton communities. For example, nitrogen enrichment led not only to an increase in epilithic algal abundance but to a shift from a diatom/N_2-fixing cyanobacteria-dominated community to one dominated by diatoms (Hawes and Smith, 1992). Where combined nitrogen insufficiency is maintained, N_2 fixation by attached cyanobacteria appears to be a successful strategy for survival in N-deficient environments on both a sustained and on a seasonal basis (Reuter *et al.*, 1983, 1986). However, species composition of algal periphyton is often relatively unresponsive to small changes in the nutrient concentrations and dynamics in the overlying water (e.g., Cattaneo, 1987; Pringle, 1987; Riber and Wetzel, 1987; Fairchild and Sherman, 1993; Neiderhauser and Schanz, 1993). Such recycling allows a short-term (days to weeks) functional separation of the metabolism within the periphyton from the nutrient concentrations in the overlying water, which indicates

the importance of intensive recycling of nutrients within the microbial community. Although that separation cannot persist indefinitely, it represents a marked adaptive advantage in which inputs from the overlying water can be directed largely to new net growth and production to augment the recycling occurring within the community between algae and bacteria (Wetzel, 1993a; see later discussion). If enhanced nutrient concentrations are sustained over long periods of time, distinct species change in the attached algal communities. For example, along a long gradient of nutrient enrichment as a point source to a wetland of the Everglades, periphytic algal growth decreased with greater distances from the point source of nutrients and eutrophic diatom species were replaced by oligotrophic diatom species as the total phosphorus concentrations decreased below ca. 15 μg liter^{-1} (McCormick *et al.*, 1996, 1998). Because of light limitations by the dense macrophytes under the eutrophic conditions of the gradient, periphyton production was greater in the oligotrophic sites despite the reduced phosphorus availability.

Rates of diffusion from the overlying water to the periphyton communities are influenced by the thickness of the boundary layer as well as solute or gas concentration gradients. Because the thickness of the boundary layer, within which fluxes occur by diffusion, decreases with increasing current flow across the surface, the boundary layer is less in rivers than in lakes. Regardless of flows, nonturbulent boundary layer thicknesses cannot be reduced below ca. 10 μm (Raven, 1970; Smith and Walker, 1980; Koch, 1990). In protected areas, such as in backwater areas, refuges, or within aquatic plant beds of both standing and flowing waters, very much lower water current velocities and much greater boundary layer thicknesses (10^2–10^5 μm) occur (e.g., Losee and Wetzel, 1993; Sand-Jensen and Mebus, 1996; Stevens and Hurd, 1997). In addition, the thicknesses of the microbial communities of standing waters are very large, often several millimeters or even centimeters, than in streams. Water movements reduce the thicknesses appreciably by the sloughing off of cells and export downstream (cf. Stevenson, 1996b).

Within limits, increasing current enhances nutrient uptake rates and as a result often also photosynthesis, respiration, cell division, biomass, and productivity (cf. many references cited in Stevenson, 1996b). Obviously, water movements across periphyton interfaces would replenish nutrient concentrations in microzones within the boundary layers where they have been reduced by metabolic uptake and chemical reactions. The advantage accrued by increasing water velocities is highly variable, but the saturating current velocity for algal assemblages in many flowing habitats is in the range of 4 to perhaps 20 cm s^{-1}. As periphyton densities and community thicknesses increase, collective metabolism per unit area and growth rates decline, and nutrient demand increases. Depending on the architecture of the attached communities, reliance on the nutrients from the overlying water stabilizes and there is generally a shift to greater internal recycling of nutrients and gases within the periphyton community (Fig. 19-10) (Wetzel, 1993a). As communities develop and increase in thickness, instability can occur and cells and portions of the community may slough off. Alternatively, very dense biomass development of filamentous algae, such as *Cladophora,* requires water currents, either unidirectional in streams or multidirectional as in wave-turbulent areas of lakes, presumably because of the inadequacy of internal recycling within the community.

With increasing current velocities, shear stress resulting in drag on periphyton causes losses and export of cells downstream (cf. Stevenson, 1996b). In addition, at high current velocities and small boundary layers, the metabolism of attached algae can be reduced for reasons not well understood. Regenerated nutrients and extracellular enzymes may be lost across the interface to the moving water before they can be effectively utilized.

Attached benthic algal and microbial communities themselves, as a whole, are not porous, but rather are relatively impervious to throughflow. In contrast, many of the substrata upon which the algae grow, such as sand and organic particles, are very porous to intrusions from surface flows and from groundwater sources. The scale of this movement, however, is much larger than that of the metabolic environment of the individual cells of the attached microbial communities. An important distinction is that although the substrata may be porous, the periphyton communities are not; within the periphyton, fluxes of nutrients are by diffusion along concentration-mediated gradients. Those gradients are highly dynamic as mediated by the photosynthetic and respiratory metabolism of the microbiota and, in the case of macrophytes, the living substrata upon which the attached community may be growing.

3. Nutrient Interactions of Attached Algae with Substrata

Attached microbial communities are well positioned to utilize nutrients and organic compounds released from the substratum upon which they are growing as well as from the water column. Marked differences in the species and quantities of epiphyte communities have been observed on natural as opposed to artificial plants in oligotrophic and mesotrophic habitats (Cattaneo, 1978; Cattaneo and Kalff, 1978; Eminson and Moss, 1980; Gough and Gough, 1981; Burkholder and Wetzel, 1989a,). Artificial nutrient

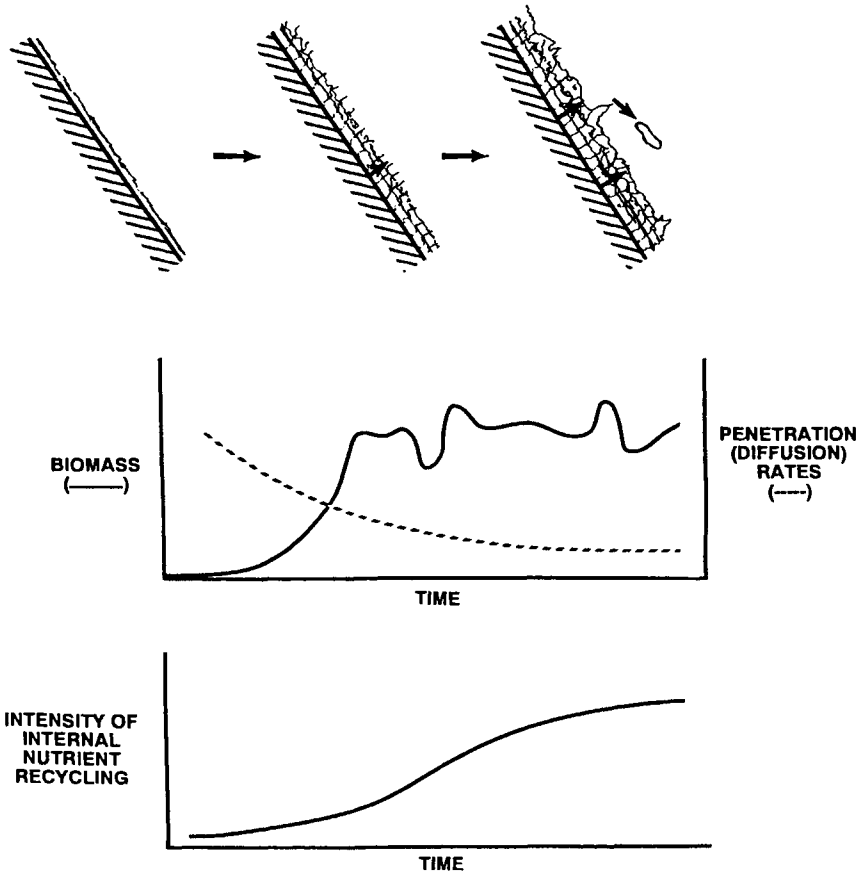

FIGURE 19-10 Successional development of, and increased nutrient recycling within, microbial communities on substrata (see text). (From Wetzel, 1993a.)

enrichment by experimentally following biomass differences on nutrient-diffusing artificial substrata in comparison to nutrient enrichments of the overlying water column have demonstrated that nutrients from the substratum are effective in increasing growth as well as altering community species composition (Fairchild *et al.*, 1985; Carrick and Lowe, 1988; Pringle, 1990). Although the capability for nutrient utilization is obvious from these studies, the question still remains about the utilization rates and significance of nutrient acquisition from the substrata under natural conditions.

Despite the early negativism that periphytic communities were obtaining essentially nothing nutritionally from the substrata, modern experimental evidences indicated quite the contrary—many periphytic communities are highly dependent upon the substrata for mineral and organic nutrients, particularly in oligotrophic and mesotrophic environments where the greatest periphyton productivity occurs. The influence of the supporting macrophytes in determining the epiphytic algal community is greatest in infertile waters. As the surrounding water becomes more fertile, external environmental factors influence epiphytic growth more than do inputs from the host macrophyte.

These relationships are well demonstrated among epiphytic algae and bacteria. In addition to the very large surface areas for colonization and retention of algae and other microbes, submersed macrophytes also provide significant sources of nutrients from both living as well as senescing tissues (Harlin, 1973; Moeller *et al.*, 1988; Burkholder and Wetzel, 1990; Burkholder *et al.*, 1990; Burkholder, 1996; Wetzel, 1996). The nutrients from the substrata internally supplement those diffusing into the attached communities from the water within and passing through the littoral zone. Complex nutrient interactions exist among algal species. For example, certain algal species growing adnate to the macrophyte can obtain >60% of their phosphorus from the macrophytes (Fig. 19-11). Algae near the outer portion of the community obtained less phosphorus from the macrophyte, but nonetheless significant quantities emanated from the plant. Even when phosphorus concentrations are very high in the water, some phosphorus, and presumably other nutrients, is

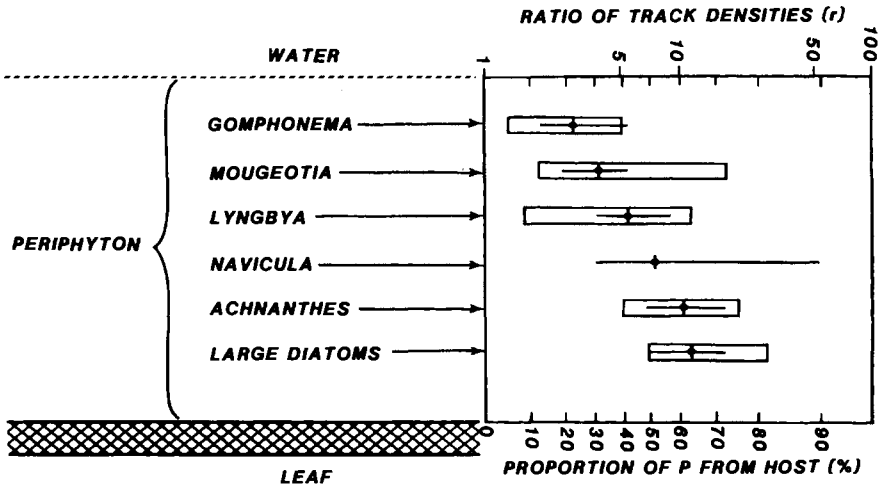

FIGURE 19-11 Sources of phosphorus within an epiphytic community on the submersed macrophyte *Najas flexilis*. Epiphytic algal taxa are arranged according to increasing proportion of phosphorus received from the host plant. The relation between *r* (*upper*) and the proportion (*lower*) is implicit in the dual scaling. A 90% confidence interval was calculated from raw data (open box) and corrected data (bar). (From Wetzel, 1990a, based on data from Moeller *et al.*, 1988.)

obtained from the macrophyte, simply because diffusion rates from the water into and within the complex epiphytic community are too slow to meet high metabolic demands. Little phosphorus incorporated into the periphyton passed to the macrophyte (Moeller *et al.*, 1988).

An additional example is the previously discussed (see Chap. 14) results of Jørgenson (1957), who found that diatoms epiphytic on the reed *Phragmites* competed with plankton for silica of the water early in the major growing season. Later in summer and fall, apparent utilization by the diatoms of silica from the *Phragmites* stems gave them a competitive advantage over planktonic forms (see Fig. 14-23). Certain other littoral algae also have high requirements for silicon (e.g., Moore and Traquair, 1976; Hooper-Reid and Robinson, 1978). Spring and autumnal population maxima are common in epiphytic diatom communities on submersed macrophytes and have been correlated with nutrient availability (e.g., Siver, 1978). Benthic microalgae are also important regulators of silica fluxes; epipelic diatom utilization can reduce fluxes to the overlying water and potentially influence phytoplankton growth and species composition (Sigmon and Cahoon, 1997).

As macrophytic tissue senesces, much of the phosphorus is translocated to rooting tissues. However, an inward swelling and disorganization of the epidermal cells of the macrorphyte occur (Rogers and Breen, 1981). Bacterial degradation penetrates and slowly degrades epidermal cell walls. This loss of cellular integrity of the leaves results in leaching from the leaves. Nutrients and dissolved organic compounds are readily utilized by periphytic microflora, which tend to develop profusely during autumn and winter periods in temperate regions. For example, more labile amino acids were readily assimilated and retained within periphyton communities to a greater extent (ca. 43%) than were more recalcitrant dissolved organic substrates leached from decaying emergent macrophytes (3–4%) (Bicudo *et al.*, 1998).

Microdistribution of species and groups of epilithic algae is correlated directly with differences in microdistributions of rock facies and differences in solubility of specific elements from the rock (Smith *et al.*, 1992). Mineral nutrient (Fe, Si, and trace elements) can leach from the rock substratum and be utilized by the attached microflora with alterations in microdistributions of algal species. The distribution of epipsammic algae is influenced and their productivity often increased by nutrient content and microscale differences in diffusion and microflows among interstitial waters through sandy sediments, as well as sand grain morphology and topography (Krejci and Lowe, 1986, 1987). In both streams and lakes, hyporheic and groundwater flows can enhance nutrient availability and productivity of attached algae, often in very patchy areas of the benthic materials where local variations of inflows enter the stream or lake (e.g., Hagerthey and Kerfoot, 1998).

Epipelic algae growing upon organic sediments often develop into dense communities, both loosely attached and in dense, matlike aggregations. Often these communities are several millimeters in thickness. Even

in relatively sparsely developed communities on sediments, photosynthesis of the epipelic algae and community respiration can markedly affect nutrient fluxes from the sediments to the overlying water (reviewed by Burkholder, 1996; Wetzel, 1996). Fluxes are affected by metabolic alterations of redox and coupled chemical mobilities and by direct assimilation and utilization. The importance of epipelic photosynthesis, oxygen, and pH in a microzone at the sediment–water interface and bacteria to the mobility of phosphorus from the sediments and to nitrogen fluxes from the sediments was discussed in detail earlier (Fig. 13-8; pp. 215, 253, and 602). The production of oxygen and penetration of oxygen into the sediments can result in supersaturated oxygen conditions of interstitial water and rapid shifts, in a matter of minutes, in redox potentials between highly reducing to highly oxidized conditions. Fluxes of phosphorus from the sediments to the overlying water are nearly totally suppressed under these oxidizing conditions, as well as from microbial utilization (Carlton and Wetzel, 1988). Such marked diurnal fluctuations in oxygen and other chemical microgradients have been shown in various epipelic loosely attached algae and mat-type algal communities, (e.g., Jørgensen *et al.,* 1979, 1983; Hansson, 1989). Attached benthic algae also scavenge nitrogen as NH_4—N from interstitial waters of sediments (Jansson, 1980).

It should be recalled that the exchange of nutrients and metabolic products is not all from the macrophyte or detritus to the attached periphyton community. Much discussion (summarized later) has evolved on the negative effects of dense periphyton communities on the physiology of the supporting macrophytes, such as light reduction and especially inhibition by competition for nutrients and gases from the surrounding water. As we have seen in the discussion of the macrophytes (Chap. 18), the rooted macrophytes rely heavily on nutrient acquisition from the sediments and on internal recycling of oxygen and CO_2 within the intercellular gas channels. Nonetheless, it is likely that gases, particularly CO_2, produced within the periphyton communities diffuse to the macrophyte for assimilation. Similarly, it is probable that certain nutrients recycling among periphyton constituents also diffuse along concentration gradients to the macrophytic cells at the interface with the periphyton. Other than the studies of Moeller *et al.* (1988), there are few experimental demonstrations of such fluxes, which is a fertile area of investigation.

4. Nutrient Recycling within the Periphyton Community

The relatively significant hydraulic isolation by diffusive boundary layers of periphytic communities from the overlying water, as well as the close physical proximity of their cells, indicates a tight physiological coupling between attached algae and bacteria. Much of the evidence for this interdependent metabolic relationship is circumstantial. Dissolved organic matter released from stream benthic algae during photosynthesis was taken up by periphytic bacteria, and attached bacterial productivity was positively correlated with the release of dissolved organic matter from benthic algae (Haack and McFeters, 1982; Kaplan and Bott, 1989). The productivity of bacterial periphyton may depend to a greater extent upon external dissolved organic substrates in early stages of colonization and then shift to a greater reliance on organic substrates from algal production as the communities thicken and become more complex in structure (cf. Sobczak, 1996). More direct experiments in which photosynthesis of attached algae was inhibited under controlled conditions demonstrated that periphytic bacterial productivity depended on algal photosynthesis (Neely and Wetzel, 1995). Either algal exudates of organic matter stimulated bacterial production or photosynthetic oxygen increased aerobic bacterial activity, but in either or both cases a direct metabolic coupling was indicated.

Attached bacterial metabolism may also enhance algal metabolism and growth in periphyton, as has been shown often in mixed cultures, for a number of potential reasons (e.g., Lange, 1971; Haines and Guillard, 1974; Mouget *et al.,* 1995). Enhancement of algal growth can result from bacterial reduction of oxygen tension that could reduce photorespiration or from increased production of CO_2 or growth factors such as vitamins that the algae cannot produce. Phosphorus uptake kinetics of periphyton, for example, were found to be acutely limited by boundary-layer mass transfer and a power function of flow velocity (Riber and Wetzel, 1987). Kinetic calculations based on turnover measurements indicated that internal recycling of phosphorus and recycling from the boundary layer, rather than external uptake, accounted for most phosphate turnover within intact periphyton. Under optimal conditions, it was estimated that the turnover time of phosphorus was so rapid that phosphorus was recycled between algae and bacteria every 15 s. Similarly, denitrification rates by denitrifying bacteria within epiphytic periphyton are high in the dark and on senescent macrophyte tissues but inhibited by oxygen produced by the periphytic algae or the living macrophyte tissues (Eriksson and Weisner, 1996). Analogous results were found for the effects of light in epipelic periphyton, where photosynthetic oxygen of algal photosynthesis reduced the rate of denitrification within the microbial community precipitously (Risgaard-Petersen *et al.,* 1994).

Recently, efforts have been made to evaluate enzyme activities produced by periphyton communities as an estimate of potential capacities to hydrolyze organic substrates for specific nutrients, such as phosphorus or nitrogen, and energy. Many assays estimate enzyme activity by enzymatic degradation of a nonfluorescent substrate into a highly fluorescent product in the water surrounding the periphyton (e.g., Chappell and Goulder, 1992, 1994; Jones and Lock, 1993; Scholz and Boon, 1994). Because enzymes can occur and function within and throughout the attached microbial community, their synthesis and use can be only partially related to enzyme concentrations in the overlying water. Moreover, the enzymes may be hydrolyzing organic substrates of the substratum to which they are attached. The lack of explicit evaluation of sources and of where the enzymes are being produced and utilized by the use by the attached microbial communities confounds how they are functioning. Recent substrate assays allow evaluation of individual insoluble fluorescent products at the cellular levels for specific enzyme activities such as phosphatase and protease (Huang *et al.*, 1998; Francoeur and Wetzel, 2000).

Negative interactions can also occur. For example, competition for the same nutrients, well known among the plankton, likely operated among attached microbiota as well. Algae and bacteria may produce substances that are inhibitory to the growth of the competitors. Because of the large number of species present in periphyton communities, it is probable that both positive and negative responses are occurring simultaneously in the same community.

Aquatic fungi, primarily hyphomycetes, are abundant constituents of periphyton on and within submersed leaves, wood, and other organic detritus (e.g., Bärlocher, 1992; Shearer, 1992). Fungal growth and productivity usually far exceed that of attached bacteria on these substrata (cf. Chap. 21). However, hyphomycetes are rare on nonorganic substrata such as rocks. Even though fungi utilize simple, soluble organic molecules, they likely compete ineffectively with bacteria that have high affinities for these substrates (Suberkropp and Klug, 1976). However, there is some evidence for mutualistic fungal–bacterial interactions even at the species-specific level (Bengtsson, 1992).

5. *Light Availability and Utilization*

Light attenuation in relation to periphyton photosynthesis must be examined at two spatial scales, namely, with depth in the water column before reaching the periphyton and at the microscale within periphyton communities. The selectively spectral diminution of light with depth has been discussed at length in Chapter 5 (pp. 56–60), where it was shown that dissolved organic matter selectively removes large portions of the ultraviolet and blue portions of the spectrum and the water molecules per se selectively attenuate the infrared and red portions of the spectrum. Particulate matter such as phytoplankton is relatively unselective but can attenuate total photosynthetically active radiation appreciably when in high densities.

In very clear lakes, light can penetrate well below the common lower limit (ca. 10 m) of growth of vascular aquatic plants and support appreciable periphyton communities on rocks, sediments, and particulate detritus. For example, in Lake Tahoe of California—Nevada light adequate to support photosynthesis of epilithic periphyton can penetrate to 60 m (Loeb *et al.*, 1983). Although littoral attached communities may require modest light (ca. 200 μmol m^{-2} s^{-1}) for photosynthetic light saturation (e.g., Turner *et al.*, 1983; Hill, 1996), net photosynthesis occurs at much lower intensities, such as in the range of 5–25 μmol m^{-2} s^{-1} (Wetzel *et al.*, 1984; Lorenz *et al.*, 1991). As discussed in the descriptions of community and productivity dynamics later, depth and turbidity-associated alteration of light is clearly a factor regulating development of periphyton. Experimental analyses of light interactions under natural conditions are few but corroboratory (e.g., Hudon and Bourget, 1983; Marks and Low, 1993).

Light obviously affects rates of photosynthesis and thus influences primarily growth. Often, estimates of algal periphyton are made by evaluating biomass, commonly as chlorophyll *a* per unit area. Instantaneous biomass does not necessarily estimate growth rates over time, however, where mortality from disturbance, grazing, pathogens, and other factors is significant. In headwater streams where streambank vegetation is abundant and shades the channel, light reduction can markedly suppress periphyton photosynthesis. Algal biomass is often 5-fold times higher in unshaded sites in comparison to those with full tree canopy, particularly when grazing pressure is low or moderate (many references cited in Hill, 1996). In both lakes and streams, light- or nutrient-enhanced primary production that is not expressed in increased periphyton biomass when grazing is heavy is instead reflected in increased grazer growth or densities (Hill *et al.*, 1995; Moeller *et al.*, 1998).

Light is attenuated very rapidly within periphyton communities, but the community structure is heterogeneous and spatially variable on substrata. As a result, light gaps occur, and variable light attenuation occurs among cell aggregations, calcium carbonate crystals, and weakly pigmented algal cells and through dead diatom frustules that act as light conduits (Losee and Wetzel, 1983). Different species dominating the epiphytic community can also influence the nature of

cellular structure and relative penetration of light into the communities as a whole (Dodds, 1992).

In addition to reductions in quantity, epiphytic microbiota can also modify severely light quantity and quality reaching the supporting macrophyte. It was demonstrated experimentally that it is primarily the photosynthetic pigments of algae and cyanobacteria that attenuate selectively light in the red (ca. 675 nm) and particularly the blue (ca. 430 nm) portions of the spectrum (Losee and Wetzel, 1983; Jørgensen and Des Marais, 1988; Plough *et al.,* 1993). Heterotrophic bacteria, dead diatom frustules, and carbonate crystals were nonselective. The recent development of fiber-optic microprobes (100 to <50 μm in size) now allow detailed examination of light quantity and quality within periphytic communities with minimal disturbance (e.g., Jørgensen and Des Marais, 1988; Dodds, 1989; Plough *et al.,* 1993; Kuhl and Jørgensen, 1994). Backscattering of light within these communities increases the total scalar irradiance to which embedded algal cells are exposed.

Algae of periphyton communities are relatively well protected by carotenoid pigments against high light intensities, and little photoinhibition has been demonstrated (cf. review of Hill, 1996). Algal productivity and photosynthetic oxygen production of periphyton were significantly reduced by small enhancements of ultraviolet irradiance, which in turn reduced the bacterial productivity coupled to rates of algal photosynthesis (Kahn and Wetzel, 1999). Microscale reductions in water level of only a few millimeters, as is common in shallow littoral and wetland areas on a daily basis, can result in marked increases in UV irradiance intensities and alterations in periphytic metabolism. There is some evidence (Bothwell *et al.,* 1993; Francoeur and Lowe, 1998) for long-term adaptation by periphytic diatoms in streams, however, where initially inhibitory effects of UV on growth were reversed after several weeks of species succession.

F. Growth-Regulating Mortality and Losses

In addition to growth regulation and exploitation competition for resources, a number of processes contribute to mortality, losses, and interference competition: predatory mortality, largely by grazing invertebrates and fishes; natural physiological senescence, death, and population turnover; diseases and viral mortality; and physical disturbances from water movements and substrata instabilities. Each is briefly summarized here and in Table 19-1.

1. Grazing Mortality of Periphyton

Ingestion of microbial communities attached to surfaces has many ramifications for nutrient cycling, productivity, and energy flows in inland waters. Several aspects need to be considered, namely: (1) direct ingestion and mortality of periphyton; (2) release of incompletely metabolized dissolved and particulate organic detritus by the grazers; (3) effects of grazing mortality on the relative productivity of the periphyton communities and the substrata (e.g., living macrophytes) supporting the communities; and (4) nutrition and energy derived by the grazing animals (see Chap. 22).

The growth and productivity of the sessile attached microbiota, particularly epiphytes on submersed portions of macrophytes, can be affected by grazing activities of animals (e.g., insect larvae, snails, crayfish, tadpoles, and certain phytophagous fishes) (Flint and Goldman, 1975; Mason and Bryant, 1975; Bowen, 1978; Eichenberger and Schlatter, 1978; Kitchell *et al.,* 1978; Hunter, 1980; Hagashi *et al.,* 1981; Power *et al.,* 1985; Lamberti *et al.,* 1987, 1992; Brönmark, 1989; Feminella *et al.,* 1989; Feminella and Resh, 1991; Steinman *et al.,* 1995; Steinman, 1996). In certain cases, when the epiphytic algal biomass is low, growth and productivity per unit area of the attached algal and bacterial community can be stimulated (turnover rates increased) by moderate levels of grazing. Moderate grazing could improve access of algae to nutrient and light resources from the overlying water and enhance algal growth as a result. For example, in grazing of stream periphyton communities by snails, the physical disruption and release of nutrients by ingestion and partial digestion can accelerate nutrient regeneration to the overlying water that is normally retained and recycled within the periphyton community. Similar results were found among grazing oligochaetes and snails on epiphytic periphyton of a lake (Kairesalo and Koskimies, 1987). From a quarter to over half of the phosphorus ingested as food was released from the animals through defecation and excretion.

Heavy grazing pressures often result in reductions in overall periphytic biomass or productivity under the commonly used experimental conditions of high grazer density without natural predation pressures upon the herbivores. However, many factors influence the attached microbial–grazer interactions (cf. Wetzel, 1983b; Steinman, 1996), including (a) herbivore type; (b) periphyton density and stage of development; (c) nutrient availability (concentrations, gradients, and water movements at the interface); (d) light quantity and quality; and (e) past disturbance frequency. Clearly, increased nutrient availability and light commonly have positive effects and grazing has negative effects on biomass and productivity of periphyton (e.g., Hart and Robinson, 1990; Rosemond, 1993; Rosemond *et al.,* 1993; Moeller *et al.,* 1998). Compensatory responses of both periphyton and grazing communities are

marked and rapid, and as a result of these variable impacts, patterns resulting from the effects of herbivory are difficult to delineate. Extreme care is needed in extrapolation of grazing studies under intensively controlled laboratory conditions to field situations (cf., e.g., Fuller *et al.,* 1998). Although the instantaneous biomass of periphyton may be reduced by grazing, often the productivity of the periphyton community is enhanced by the constant cropping of portions of the attached communities. Little if any effects of macroinvertebrate grazing could be detected on the detachment and redistribution of attached bacteria (Leff *et al.,* 1994).

Very little evidence exists for true species-specific selectivity of attached microflora by grazers. Some experimental studies suggest that algivorous protozoan herbivores and oligochaete worms select prey diatoms on the basis of size and certain species (Bowker *et al.,* 1985; McCormick, 1991). Grazing macroinvertebrates are generally omnivorous and randomly ingest algae, bacteria, particulate detritus, and inorganic deposits (e.g., $CaCO_3$). The structure of benthic microbial communities, although highly variable, can influence grazing efficacy. For example, prostrate species are attached adnate to the substratum, upright or stalked species form a middle level, and filamentous species often emerge from the community to an upper level (Hoagland *et al.,* 1982). Mayfly larvae with gathering collector-feeding structures tend to feed along the outer layers among the loosely attached portions of the periphyton. Snails and caddisfly larvae use rasping and scraping mouth parts and are adapted to feed among the low-profile, adnate, attached periphyton. As a result, larger diatoms (>20 μm) may be more effectively removed by these herbivores than small green algae and cyanobacteria (Cuker, 1983). Herbivore abundance may not be in synchrony with seasonal variations in periphyton production, which may result in apparent minimal grazing impacts. Low-to-moderate grazing usually results in no appreciable changes in attached algal diversity, but intense grazing pressure can reduce diversity (e.g., Lowe and Hunter, 1988; Mulholland *et al.,* 1991). Certain fatty acid components of attached algae are distinctly inhibitory to grazing invertebrates (e.g., LaLonde *et al.,* 1979), and fatty acid composition of the periphyton can be altered by grazing (Steinman *et al.,* 1987). Whether this response is an allelochemical induction, as occurs among the phytoplankton (cf. Chaps. 15 and 16), is unclear.

There is some evidence that grazing mortality of periphyton is a greater percentage of total death and turnover of attached communities in stream ecosystems than in standing waters. Most of the microflora attached to macrophytes and other substrata is not consumed by animals, but instead enters detrital decomposition pathways within the ecosystem (cf. Chap. 23).

2. Disturbance

Disturbance to the habitat and general milieu of periphyton communities is relative in relation to physical disruptions, such as by water movements, and external impacts such as chemical alteration (e.g., acidification) or pollution. The latter topic is a subject of its own and is extensively treated in pollution and water quality literature. For example, much of the saprobic system of evaluating water quality is based on indicator species of attached algae and other microbiota under different conditions of pollution (e.g., Sládeček, 1973).

In lakes with relatively stable water levels, periphyton is well adapted to living in shallow areas of turbulence from wave actions. When periphyton that developed in relatively quiescent, nonturbulent habitats are subjected to unusual water turbulence, such as that associated with an episodic storm event, loosely attached microbiota can be dispersed. Stalked diatoms and similar microbes attach tightly to substrata but are sufficiently flexible to tolerate appreciable water movement (Cattaneo, 1990; Hoagland and Peterson, 1990).

In reservoirs, and to a certain extent also in wetlands, water levels can fluctuate widely. Obviously, the lowering of the water level and desiccation of periphyton communities suppresses growth and increases mortality. Although many diatoms and cyanobacteria are capable of surviving long periods of desiccation, others such as desmids cannot (cf. review of Goldsborough and Robinson, 1996). Fluctuating water levels in reservoirs often expose unconsolidated sediments to wave turbulence and result in resuspension and high turbidity. Similarly in shallow ponds and wetlands, high wind activities can increase turbidity and reduce light penetration. Suppression of photosynthesis and growth of periphyton accompanies such light reductions. If turbidity is short-lived, however, nutrient availability can be increased from the sediment disturbance and result in a positive effect on growth. Conversely, epidemic developments of the exotic zebra mussel (*Dreissena polymorpha*) in lakes can reduce planktonic turbidity by feeding activities and result in improved underwater light distribution (Nalepa and Schloesser, 1993). Increased periphyton growth can occur both in response to enhanced light but also because of the greatly increased surface area for colonization by the profuse development of mollusk shells.

In river ecosystems, the physical effects of turbulence and drag on cells of periphyton can be severe in removal of loosely attached cells and exporting them downstream and in disturbing substrata (Peterson *et al.,* 1994; cf. review of Stevenson, 1996b). Although

attached microbial communities are well adapted to water movements, particularly up to about 15 cm s^{-1}, at sudden spates of greater velocities, the export of cells increases precipitously. Conversely, immigration of cells from upstream and colonization on substrata decrease as current velocities increase.

Complex indirect effects on periphyton communities of fluctuations in current velocities in rivers occur (Stevenson, 1996b). The size of sediment particles moved is proportional to current velocities (cf. pp. 97ff), and increasing currents can move substratum and attached microbes with devastating effects from abrasion and redistribution to a less suitable habitat downstream (buried, deeper or shaded areas, et cetera). The time between spate events of sufficient magnitude to move substrata is important. If sufficiently long to allow reasonable development of the microbial communities prior to the next major disturbance, overall community productivity can be quite high. Frequent or unusually high hydrographic events can markedly suppress periphyton productivity.

Changes in current velocities, particularly strong episodic events, can also modify the distribution and movement of herbivorous benthic invertebrates and fish, particularly in central areas of stream channels of fast currents (Poff and Ward, 1992; Hart and Finelli, 1999). Any disturbance of the sediments, such as from nesting of insects or fish, similarly affects the development of periphyton and alters the spatial distribution of attached microbiota in streams.

3. Other Losses

Losses of natural communities of attached microbiota by natural senescence and death, by parasitism particularly by viruses, and by disease are poorly known. As among the phytoplankton and bacterioplankton, nonpredatory losses are certainly significant and likely constitute over half of the natural mortality. This area is a fertile field for study.

G. Community Analyses and Seasonal Dynamics

The development of attached microbial communities on a new surface passes through several stages. Firstly, accrual occurs with colonization of the substratum and subsequent growth in approximately an exponential sigmoid curve (Fig. 19-10). The duration of the accrual phase toward maximum biomass varies with conditions, of course, but is commonly in the range of one to 2 weeks under natural conditions. A shift then occurs to a predominance of internal nutrient recycling and a greater balance between growth and loss processes by death from parasitism, disease, and grazing as well as sloughing and export of cells from the community (Fig. 19-10). Growth is approximately balanced where high productivity is maintained photosynthetically by internal recycling of nutrients and gases and utilization of external resources from the overlying water and counterbalanced by losses and disturbances.

Quantitative evaluations of attached benthic algal populations are much more difficult than qualitative floristic analyses. Recognition of the various habitats and their associations is a problem common to both analyses which is accentuated by ineffective sampling techniques that are difficult at best. It is difficult to separate epipelic algae from sediments, but separation is necessary for accurate enumeration. Phototactic responses of the algae can assist in this separation; alternatively, one can use other biomass methods such as pigment content (correcting for pigment degradation products common to sediments). Quantitative sampling of epilithic and epiphytic algal/cyanobacterial populations is even more difficult, but a number of devices and procedures have been devised (see the reviews of Sládečková, 1962; Lowe and Laliberte, 1996; Stevenson, 1996; Wetzel and Likens, 2000) that permit some degree of quantification. The problems of quantitative sampling of attached algae are further compounded by the settling of casual species originating from the plankton and metaphyton into the benthic populations, especially during winter. Only detailed sampling of the different communities combined with metabolic assays of growth can resolve this problem.

1. Use of Artificial Substrata

Because of extreme habitat and community heterogeneity, artificial substrata of uniform composition and colonizable area are commonly used to estimate colonization and growth characteristics of attached algae. In addition to examination of microbiota on natural substrata, artificial substrata that have been used include glass slides, glass fiber filters, concrete blocks, rocks and rock plates, sand, various plastic and metal plates, and wood.

There are several restrictions inherent in the use of artificial substrata. Marked differences in colonization rates and biomass accrual have been found in relation to the position of the supported substrata and their location within the aquatic system. For example, vertically positioned plates on which sedimenting organisms from the plankton or metaphyton could not accumulate contained less biomass but more realistically simulated population characteristics found on natural substrata than did those positioned horizontally (e.g., Castenholz, 1961; Pieczyńska and Spodniewska, 1963). The influence of water movement or simply the process of retrieving the slides following incubation can lead to significant losses of attached microflora. Some

organisms will not adhere to artificial substrata such as glass until early successional forms have colonized the substratum, which may or may not occur within the period of incubation (e.g., Blinn *et al.*, 1980). Apparently glass is not seriously selective for the attachment of diatoms (Patrick *et al.*, 1954), although diatoms can utilize some of the silica from the glass. Grazing can lead to alterations of attached communities that may influence the results, depending on whether the questions being addressed concern specific attached flora or the entire attached community.

Some investigators have positioned artificial substrata in the pelagic zone of lakes or main flow of streams quite removed from sites of natural substrata. Although these analyses may have some value in a relative sense, such as in evaluating responses to inorganic, organic, or acidic toxicants in different water types or venues (Genter, 1996; Hoaglund *et al.*, 1996; Planas, 1996), they are of relative or little value in evaluating natural attached communities.

The most serious criticism that can be directed against studies using artificial substrata centers on the implicit assumption that any metabolite, inorganic or organic, of the living or nonliving substrata has no appreciable effects on the metabolism and growth of the attached community. Similarly, it is assumed that the metabolism of the attached microfloral community has no reciprocal effects upon the substratum. Recent evidence for such synergistic effects is overwhelming that much more than a passive relationship exists among the attached microbiota (see discussion on pp. 590–594).

With these thoughts in mind, the difficulties of quantitatively evaluating natural population growth on natural substrata become apparent. Even though the mutual metabolic relationships are real, especially among epiphytic algae and the supporting macrophytes, measuring the effects of the heterogeneous attached populations on the highly variable substrata often exceeds the capacities of existing methods. The problem is a technical one that must be approached without the use of artificial substrata. Alternatively, when used critically, artificial substrata can be a meaningful tool for the approximate estimation of biomass accrual of many attached microorganisms. Much of our existing information on these communities is based on analyses using artificial substrata. Only a few investigations have addressed the *in situ* rates of algal productivity by means of metabolic techniques.

2. Examples of Population Fluctuations

The detailed investigations of the population dynamics of epipelic algae of several lakes of the English Lake District (Round, 1957a–c, 1960, 1961a,b) serve to illustrate several characteristics of these populations, as well as the potential spatial, temporal, chemical, and biotic factors affecting growth. Diatoms completely dominated the epipelic community, and patterns of distribution could be discerned on the basis of general chemical features of the sediments and overlying water. Other algal groups were less well represented. The Volvocales were very sparse, and the Chlorococcales were represented only by the genera *Pediastrum* and *Scenedesmus*. Although not abundant, the desmid flora was richer in species than other groups. Euglenoids were much more common on more organic-rich sediments. Little correlation was found between the growth cycles of the epipelic and planktonic cyanobacteria, and in some lakes, a conspicuous development occurred on the sediments but not in the plankton. Epipelic cyanobacteria developed equally well in alkaline, neutral, and slightly acidic waters.

In general, a larger diatom biomass corresponded to a higher organic-matter content of the sediments, and growth was better on sediments with more leachable silica. Moderate organic-matter content of the sediments favored cyanobacterial populations, while low populations were associated with sediments of very high and very low organic-matter content. Populations of the poorly represented Chlorophyceae and the flagellated forms were distinctly greater on organic-rich sediments. Although little correlation was found between population numbers and sediment content of sodium, potassium, iron, or manganese, the diatom, cyanobacterial, and flagellated algal populations were directly correlated with calcium content. Algal growth was also greater on sediments with high phosphate content.

Although population numbers of epipelic algae exhibited large variations from lake to lake, and between sites within lakes, and with depth, certain consistent patterns emerged. The main growth period of epipelic diatoms and cyanobacteria of lakes of this moderate temperate region[3] was in the spring, commencing about February (Fig. 19-12). Except for the wave-active shallow zone (0–1-m depth), population numbers were relatively constant on sediments between 1- to 6-m depths; below this depth, numbers decreased precipitously to practically nil at depths greater than 8 m. The growth of the dominant benthic diatom, *Tabellaria flocculosa*, was shown experimentally to be largely related to light intensity, which decreased rapidly with increasing depth (Cannon *et al.*, 1961; Hillbricht-Ilkowska *et al.*, 1972). Strictly phototrophic diatoms are more sensitive to light than cyanobacteria, whose

[3] Ice cover is rare and usually short-lived, typically only a few days in duration.

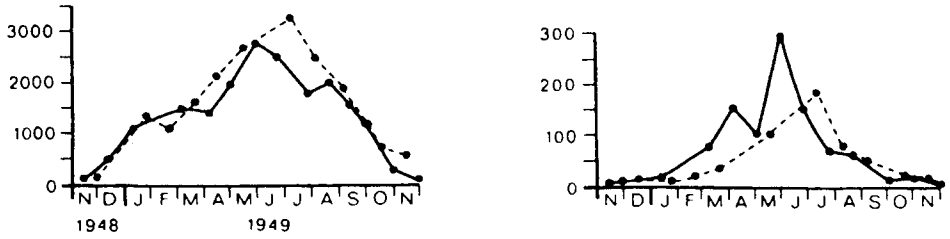

FIGURE 19-12 Seasonal cell counts of epipelic diatoms (*left*) and cyanobacteria (*right*), in which all the depth stations are added together for each sampling date in the photosynthetic zone (1–6 m) of Lake Windermere (———) and Blelham Tarn (- - - -), England. (Modified from Round, 1961b.)

depth distribution usually extends considerably deeper than that of the diatoms. The general seasonal biomass of epipelic algal populations in the photosynthetically illuminated zone generally followed the curves of incident light and water temperature.

In streams, light availability frequently limits benthic algal growth (e.g., Whitton, 1975; Wetzel, 1975b; Marker, 1976; Aizaki, 1978; Biggs, 1996; Hill, 1996). Light availability can be altered markedly by seasonal changes in the leaf canopy of deciduous trees adjacent to the stream. The succession of species within the overall annual cycle of epipelic algae is a much more elusive and complex matter. Among planktonic populations of algae, discussed in some detail in Chapter 15, the changes in physical and chemical parameters, particularly those associated with periods of circulation in stratified lakes, are very large and can influence dominance and competitive abilities of the species. The sudden collapse of populations at certain times of the year is related, in part, to these "shock" events of disturbance.[4] Epipelic populations tend to occur largely above the metalimnion, so the effects of disruption of stratification may be less on these populations than among the plankton. The seasonal succession of attached algal species is, however, just as pronounced as succession among the planktonic species (Round, 1972).

No temperate epipelic algal species is known to persist as a numerically dominant species over an entire year. Specific epipelic algal populations tend to increase quite rapidly and then decline equally rapidly. Often, several successive species associations tend to dominate during an annual cycle, each phasing in to the next from live cells that have remained in the habitat for some time after cell division has ceased. The substrata provide innumerable microhabitats, certainly many more than exist under planktonic conditions of the pelagic zone. Therefore, one would expect a large number of coexisting species in the attached algal community at almost any time of the year. Sampling techniques that tend to aggregate algae from many different microhabitats can obscure this distribution.

Annual and seasonal cycles of epipelic algae are marked and complex (e.g., Round, 1964a; Ilmavirta, 1977; Sheath and Hellebust, 1978; Romagoux, 1979). Diatom growth in lakes often commences in early spring and reaches maximum cell numbers in April to May in the temperate zone, after which a decline occurs in midsummer prior to a smaller autumnal peak that is over by November. Although this pattern is similar to that of planktonic species, the epipelic algal pattern occurs more slowly than that found among planktonic algae. On shallow sediments, the epipelic algal populations tend to exhibit early winter and spring maxima, followed by a later midsummer maximum.

Spring maxima are common among attached algal populations of streams, although these populations are subject to irregular decimation and disturbance by moving substrata during spates (see, e.g., Douglas, 1958; Sand-Jensen *et al.*, 1988). In woodland streams, the seasonally changing light passing through the terrestrial canopy can shift the productivity pattern from one that is autotrophic in the spring to one of essentially heterotrophic dominance later in the season (Kobayasi, 1961; Biggs, 1996; and also discussion in Chap. 22). That seasonal pattern may also reflect a seasonality in herbivory by aquatic invertebrates, which tends in the temperate zone to be greater in the autumn and early winter. Where disturbance is common, particularly from spates and flood events, seasonal patterns with a spring maximum are frequently interrupted. Immediately after a flood event, periphyton may recover rapidly and achieve maximum biomass during a window of time when invertebrate grazer densities are low because invertebrate reproduction and recolonization is much slower (Grimm and Fisher, 1989; Power, 1992; Peterson, 1996).

The seasonal population dynamics of epiphytic algae growing on submersed portions of macrophytes are

[4] A concept discussed by Round (1971).

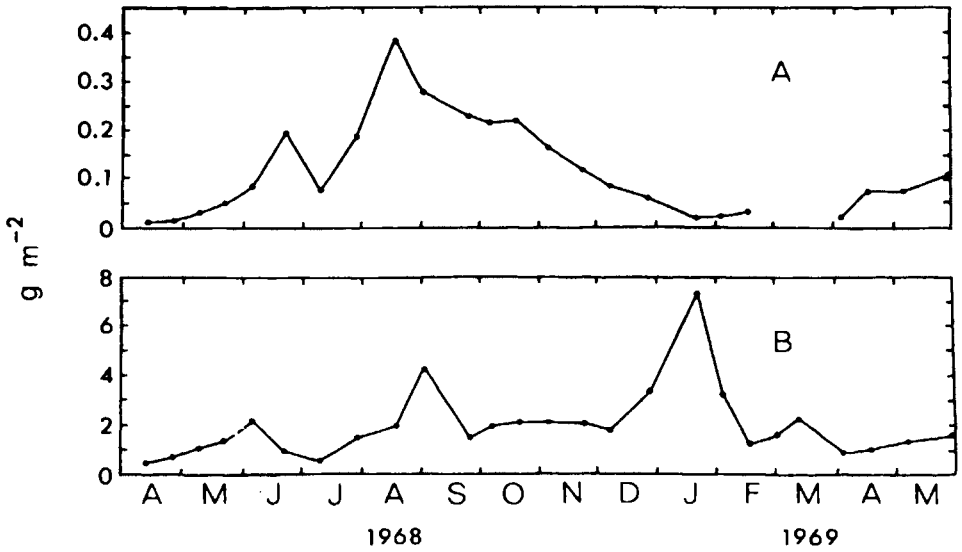

FIGURE 19-13 Chlorophyll *a* concentrations, extrapolated upward to g m^{-2} of the littoral zone on the basis of estimated surface areas of the macrophytes, of algae attached to artificial substrates in dense stands of the littoral zone dominated by (*A*), the emergent bulrush *Scirpus acutus*, and (*B*), the submergents *Najas flexilis* and *Chara*, Lawrence Lake, Michigan. Note the marked differences in the scales of the ordinate in g m^{-2}. (After Allen, 1971.)

much more involved because the surface area available for colonization and growth is continually changing as the macrophytes grow, senesce, and enter detrital phases. Computations of the population changes of the total epiphytic algal community are rare, but changes obviously are quite different among different supporting macrophyte communities (Kowalczewski, 1975a,b; Cattaneo and Kalff, 1980; Müller, 1996). For example, changes in the biomass of attached algae associated with a zone of the emergent bulrush *Scirpus acutus* were more than an order of magnitude lower and out of phase with those of algae attached to substrates in a shallow zone dominated by submersed plants (*Najas flexilis* and *Chara*) (Fig. 19-13). Detailed analyses were made of the population and community dynamics of epiphytic algae and cyanobacteria on leaves of the submersed sedge *Scirpus subterminalis* in a hardwater temperate lake (Burkholder and Wetzel, 1989a). Epiphytic diatoms comprised a mean of 90% of the total epiphytic algal biovolume, whereas cyanobacteria contributed a mean of 88% of the total algal–cyanobacterial cells. Epiphytic cyanobacteria were a negligible portion of the algal biomass except during autumn, when they contributed 40% of the total. However, cyanobacteria were estimated to produce >50% of the total algal carbon (Fig. 19-14).

Part of the reason that the productivity of epiphytes is so high is their persistence within the water column throughout much of the year (Fig. 19-15). Most submersed macrophytes are perennial plants; many species grow or persist in a dormant or "evergreen" condition for much of the year (cf. Chap. 18). The above-sediment biomass of submersed macrophytes commonly reaches a maximum in the spring–early summer period and gradually declines as resources are diverted to rooting tissues. An appreciable macrophyte biomass and surface area can persist all year in subtemperate regions and even under ice in temperate regions.

Epiphytic biomass and productivity tend to be relatively constant throughout the year (Fig. 19-15). Competition among epiphytic algae and phytoplankton for nutrients can reduce epiphytic development in the midyear period. This late spring maximum decline potentially results from increasing nutrient limitations, temperature, and grazing pressure. Epiphytic growth, particularly by cyanobacteria, often increases markedly in late summer and autumn. At this time, lake mixing occurs during autumn, nutrient supplies increase in the water, temperatures decline, macrophyte senescence accelerates, and epiphytic diatom/cyanobacteria populations increase (Fig. 19-15). Diatom productivity is particularly high in winter and spring periods.

Most of the nutrients of actively growing macrophytes are obtained from the sediments. As was demonstrated, most (95–99%) of phosphorus, for example, is obtained from sediment interstitial water and is retained within the plant and recycled repeatedly (cf. Chap. 13, Fig. 13-9). Nutrients from littoral water are very actively assimilated by the loosely attached epiphytic periphyton, incorporated into the periphyton,

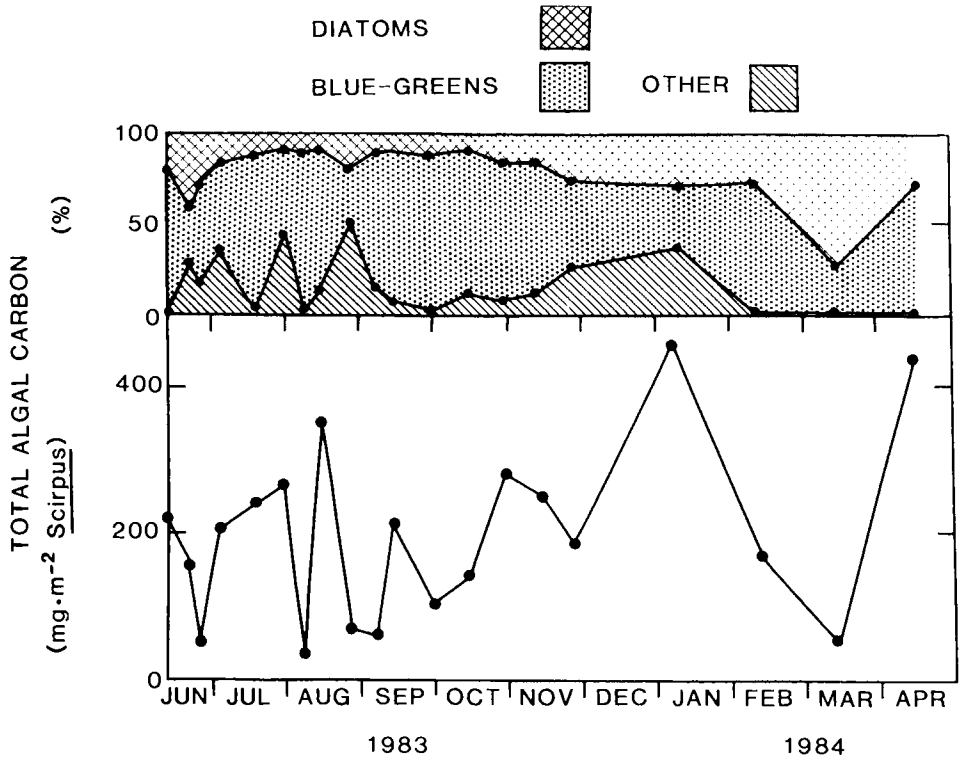

FIGURE 19-14 Organic carbon content of epiphytic algae and cyanobacteria (blue-greens) on apical portions of the submersed sedge *Scirpus subterminalis* in Lawrence Lake, southwestern Michigan. (From Burkholder and Wetzel, 1989a.)

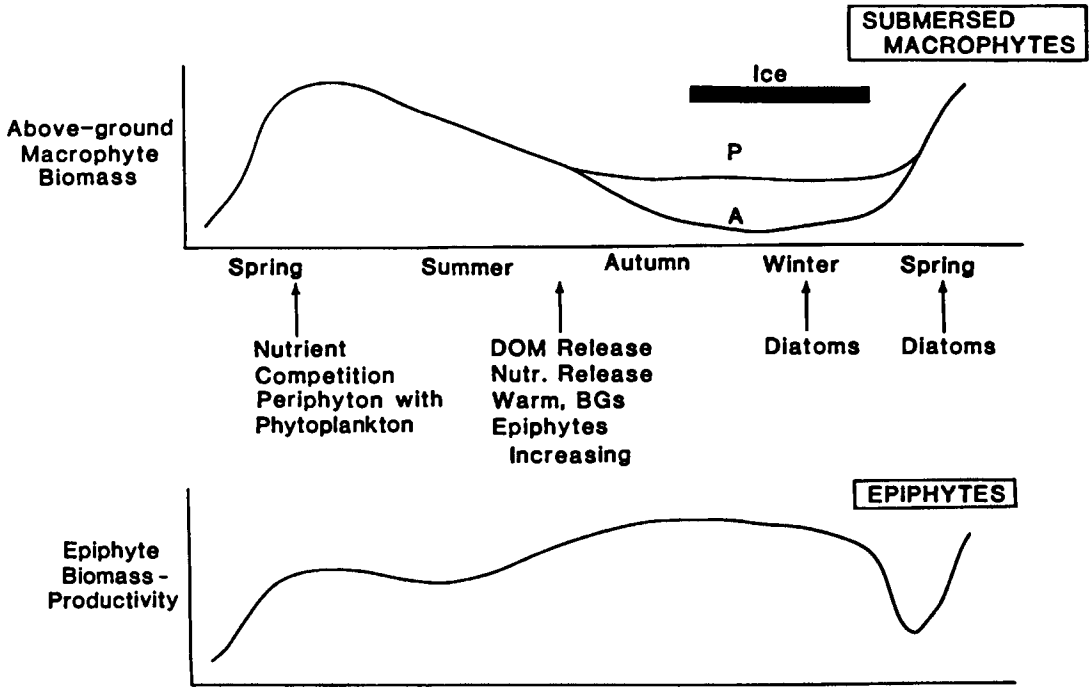

FIGURE 19-15 Generalized relationship of epiphytic biomass and productivity in relation to variations in aboveground biomass of submersed macrophytes (see text for discussion). *P* = perennial and *A* = annual plants; *BG* = cyanobacteria. (From Wetzel, 1990a.)

and intensively recycled. Relatively little of these nutrients pass to the macrophyte. The periphyton, rather than the submersed macrophytes, functions as the primary scavenger for a limiting nutrient such as phosphorus from the water. During dormancy phases and senescence of aboveground foliage, much of the critical nutrients is translocated to rooting tissues. Losses from the leaves are readily utilized by the periphytic community, which tends to develop profusely during autumn and winter periods. As the senescing macrophytes with their epiphyte communities collapse to the detrital mass near the sediments, much of the nutrients is incorporated into the sediments and is actively retained and recycled by the sediment epipelic microflora (Fig. 13-9). The fluxes from the sediments to overlying water are actively influenced by photosynthesis of epipelic algae within the microzone at the sediment–water interface and by the bacterial metabolism below the interface (see Chaps. 12 and 13).

The general assumption that the chemistry of the overlying water has a direct controlling effect on epipelic algae has not been verified experimentally. If buried in the sediments, the algae may also be exposed not only to lower intensities of light but also to anaerobic conditions within the sediments. Many benthic algae can survive anaerobiosis for several days and may retain considerable photosynthetic potential in the absence of oxygen (Moss, 1977). For those species adapted to epipelic existence, the proximity to the totally different chemical milieu of the interstitial water within and immediately adjacent to the sediment–water interface can give them a distinct advantage that is quite unrelated to chemical events occurring in the overlying water. For example, the biomass of epipelic algae commonly increases as the organic carbon, nitrogen, and phosphorus content of the sediments increases (Skorik *et al.*, 1972). A large portion of the ammonia nitrogen of interstitial water of sediments was found to be assimilated by benthic algae (Jansson, 1980). Dissolved organic nitrogen compounds released to the overlying water originated largely from the algae. Nitrogen fixation by epipelic, as well as epiphytic, cyanobacteria and heterotrophic bacteria is common (Finke and Seeley, 1978; Moeller and Roskowski, 1978) and, as indicated earlier (Chap. 12), can constitute a significant input of combined nitrogen to some lakes. Yet the epipelic forms are not completely exempt from the characteristics and events of the overlying water. For example, a high content of dissolved organic matter or a seasonally variable development of planktonic algae or of macrophytic vegetation populations would markedly affect the quality and quantity of light reaching the sediments, the thermal régime of the sediments, water movements near and along the sediments, et cetera. Although it is intuitively apparent that changing events in the overlying water can influence the species succession and productivity of epipelic algae, studies of these interactions are essentially nonexistent. The whole area of investigation is uncharted and difficult but is one that is approachable by the systematic application of modern research techniques.

II. METABOLIC INTERACTIONS IN THE LITTORAL REGIONS

A. Relationships between Algae and Bacteria of Periphyton

The macrophytes release large quantities of both inorganic compounds (e.g., oxygen, carbon dioxide, phosphates, silica, et cetera) and organic compounds secreted during active photosynthesis and released by autolysis during senescence into the immediate proximity of adnate epiphytic microflora and littoral waters (e.g., Howard-Williams *et al.*, 1978; Siver, 1980; cf. Chap. 18). As we have seen, this proximity alone is conducive to transfer and exchange of nutrients (PO_4 and CO_2) between the epiphyte and the supporting plant. In hard waters, precipitation of calcium carbonate is induced by photosynthetic activity (Chap. 11) to form a matrix intermixed with the microflora and mucoid substances (predominantly polysaccharides and peptides). The epiphytic bacteria actively utilize, in part, organic substrates released by the macrophytes and algae. Dissolved organic compounds not utilized by this association and not adsorbed within or to surfaces of precipitating calcium carbonate, enter the pool of littoral dissolved organic matter for further degradation by bacteria (Fig. 19-16). In turn, epiphytic bacteria produce CO_2 and certain organic micronutrients (e.g., vitamin B_{12}) (cf. Wetzel, 1969, 1972), that can serve as growth factors for the macrophytes or algae, or both. Photoassimilative active uptake of labile organic substrates has been demonstrated for a submersed angiosperm in axenic culture and for a species of the macroalga *Nitella* (Smith, 1967; Wetzel, unpublished).

There is evidence to support the conclusion that most phytoplanktonic algae cannot actively augment photosynthesis by heterotrophic utilization of organic substrates when in competition with bacteria that actively assimilate the same substrate (e.g., Mayfield and Inniss, 1978; cf. Chaps. 15 and 17). The immediate juxtaposition of attached algae to the metabolically active area of a living plant and bacterial concentrations can give them a distinct competitive advantage over their planktonic counterparts living in a habitat where

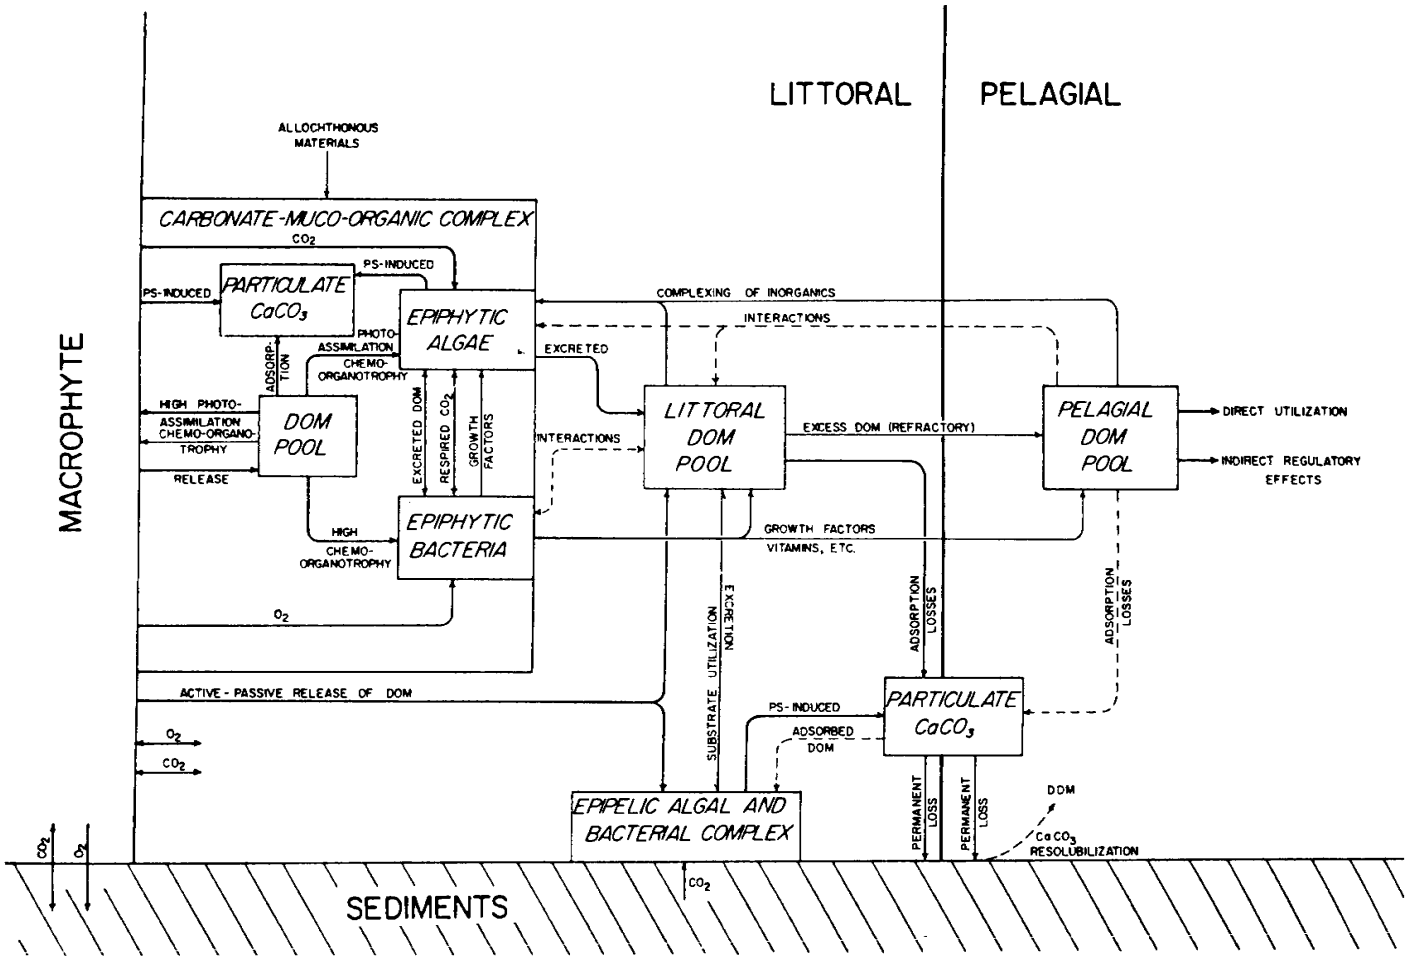

FIGURE 19-16 Diagrammatic representation of major metabolic pathways and interactions in the littoral zone of a typical lake; see text for discussion. *DOM* = dissolved organic matter; *PS* = photosynthesis. (Modified from Wetzel and Allen, 1970.)

nutrients are much more dispersed (see, e.g., the studies of Allen, 1971).

Analogous interactions certainly exist within the epipelic associations of algae and bacteria. Unfortunately, even less is known about the qualitative and quantitative metabolic interrelationships of these attached forms and their substrate than is known about the epiphytic microflora. Potential sources of inorganic nutrients and labile dissolved organic substrates are likely to be greater under reducing conditions of the sediment–water interface than at the surfaces of macrophytes.

Dissolved organic substrates emanating from littoral sources or from the drainage basin are degraded, flocculated, and adsorbed as they travel to the pelagic zone (cf. Chaps. 18, 20, and 23). The rates and kinds of "processing" that occur en route are highly variable and depend upon the dynamics of seasonal and individual differences in the physical and chemical parameters of lakes. The littoral region can be viewed as functioning as an effective but selective metabolic sieve or sink for certain dissolved organic compounds and inorganic nutrients from littoral and external sources toward the pelagic zone (e.g., Howard-Williams and Lenton, 1975; Klopatek, 1975; Lee *et al.*, 1975; Gaudet, 1977, 1978, 1979; Howard-Williams and Howard-Williams, 1978; Mickle and Wetzel, 1978a, b, 1979; Prentki *et al.*, 1978; Stewart and Wetzel, 1981a; Wetzel, 1990a, 1992). During this transport, the more easily degradable organic substrates tend to be decomposed in the littoral zone and compounds of greater recalcitrance (i.e., slower turnover rates) tend to move toward the open water. Therefore, even though the amounts, rates of utilization, and fate of inorganic and organic compounds released from the littoral zone vary seasonally and differ from lake to lake, their direct and indirect effects on the metabolism of the pelagic microflora can be great in many lakes.

B. Effects of Light Availability

Within dense stands of emergent macrophytes, the rapid attenuation of light plays a major role in the reduction of photosynthesis of littoral algae. For example, in reed stands of *Phragmites*, Straškraba and Pieczyńska (1970) found a rectilinear relationship between the percentage transmission of light through the emergent parts of the reed and shoot density. As much as 96% of the incoming radiation was removed above the water, whereas the density of the stand had little further influence on the light availability under water. The rather low light intensities occurring in reed stands, especially those of an average or high density, substantially lowered photosynthesis and biomass of phytoplankton entering the stands from the pelagic region. Photosynthetic activity of attached algae is similarly reduced in these dense stands. Cutting experiments showed a large increase in photosynthetic activity of each algal group, and the increase was directly proportional to the percentage improvement of light conditions (Table 19-2). In less dense stands of emergent plants, as, for example, in low-growing sedges, light reduction is not as serious, but a strong limitation of photosynthesis of phytoplankton still has been observed (Straškraba, 1963). Some decompositional organic compounds released from the plants were also believed to contribute to this reduction.

TABLE 19-2 Effect of Increased Light Availability on Photosynthetic Activity of Phytoplankton and Attached Algae in a Dense Stand of *Phragmites communis* before and after Removal of Plant Shoots, Smyslov Pond, Czechoslovakia, in September[a]

Attached algae				
Gross production (mg O_2 dm^{-2} day^{-1})	3.1		8.7	

[a] From data of Straškraba and Pieczyńska (1970).

Another striking example of the importance of the shading of light from periphyton by emergent macrophytes was determined in the Everglade wetlands of Florida (Grimshaw *et al.*, 1997). Photosynthetically active radiation reaching the periphyton communities was reduced by only 35% in the more open sloughs of the emergent sawgrass (*Cladium mariscus*) but by 85% or more in dense stands of cattail (*Typha domingensis*). Photosynthetic rates of periphytic algae and cyanobacteria in sawgrass habitats were reduced by about 30% from those in openwater slough habitats; the net production rates of periphyton communities in the cattail communities were reduced by 80 ± 8% of rates in the open communities.

Light reduction by a seasonal development of an emergent macrophyte canopy can cause a seasonal reduction in the epiphytic periphyton as well. For example, the productivity of epiphytic algae on *Equisetum* was very high in early summer but declined during the summer as shading by the macrophytes increased (Kairesalo, 1984). Herbivory by snails also increased as the summer season progressed.

Light availability can also be reduced by abiotic factors at intermittent intervals and have marked effects on periphyton productivity. For example, algal biomass epiphytic on floating meadows of aquatic plants in an Amazon floodplain lake was severely reduced by inorganic turbidity imported by river water (Engle and Melack, 1993). Nonetheless, high turbidity impacted composite phytoplankton growth more severely, and as a result epiphytic algal productivity per unit area was much higher than that of the phytoplankton.

C. Attached Algae as a Source of Phytoplankton

The concept that littoral benthic algae can give rise to plankton algae emerged many years ago. It was assumed that plankton algae formed resting spores that overwinter in or upon the sediments and that under conditions favorable to germination and population development, algae on the sediments served as the inoculum for the phytoplankton. In moderate-size to large lakes, there is no evidence for any conspicuous buildup of algae on the sediments before a plankton bloom, but rather only afterward when the dead plankton settle out onto the sediment (Round, 1964).

An alternative concept is that planktonic populations are always present in the water, although in extremely low concentrations. These few remnants of past populations can then serve as the inoculum for a rapid population increase under favorable growing conditions. This situation seems to be the case for most species.[5] In one of the better studies of algae, resting spores of the diatom *Asterionella formosa* were not observed, and no evidence exists that appreciable numbers originate from shallow areas (Lund, 1949). Massive population developments more commonly originate from exponential growth of live cells present in the pelagic waters.

Some phytoplankton do settle out during periods of reduced turbulence and remain in a resting state on the sediments until water movements are again sufficient to reintroduce the resting cells back into the plankton.[6] *Aulacoseira*[7] *italica* is a large diatom that clearly does enter a resting stage on the sediments, particularly under ice cover and during summer stratification (Lund, 1954, 1955). There is no evidence, however, for active growth on the sediments, which are often below the photic zone. Resuspension of filaments during autumnal and spring circulation serves as a large inoculum for the rapidly developing pelagic population. Similar results have been found for cyanobacteria (Preston *et al.*, 1980; Fallon and Brock, 1981; cf. Chap. 15).

In shallow lakes, ponds, and backwater areas of streams and wetland, the separation between epipelic or epiphytic algae and littoral metaphyton is less distinct. It is common to find strictly benthic algae or predominantly planktonic forms intermixed, especially following irregular storm turbulence (see, e.g., Lehn, 1968; Moss, 1969a; Moss and Abdel Karim, 1969; Brown and Austin, 1973a). In shallow lakes in which thermal stratification is irregular and intermittent, shifts in the percentage composition of largely planktonic or of epipelic algae can be rapid. For example, in a pond in southern England, nonmotile species dominated planktonic populations only when the water column was relatively turbulent. Motile species persisted in the water column, and the largest biomass of any species occurred when the water column was stratified. In the shallow Obersee of Lake Constance, southern Germany, littoral diatoms and algae of the metaphyton are transported to the open water, especially during spring storms (Müller, 1967).

III. PRODUCTIVITY OF LITTORAL ALGAE

A. Quantitative Evaluations

Quantitative evaluation of attached algae is basic to analyses of population changes and productivity but is confounded seriously by the simultaneous collection of much debris and dead cells in various stages of decomposition. Identification, enumeration, and estimation of biovolume, with all proper precautions and statistical evaluations, have a number of advantages for detailed analyses (Lund and Talling, 1957; Lund *et al.*, 1958; Vollenweider, 1969b; Wetzel and Likens, 1991, 2000; American Public Health Association, 1998). Although developed for plankton, these methods of analysis usually are equally applicable to studies of littoral algae. Species enumeration can be used to estimate productivity when coupled to meaningful biomass parameters such as cell volumes or carbon at the species level (cf. Chap. 8). Cellular constituents such as pigment concentrations can be used effectively as an estimate of attached algal biomass (e.g., Szczepański and Szczepańska, 1966). It is particularly imperative, however, to correct for pigment degradation products (Wetzel and Westlake, 1969; Wetzel and Likens, 2000) and not to overextend these estimates, which vary

[5] Termed *holoplankton* in older literature, in contrast to meroplankton that have resting stages in sediments and are not observed in the open water for long periods of time (i.e., they are planktonic only at certain times in their life history).

significantly in response to an array of physiological conditions.

B. Biomass Measurements

To a limited extent, a temporal series of biomass measurements permit estimates of rates of primary production. These estimates generally underestimate actual productivity because of losses via excretion of organic compounds, respiration, mortality, decomposition, grazing, et cetera. The observed rates also are influenced by the rate of colonization of new propagula, which is generally faster when conditions for growth are better. Hence, the observed accumulation of biomass is a composite of colonization and production. The climax accumulations of biomass on substrata yield little insight into the production dynamics that have occurred before the cumulative maximum in balance between production and losses.

The rate of community turnover is an average of several variable species rates and is difficult to determine from biomass analyses. Subjective errors also occur in determinations of attached algae of lakes and streams; important factors include the frequency of sampling and estimation of the degree of colonization that represents a climax stage of the community (Sládeček and Sládečková, 1964; American Public Health Association, 1998). Apparently higher turnover rates result as the sampling interval is decreased, especially when the intervals are shorter than a month; sampling frequency must be compatible with reproductive rates of dominant algal populations.

Productivity values of littoral algae are difficult to compare from one lake to another, or even seasonally within a lake, because of the diversity of techniques employed. Very few *in situ* metabolic measurements have been made on these communities. As mentioned earlier, many analyses have employed artificial substrata to reduce the natural heterogeneity of the algae. The resemblance of benthic algae on artificial substrates to those on adjacent natural substances is highly variable and deviates significantly, both qualitatively and quantitatively, with seemingly minor differences in substrata, environmental differences in microhabitats, and particularly in rates and duration of colonization. The discrepancies found between populations on natural and artificial substrata are sufficient to necessitate a critical evaluation of each study in which artificial substrata is used (see, e.g., Tippett, 1970; Warren and Davis, 1971). The extent of compromise must be determined in the application of any ecological method, and this problem becomes especially acute among littoral communities.

The admixture of estimates of productivity values in the ensuing discussion should be viewed as representing the range encountered under natural conditions. Although no attempt has been made to summarize all of the literature, which is quite diverse and of variable precision, the examples are presented to point out primary characteristics and emphasize the major contributions that the attached flora can make to freshwater ecosystems.

C. Spatial and Temporal Variations

The rates of primary production of attached algae are obviously dependent upon the substrate area available for colonization within the zone of adequate light. In some lakes, the littoral substratum may be relatively uniform for much of the perimeter, but in most cases, the variation is great. Moreover, living macrophytic substrata are constantly changing, especially in the more seasonal temperate regions. An example of this spatial heterogeneity in productivity can be seen in a 2-yr analysis of littoral components—macrophytes, littoral phytoplankton, and attached, largely epiphytic, algae—in Mikolajskie Lake, northern Poland (Pieczyńska, 1965, 1968; Kowalczewski, 1965; Pieczyńska and Szczepańska, 1966). Simultaneous measurements in midsummer along numerous points of the littoral zone showed much variation, which was accentuated during sporadic mass appearances of sessile cyanobacterium *Gloeotrichia* and the filamentous green alga *Cladophora* (Fig. 19-17). Similar spatial variations in numbers and species assemblages have been demonstrated in the littoral of a eutrophic lake in British Columbia (Brown and Austin, 1973b).

Seasonal fluctuations in primary productivity of attached algae are also quite variable, and are analogous to changes in biomass discussed earlier. In general, estimates of biomass accrual, such as chlorophyll, and

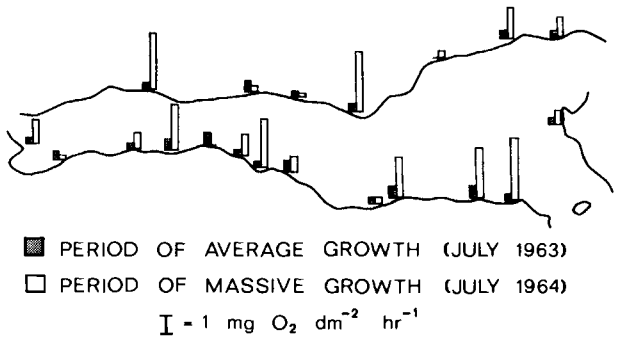

FIGURE 19-17 Spatial variations in the simultaneously measured rates of primary production of attached algae in different areas of the littoral zone of Mikolajskie Lake, central Poland. (After data of Pieczyńska and Szczepańska, 1966.)

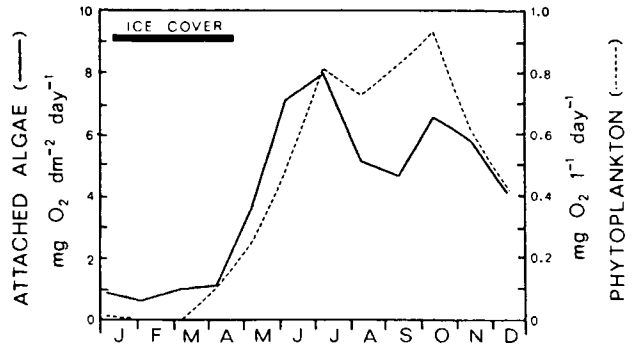

FIGURE 19-18 Rates of primary production of attached algae and phytoplankton in the littoral zone dominated by the emergent macrophyte *Phragmites*. (Modified from Pieczyńska and Szczepańska, 1966.)

in situ measurements of production rates by carbon uptake or oxygen production are fairly similar, particularly during periods of active growth (see Pieczyńska and Szczepańska, 1966; Allen, 1971; Hickman, 1971a; Hunding and Hargrave, 1973; Goldsborough and Brown, 1991; Robinson *et al.*, 1997). Reductions in temperature and light under winter conditions clearly are the dominant causal mechanisms limiting photosynthesis both seasonally and vertically with depth (see Figs. 19-18 and 19-19). The productivity of attached algae collected under ice and exposed to increased light was found to increase greatly and approached values obtained under summer conditions. In the example from Mikolajskie Lake, productivity in the spring increased rapidly in both the attached algae and littoral phytoplankton, decreased in midsummer during maximum development of the littoral macrophytes, and then increased in the fall with a bloom of diatoms. Where submersed macrophyte biomass persists in 'evergreen' form under ice, and that ice is not covered by dense light-reducing snow for long periods, attached algal productivity, particularly by diatoms, can be very high (Fig. 19-15).

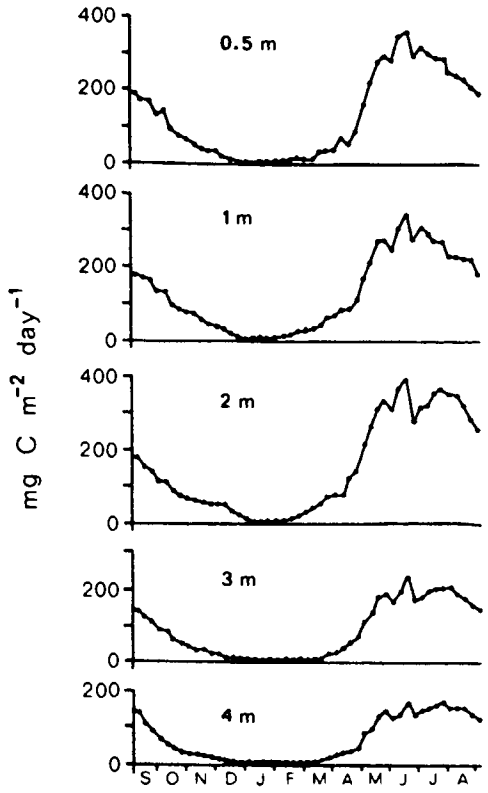

FIGURE 19-19 Weekly mean values of gross primary production rates of epipelic algae in shallow Marion Lake, a composite from five littoral stations, southern British Columbia. (Redrawn from Gruendling, 1971.)

Photosynthetic enhancement of epipelic algae was shown experimentally when sediment samples were moved to shallower depths with improved light conditions (Table 19-3). Hunding (1971) has shown that benthic diatoms exhibited light-saturated photosynthesis over a wide range of light intensities. During summer, light-saturated photosynthesis even at very high irradiances showed no photoinhibition up to 38 klux (= 742 μmol quanta m^{-2} s^{-1}). The light-saturated

photosynthetic value decreased in autumn, indicating that maximum photosynthetic rates are probably maintained under reduced prevailing light conditions at that time of year. Similar depth relationships can be seen in comparisons of pigment biomass and primary productivity of epipelic algae in a small English lake (Table 19-4) and in a clear, deep alpine lake (Capblancq, 1973).

Within sediments, the rates of carbon fixation and the chlorophyll concentrations of epipelic algae are attenuated very rapidly with depths of a few millimeters (Table 19-5), whereas significant rates and pigment concentrations of epipsammic algae penetrate somewhat deeper. As discussed earlier, the light-mediated metabolism of these algae is probably intermittent and occurs predominantly when wave action circulates sand grains up near to the sediment surface. Biomass and rates of production of epipsammic algae were consistently greater throughout the year than those of epipelic algae in the same lake system.

[a] All samples incubated at the same light conditions. From data of Hickman and Round (1970).

Seasonal cycles of primary productivity of epiphytic algae differ considerably in relation to the type of supporting macrophyte. In the Lawrence Lake example shown in Figure 19-20, the annual maxima occurred in midsummer when macrophyte biomass, and hence substrata for colonization and growth, was greatest. At this time conservative estimates exceeded 8 g C m^{-2} littoral zone day^{-1} of carbon fixed by epiphytic algae in this oligotrophic lake. Even though the rates of production per substratum area were similar among the emergent bulrush *Scirpus acutus* site and that of the much more dissected submersed macrophytes *Najas* and *Chara*, the much greater area available for colonization in the submersed macrophyte site increased the rates of production by epiphytic algae in the littoral zone area dominated by the two more dissected macrophytes. In both cases, annual maxima were found in August near the sediments at the basal portions of the macrophytes. Although the winter rates of carbon fixation by attached algae among the *Najas–Chara* were 100–200 times greater than those among the *Scirpus*, the values per substrate area among the more open *Scirpus* littoral were consistently much higher, ranging from double to an order of magnitude higher per area of plant. Causes for this difference are unknown, but the more open *Scirpus* bed had greater light and water movement than occurred in the dense *Chara* beds. Furthermore, as discussed in Chapter 18, the macroalga *Chara* is known to release sulfur-containing organic compounds that are antimicrobial.

In an oligotrophic lake in New York, photosynthetic rates of epiphytic algae were approximately 5% of the photosynthetic rates of the supporting macrophytes (Sheldon and Boylen, 1975). Epiphytic algal densities increased with the seasonal growth patterns of the macrophytes; maximal algal colonization of leaves of the plants, however, was similar per unit time. Epiphytic algal productivity from older leaves, lower on the macrophyte, was as much as 10-fold greater than that of epiphytes from younger top leaves. Similar results were found in the more detailed studies of Burkholder and Wetzel (1989a).

Rates of epiphytic bacterial utilization of simple organic substrates (glucose and acetate) followed first-order active transport kinetics (Allen, 1971). These rates were nearly an order of magnitude greater per unit area in the submersed macrophyte littoral region than among the emergent plants. This difference is potentially related to the greater quantities of organic substrates released by the submersed plants than by emergent macrophytes.

A comparison of production rates of attached algae among lakes and climatic regimes is difficult because of the variety of methods that have been used. However, there is a clear tendency for the rates of primary productivity of the attached algae to increase with decreasing latitude and longer growing season (Tables 19-6 and 19-7). The turnover times of the attached algal populations also tend, not unexpectedly, to decrease under the better growing conditions. The highest production values recorded are from subtropical springs in which constant temperatures, high flow, and adequate nutrient supplies combine to enhance high rates of production. A similar relationship is seen among streams (cf. Wetzel, 1975b; Aizaki, 1978; Wetzel and Ward, 1992), although available data are few and very difficult to compare in a satisfactory manner.

A comparison of the rates of in-stream primary productivity of attached algae among intensively studied sites from many geographical and geological regions of North America showed rates to be similar (Table 19-8). Concentrations of chlorophyll *a* of benthic microbiota spanned an order of magnitude (10–100 mg m^{-2}) with little geographical differentiation within a seasonal range of ca. 1–300 mg m^{-2}. Highest amounts were found in open plains or desert regions of high productivity.

Gross primary productivity of within-stream benthic algae (Table 19-9), as well as community respiration (e.g., consumption of dissolved oxygen in 24 h), commonly increases with downstream direction (e.g.,

[a] Enriched by fertilizer and sewage.

Bott *et al.*, 1985). Photosynthetic efficiencies of benthic algae are generally below 4%, with averages near 1%, and decline downstream with increasing light availability (Fig. 15-20).

D. Production Rates of Attached Algae versus Phytoplankton and Macrophytes

Few detailed studies exist in which *in situ* measurements of productivity of attached algae, phytoplankton, and macrophytes have been made simultaneously (Table 19-10). However, these studies are important in that they demonstrate the magnitude of effect that littoral productivity can have on lake systems. The range is great. In the large, shallow Borax Lake in northern California, epilithic algae are a major source of organic matter. Because the littoral area is small, when productivity per unit area is expanded for the whole lake surface, the attached algal contribution is reduced but still constitutes nearly one-half of total primary productivity. In Marion Lake, the primarily epipelic algae dominate the lake system. In Lake Wingra, Wisconsin, the submersed macrophytes are major components of the total primary productivity. Littoral attached algae, largely epiphytic, of Lawrence Lake constitute nearly three-fourths of the primary lake productivity, in spite of the limited littoral area of this small, moderately deep lake (Table 19-10). In contrast, the littoral contribution to the total productivity of the two Ontario lakes constitutes only a few percent because the morphometry and geology of these lakes do not lend themselves to extensive littoral development.

A few other, less complete studies that do not permit full comparisons should be mentioned to relate the relative rates of photosynthesis of attached algae to those of phytoplankton. Slow-growing submerged mosses, almost exclusively *Marsupella aquatica*, cover some 40% of the bottom from between 2 to 35 m of clear, low mountain Lake Latnajaure in Swedish Lapland (latitude 68°). This large, deep ($\bar{z}$ = 16.5 m, z_m = 43.5 m) lake is covered with over a meter of ice for about 10 months of the year and has a mean annual water temperature of 2°C. During the period of investigation in August and September, the average primary productivity for the whole lake was between 3.5 and 4.0 kg C per day (Bodin and Nauwerck, 1969). The average turnover time of the biomass of the perennial moss was about 30 y, between extremes of about 15 y at a depth of 5 m and 125 y at depths greater than 30 m. Of the total primary productivity of the lake, the phytoplankton were responsible for 60%, the moss for 20%, the epipelic diatoms for 15%, and the epiphytic algae on the moss for 5%. Similar results have been found in Char Lake in the Canadian Arctic at latitude 75° N (Kalff and Wetzel, unpublished).

Evaluation of the productivity of phytoplankton and attached algae of a large, deep alpine lake of the central Pyrenees Range also indicated the major contribution of the macroalga *Nitella* and of epilithic algae to the total primary productivity (Capblancq, 1973). The attached algae of the littoral zone (0–6 m) and *Nitella* (6–19 m) formed a biomass some 140 times greater than the mean biomass of the phytoplankton during summer, and *Nitella* constituted about 80% of the total benthic algae. Based on *in situ* productivity measurements, the contribution of benthic algae to the total primary productivity of this lake was estimated to be 30%.

The work of Straškraba (1963) on two large, shallow fishponds of southern Czechoslovakia deserves particular mention. Based on extensive annual cycles of the nitrogen content and biomass dynamics of all plant and animal components of these shallow lakes, it was determined that about 73% of the primary productivity resulted from largely emergent macrophytes, 20% from attached, mainly epiphytic algae, and 7% from phytoplankton. It was shown that <10% of the primary productivity was utilized by higher trophic levels.

Studies evaluating the relative photosynthetic rates of algae of the littoral in comparison to the rates of phytoplankton are few. But the suggestion that the most productive site is epiphytic on macrophytes repeatedly appears, as shown, for example, Table 19-11 for a shallow English lake, Lawrence Lake, discussed earlier (Table 19-10), and in the littoral of Mikolajskie Lake (Table 19-12). Among the most detailed and instructive studies of the relative contributions of the attached algae of different substrata is from long-term analyses of periphyton of the extensive wetland on the shores of Lake Manitoba (Robinson *et al.*, 1997). Epiphytic and particularly metaphytic algae totally dominated the littoral algal productivity (Table 19-13), and production rates declined markedly as mean water levels were raised by half a meter.

These results support earlier discussion on the importance of factors of light, which is often coupled to water levels in shallow areas, wave action–sediment movement, and inorganic–organic nutrient exchanges between macrophytes and attached algae. It is apparent that growth conditions are often better in the littoral attached habitat than in the planktonic habitat. The significance of littoral productivity to a lake system depends to a great extent on the physical conditions of the lake morphometry, light availability, and characteristics of the substrata available for algal attachment and growth.

E. Changing Littoral Productivity and Eutrophication

As lakes receive increasingly large loads of nutrients per unit volume per time, there is a strong tendency for phytoplankton to increase to the maximum capacity within existing limitations of temperature and available light (cf. Chap. 15). However, it is imperative that eutrophication of aquatic systems is not viewed in the restricted sense of phytoplanktonic productivity. Within obvious geomorphological restrictions on wetland and littoral development at the land–water interface regions, the common situation is for littoral productivity to play a major role in early and in final stages of increasing fertility of the lake system as a whole. Exceptions certainly exist, but these conditions of major littoral production are clearly widespread because a large percentage of lakes of the world are small in area and shallow.

A common natural or human-induced disturbance to lake and reservoir ecosystems involves progressive increases in loading of nutrients. These loadings, in excess of losses to sites of temporary or permanent inactivation such as sediments, result in enhanced nutrient availability for phytoplankton and other autotrophs with increased rates of growth and productivity. If nutrient loadings increase to an oligotrophic lake, increased productivity is rapid. Similarly, if the disturbance is brief (i.e., the duration of increased nutrient loading is relatively short), nutrient cycling is rapid, the ecosystem will recover rapidly, and productivity will be reduced proportionally to the load reduction.

TABLE 19-12 Percentage Contribution of Various Producers to the Annual Net Primary Productivity per m^2 in the Littoral Zone, Mikolajskie Lake, Poland[a]

Zone/component	*Percentage contribution*
Eulittoral	
Macrophytes	28
Planktonic	10
Metaphyton	21
Attached algae	41
Littoral overgrown with emergent vegetation	
Macrophytes	57.2
Planktonic	19.6
Metaphyton	0.1
Attached algae	23.1

[a] After Pieczyńska (1970).

As nutrient loading increases, particularly among shallow lakes that predominate globally (Wetzel, 1990), a marked shift in the productivity occurs from the pelagic to attached surfaces associated with living aquatic plants and the particulate detritus of senescing macrophyte biomass (Fig. 19-21). Under these conditions, the primary productivity and biomass of the lake ecosystem increase greatly. Habitat diversity among the massively dissected surfaces of submersed aquatic plants and particulate detritus of the sediments increase exponentially. As nutrient loading increases further, phytoplanktonic productivity per unit volume increases, but self-shading by the algae restricts the depth of the trophogenic zone. Within a given latitude and climate, maximum growth of phytoplankton in fertile waters is determined by light reduction induced by self-shading; growth can be increased beyond these limits only by increasing turbulence and light availability to levels greater than those normally found under natural conditions (Wetzel, 1966b). Phytoplanktonic productivity per unit area declines precipitously under these eutrophic conditions and is usually accompanied by a marked decrease in planktonic biodiversity as well.

This light limitation, usually associated with intense phytoplanktonic and epiphytic algal productivity,

TABLE 19-13 Comparison of Primary Productivity of Attached and Planktonic Algae of a Wetland of Manitoba under Different Water-Level Regimes[a]

	Mean algal biomass (mg chl. a m^{-2} wetland area)	*Mean daily productivity (mg C m^{-2} wetland area)*			
		Low water level	*Medium water level*	*High water level*	*Percentage contribution (mean all water levels)*

Metaphyton	530	2863	2372	1338	69.5
Total m^{-2}		4067	3441	1931	100.0

[a] Ice-free period (5–6 months); mean of five years. Low water = 7–28-cm depth; medium water = 37–58-cm depth; high water = 67–88-cm depth. Extracted from data in Robinson *et al.* (1997).

thus extends to submersed aquatic plants. Light attenuation is critical. Dense phytoplankton populations alone are sufficient to attenuate light to a point where it is inadequate to support growth of submersed macrophytes (e.g., Mulligan *et al.*, 1976; Jupp and Spence, 1977). Reductions in phytoplankton densities and improved light conditions (e.g., by reductions in nutrient or turbidity loading or by selective fish predation on zooplankton, which in turn alters phytoplankton composition; Chaps. 15 and 16; Leah *et al.*, 1980) can result in recolonization by submersed macrophytes. In addition, increased nutrient loading can increase epiphytic growth on macrophytes to the point of severely reducing the amount of light reaching the supporting

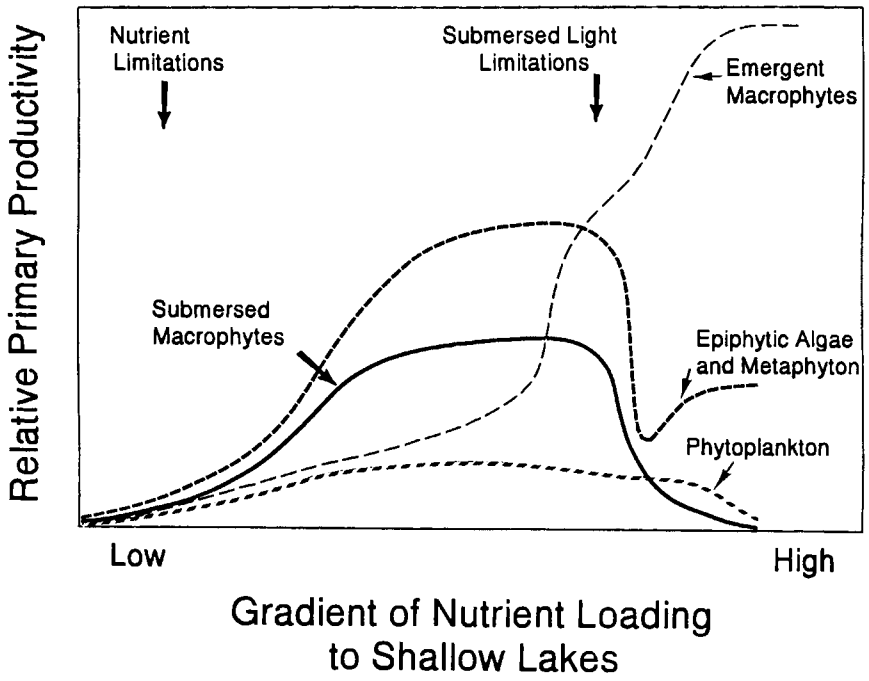

FIGURE 19-21 Relative changes in primary productivity of phytoplankton, macrophytes, and attached microflora along a gradient of nutrient loading to a spectrum of lake ecosystems. (From Wetzel, 1999a, expanded and modified from Wetzel and Hough, 1973.)

macrophytes (e.g., Sand-Jensen, 1977; Phillips *et al.*, 1978; Tsuchiya and Iwaka, 1979; Sand-Jensen and Søndergaard, 1981).

Submersed light limitation thus can reduce or eliminate submersed macrophyte growth and much of the attendant surfaces for microbial growth. The elimination of attached algal photosynthesis by attached microbiota decouples the metabolic mutualism to the attached heterotrophs and decreases collective productivity markedly (Wetzel, 1993a; Neely and Wetzel, 1995). The losses of attached microbial communities and their coupled metabolism cause a massive reduction in the capacities of the land–water interface regions of freshwater ecosystems to retain loaded nutrients and dissolved organic compounds.

Continual high nutrient loading and hypereutrophic phytoplanktonic conditions generate large areas of anaerobic reducing conditions and lower rates of decomposition of organic matter. Production exceeding decomposition leads to rapid sedimentation and the generation of increased shallow habitat conducive to colonization by emergent macrophytes (Fig. 19-21). The high productivity of emergent macrophytes increases the proportion of lignocellulose supporting tissues that are relatively recalcitrant to rapid decomposition, particularly under reducing conditions (Wetzel, 1979).

As the emergent vegetation assumes greater dominance in a lake ecosystem, and eventually covers a majority of the lake basin (see Chap. 24), an exceedingly productive combination of littoral macrophytes and attendant microflora develops. Attached, largely epiphytic algae, eulittoral algae, and metaphyton develop in association with the emergent flora. Natural changes in this general sequence are usually slow and may extend over centuries and millennia, depending on the basin morphometry. The process can be accelerated greatly by increased nutrient loading, either artificially (e.g., Hasler, 1947; Smith, 1969) or more gradually (e.g., Mattern, 1970). The collective result is markedly increased total ecosystem productivity, largely because of the high emergent macrophyte production.

The ratio of the interface zones to the pelagic permits one to estimate the importance of the littoral in relation to the pelagic zone. Most of the lakes of the world are small, and their morphometry is such that the ratio of the pelagic zone (P) to the colonizable littoral zone (L) is small (Fig. 19-22). On a global basis, the littoral zone is clearly dominant over the pelagic (low P/L ratios) among most standing-water and river ecosystems. Addition of the wetland components to the littoral zone results in low ratios ($P/W + L$) for nearly

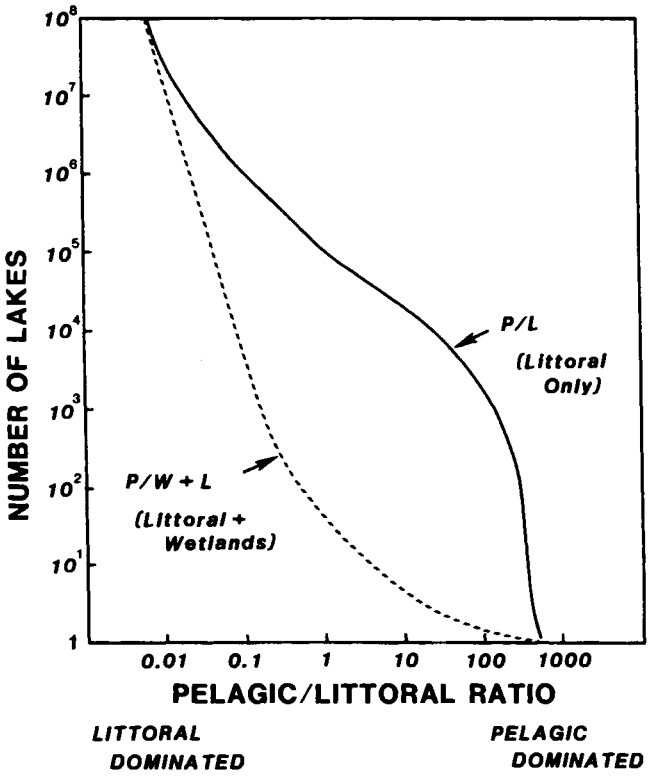

FIGURE 19-22 Number of lakes of the world in relation to the ratios of pelagic to littoral and wetland regions. (From Wetzel, 1990a.)

all standing-water ecosystems (Fig. 19-22). In these cases, there is little question that production of macrophytic vegetation, and importantly, its attendant microfloral community, has major impacts on the lake ecosystem.

The distinction between what constitutes allochthonous production (e.g., eulittoral, terrestrial, et cetera) and what is part of true autochthonous lake production is an extremely artificial one and has, indeed, led to an artificial treatment of mechanisms contributing to and influencing ecosystem metabolism. All components of the drainage basin are influential in regulating lake metabolism. Integrated data on the functional impact of these components on the entire system are essentially nonexistent. The concept of a lake as a microcosm must finally be laid to rest.

IV. PERIPHYTON AMONG AQUATIC ECOSYSTEMS

Comparison of the periphyton communities and their productivity among river, reservoir, lake, and wetland/littoral ecosystems is difficult because of the high

TABLE 19-14 Comparative Characteristics among Periphyton Communities of River, Reservoir, and Natural Lake Ecosystems and Wetland Interface Regions

Characteristic	*Rivers*	*Reservoirs*	*Natural lakes*	*Wetland/littoral areas*
Periphytic algal diversity	Low in-channel, moderate in floodplain wetlands and backwater areas	Low, often restricted by severe water-level fluctuations and turbidity; macrophyte habitat often very low	Low in epilithic, moderate in epipelic, and very high in epiphytic communities	Very high among great habitat diversity of living and dead vegetation and particulate detritus
Periphytic algal biomass and production	Low in-channel, especially in low-order, canopied streams; increasing among mid-order (3–5) streams; low in large rivers; moderate to high in floodplain wetlands and backwaters	Low, often restricted by limited substrata in photic zones and low submersed macrophytes	High on two-dimensional surfaces (sediments, rocks) to very high on three-dimensional substrata (submersed plants)	Very high on abundant livingand detrital surfaces among shallow waters
Herbivory pressures on periphyton	Moderate to high seasonally in middle-order streams	Low, restricted availability	Low to moderate, distinctly seasonal; largely a production-detrital system dominated by microbial heterotrophy	Low, largely a production-detrital system dominated by microbial heterotrophy
Attached/littoral "zooplankton"	Low, restricted to floodplain and backwater areas; dominated by *r*-selected species that are adapted to frequent disturbances	Very low, restricted stable habitat and macrophytic refuges	High, large-sized among macrophyte habitats offering predation refuges and abundant food	Nearly all sessile, attached forms; predation relatively low in comparison to more open lake littoral regions

variability among habitats and their dynamic nature. Attached algal diversity is relatively low within the high-velocity portions of river channels but is considerably greater among the greater, somewhat more stable floodplain and backwater areas (Table 19-14). The high and variable turbidity and water-level fluctuations in many reservoirs preclude the development of moderately stable and diverse substrate habitat. In contrast, habitat diversity and attached algal diversity is extremely high among the littoral areas, particularly among submersed macrophytes and in wetland areas of abundant particulate detritus.

Attached algal and cyanobacterial productivity and biomass development is moderately high in mid-order (3–5) streams and in backwater areas but low in light-restricted, canopied low-order streams and in more turbid large rivers (Table 19-14). The productivity of phytoplankton, periphyton, and macrophytes becomes much more complicated in the highly dynamic large rivers of the tropics, such as the Amazon and Paraná/Paraguary river ecosystems. During the seasonal flood pulse, large fluctuations occur in periphyton development and productivity in relation to currents within backwater pools and ponds, loss of vegetation and associated substrata, and turbidity imported with the river water (Nieff, 1990; Junk, 1997). Limited habitat, substrata, and light often preclude extensive attached algal developments in reservoir ecosystems. Productivity and high biomass turnover occur in littoral and wetland areas, particularly among the high surface areas in well-lighted regions of submersed macrophytes and particulate detrital masses.

Herbivory by immature aquatic insects, other invertebrates, and certain fish can impose significant mortality on periphyton communities of streams at certain times of the year. In standing waters, production by periphyton is often greater, and herbivory is appreciably less than in many streams. In many productive littoral and wetland areas, the periphyton community is largely a production–detrital system dominated by microbial utilization of the attached autotrophic production.

V. LITTORAL ZOOPLANKTON COMMUNITIES

Littoral zooplankton communities are made up of a diverse assemblage of protozoans and other protists, rotifers, and microcrustaceans. Many of these animals are sessile upon the sediments or macrophytes and are not truly planktonic, or are only intermittently planktonic. The number of species within littoral macrophyte zones is generally larger among all groups of organisms than in the open-water zone of lakes, ponds, or rivers (e.g., Pennak, 1966).

Littoral zooplankton have been studied much less intensively than have pelagic forms. Many of the life history, reproductive, and population characteristics of pelagic zooplankton, discussed at length in Chapter 16, are equally applicable to littoral-inhabiting zooplankton. A few conspicuous characteristics of the littoral fauna are noteworthy.

Microcrustacean communities have been found to fall into three general groups in the littoral zone: (a) highly "plant-associated" and infrequently found away from aquatic macrophytes, (b) "free-swimming" among the large plants, and (c) sessile and living mainly in littoral sediments (e.g., Pennak, 1966; Whiteside *et al.*, 1978, Fairchild, 1981). Truly planktonic species are common in areas within littoral zones devoid of vegetation but are rare within areas densely colonized by macrophytes. Among the large plants, free zooplankton are predominantly plant browsers or sediment-inhabiting species that are temporarily swimming or open-water species that enter vegetated areas and develop under conditions of reduced predation pressures from fish.

Plant-associated microcrustacean taxa are often closely associated with macrophyte species or morphologically similar plant types (Quade, 1969, 1971) and are distributed according to available surface area (Fairchild, 1981). Numbers of Cladocera feeding on detrital periphyton were significantly correlated with epiphytic diatom density, whereas filter-feeding Cladocera attached to the plants were not. Similar animal–plant associations have been found among littoral rotifers (Edmondson, 1944, 1945; Wallace, 1978). Few benthic or epiphytic microcrustacea enter the water column, even at night (Paterson, 1993).

Among the common littoral microcrustaceans are the chydorids; most chydorid species increase in numbers during spring and autumn and decrease during midsummer (Goulden, 1971; Keen, 1973; Whiteside, 1974, 1988; Vuille, 1991). In a detailed study of the population dynamics of four species of a hardwater lake in southern Michigan (Keen, 1973), for example, *Chydorus sphaericus* reached its maximum population density in the spring, declined to a low level in the summer, and then increased to a smaller fall peak preceding a winter plateau (Fig. 19-23). It is common for *Chydorus* to become abundant in the open water in summer, coincident with the minimal littoral populations. As indicated in the upper portion of the figure, production of males and ephippial females was very small in this littorally perennial species. In contrast, *Graptoleberis*, *Acroperus*, and *Camptocerus* are aestival and after a winter absence appeared in spring, from ephippial eggs, and attained maximal densities in late summer and autumn (Fig. 19-23). The latter maxima

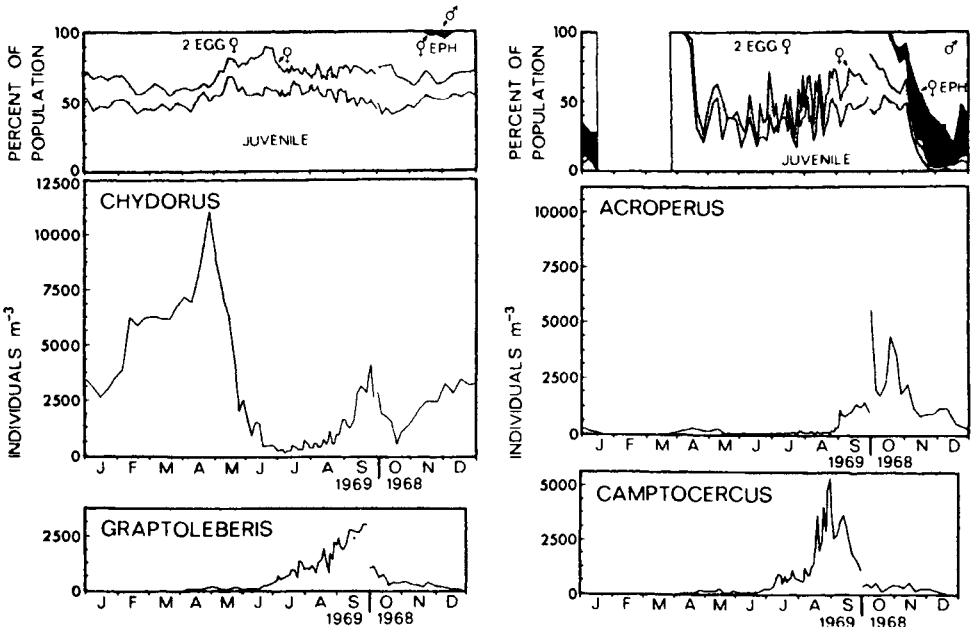

FIGURE 19-23 Annual population densities of the four major species of littoral chydorid cladocerans among submersed beds of *Scirpus subterminalis*, west littoral, Lawrence Lake, Michigan. Upper panels show percentage of the population of *Chydorus* and *Acroperus* seasonally in juveniles, females, females with eggs, males, and ephippial females. (Redrawn from Keen, 1973.)

terminated with the massive development of ephippial females and males prior to winter. Natural death and emigration were not clear but assumed to be negligible in this and several similar studies. High summer mortality was associated with active predation by small fishes (<4 cm in length) and nymphs of dragonflies (Odonata). In another analysis (Goulden, 1971), the midsummer population minima of chydorids were largely caused by predaceous tanypodine midge larvae. The midges were rare or absent in spring and autumn when the chydorids were most abundant.

In contrast, temporal and spatial correlations of distribution patterns of chironomid larvae of littoral sediments and chydorid cladocerans in the sandy littoral areas of a mesotrophic lake were very weak (van de Bund *et al.*, 1995). Alterations in species abundances need not always be associated with predation, however. For example, positively phototactic swarming of the cladoceran *Bosmina* and movement of large portions of the populations from littoral areas to the pelagic zone have been documented (Kairesalo and Penttilä, 1990).

Although the general relationships between temperature and egg and other developmental characteristics of littoral and benthic cladocerans and copepods are similar to those discussed earlier for planktonic zooplankton (Chap. 16), several differences have been found (e.g., Bottrell, 1975a,b; Sarvala, 1979). For example, egg development time is increased markedly with decreasing temperature, but among many species of cladocerans and copepods, eggs of sessile species take longer to develop than those of planktonic species, regardless of temperature. Instar duration and frequency of molting also tend to be greater among littoral species than among planktonic species. Diurnal migration has also been observed among zooplankton living among macrophytes. During the day, many populations, particularly copepods, aggregate among macrophytes near the sediments (Szlauer, 1963; Kairesalo, 1980a). Portions of the populations may then migrate to surface water strata during darkness.

Shallow lakes are often not sufficiently deep to stratify thermally and are therefore unable to provide a hypolimnetic refuge for zooplankton. In such waters, distribution of zooplankton is highly variable between littoral areas colonized by submersed aquatic plants and the open pelagic region. As indicated earlier, in littoral areas with well-developed aquatic macrophytes, the cladocerans *Alona, Chydorus, Diaphanosoma, Bosmina, Ceriodaphnia* and cyclopoid copepods are usually more abundant per area of habitat, often by a factor of 10, than in the pelagic areas (Vuille, 1991; Paterson, 1993; Lauridsen and Buenk, 1996; Lauridsen *et al.*, 1996). Some cladocerans, such as *Daphnia magna*, exhibited large diurnal changes, with highest populations during the daytime among the submersed

macrophytes and movements into littoral boundary areas at night. Some species of cladocerans avoid submersed macrophytes, particularly during active photosynthesis periods, for unknown reasons (e.g., Dorgelo and Heykoop, 1985).

Many of the observed differences among the abundance of rotifers, cladocerans, and copepods within plant beds and the open water likely reflect variations in fish predation pressure (cf. further discussion in Chap. 20). The success of the habitat as a refuge for zooplankton clearly is related to plant density. Additionally, the size of zooplankton among submersed littoral vegetation tends to be larger than the size of zooplankton of the pelagic zone, indicative of selective predation upon larger forms. *Daphnia* species are commonly reduced to very low population levels in open water but can persist amongst extensive macrophyte stands after its elimination from open-water habitat. *Daphnia* is commonly succeeded by other cladocerans, all of which maintain a high grazing pressure on phytoplankton in the littoral areas (e.g., Stansfield *et al.,* 1997).

Although grazing pressures from small (0+-age fry) zooplanktivorous fish are high, plant refuges are significant. Based on correlational data from many lakes, it is clear that predatory control of zooplankton by planktivorous fish is reduced markedly in lakes rich in submersed macrophytes, where at least ca. 15–20% of the water volume is occupied by submersed vegetation (Jeppesen *et al.,* 1997; Persson and Crowder, 1998). Similar results can be demonstrated experimentally in controlled enclosure experiments in shallow lakes (e.g., Jeppesen *et al.,* 1998). The large plants serve as a refuge for pelagic cladocerans and encourage predatory fish at the expense of prey fish that tend to avoid dense littoral areas. Small planktivorous fish use macrophytes as a defense mechanism against predators and can compete effectively with predatory fish, particularly in the juvenile stages.

VI. SUMMARY

1. Benthic algae and cyanobacteria are generally associated with or attached to substrata in land–water interface habitats. These substrata are living or dead, organic or inorganic, and in various combinations within the plants, detrital masses, and sediments within emergent and submersed plant zones and with sediments below macrophyte colonization. Extremely diverse microhabitats occur in littoral areas among substrates of sand, rock, organic sediments, and macrophytes.
2. Limnological terminology applied to attached microbiota refers to generic types of substrata to which groups of organisms are associated (cf. Fig. 8-3, p. 131ff).
3. Attached algae of littoral communities often form the dominant algal biomass in streams and shallow lakes. Over 80% of all algal species likely grow attached in submersed habitats.
   a. Diatoms dominate on all substrata among moderately productive aquatic ecosystems.
   b. Sessile cyanobacteria and flagellates increase in abundance in organically enriched lakes and certain regions of streams.
4. Developing periphyton are three-dimensionally enmeshed with hydrated mucopolysaccharide materials, secreted by bacteria and algae, that both sequester ions and isolate the microorganisms from the water column (Fig. 19-3). Accumulated detrital particles and precipitated carbonates adsorb nutrient ions and organic compounds. Some microbiota are loosely attached and project within and above the general community aggregations. The polysaccharide matrix can contain microchannels that likely function as conduits that allow accelerated diffusion within the communities.
5. Resources regulating growth include both external resources in the overlying medium, such as light and nutrients in the surrounding water, and internal resources, such as nutrients that are obtained from the substrata to which the periphyton communities are attached.
   a. Availability of habitat space markedly affects the composite productivity of the periphytic communities. Some habitats, such as many sediments, are approximately two-dimensional and provide much less surface area and have much lower periphyton productivity than a three-dimensional habitat, such as submersed macrophytes. The epiphytic communities have manifold greater productivity as the spatial volume of the habitat projects upward into the water column and enhanced light field (see Fig. 19-8).
   b. Enrichments of nutrients, particularly phosphorus and nitrogen, in the overlying water commonly result in shifts in species composition and increases in growth and biomass of attached algae on substrata. Within a specific range of current velocities, the boundary layer thickness between the periphyton and the overlying water is reduced with increasing current velocities and results in enhanced nutrient exchange with the overlying water.
   c. As communities develop and increase in thickness, instability can occur and cells and portions of the community may slough off.

6. Many periphytic communities are dependent upon the substrata for mineral and organic nutrients, particularly from submersed macrophytes and in oligotrophic and mesotrophic environments where the greatest periphyton productivity occurs. As macrophytes senesce and organic matter decomposes, a large portion of the nutrients and organic substrates released are sequestered and intensively recycled among the periphytic microbiota. This retention is particularly effective in epiphytic and epipelic periphyton.
7. A tight, mutualistic, metabolic coupling exists between attached algae and bacteria. For example, bacterial production is increased by algal exudates of organic substrates and oxygen. Enhanced algal growth can occur from increased availability of CO_2 and growth factors such as vitamins and reduced oxygen tension. Nutrients are certainly recycled and exchanged rapidly among the periphyton microbiota.
8. Light availability influences periphyton production both spatially along depth gradients and seasonally. Even though benthic algae can adapt with increased pigment concentrations to very low light intensities, light is often restrictive not only with increasing depth but seasonally, particularly among low-order woodland streams that are heavily canopied with terrestrial vegetation. Light is attenuated selectively within periphyton as well, and excessive developments of periphyton can reduce light reaching sufficiently to kill the supporting macrophytes and hence habitat space for colonization.
9. Mortality losses among periphyton communities are poorly known despite much study.
   a. Heavy grazing of periphyton by animals (insect larvae, crayfish, and certain fishes) can result in reductions of periphytic biomass and productivity. Although most periphyton are not grazed by animals, attached microbial–grazer interactions and mortality vary with herbivore type, nutrient and light availability for compensatory growth, and disturbance frequency. There is some evidence that grazing mortality of periphyton is greater in stream ecosystems than in standing waters.
   b. Disturbance to the habitat of periphyton communities can be severe from physical disruptions of substrata, such as during river flooding, and from shifts in water level, particularly among shallow habitats. Algae living on loose sediments that are subject to disturbance and displacement by water movements and animals often exhibit an ability to migrate vertically in response to changes in light. This vertical migration is phased with diurnal rhythms in cell division and photosynthetic capacity.
   c. Losses of natural periphyton communities by natural senescence and death, parasitism particularly by viruses, and disease are poorly known, but it is apparent that most of the periphyton production enters the pool of detrital organic matter in both lake and river ecosystems.
10. In temperate regions, the seasonal community biomass of attached algae commonly follows seasonal changes in incident light and temperature.
    a. Epipelic diatoms frequently exhibit population maxima in the spring and in the autumn.
    b. Seasonal population dynamics of epiphytic algae are more variable and change as the surface area available for colonization of the supporting macrophytes changes seasonally.
11. Within the streams and rivers and the littoral zone of standing waters, photosynthesis of attached algae is influenced to a great extent by light availability, although compensatory mechanisms exist that permit appreciable active growth at low levels of irradiance.
    a. The biomass of epipelic algae commonly increases with increasing nutrient content of the sediments.
    b. Epipelic algae can utilize significant quantities of phosphorus and combined nitrogen in the interstitial water of sediments and alter, by photosynthetically changing sediment redox, the flux of nutrients from the sediments to overlying water in the littoral zone.
12. Where comparisons of growth among algal populations associated with different substrates are possible, they indicate that photosynthesis is commonly higher for algae attached to sand grains than it is for those associated with organic sediments. Algae epiphytic on macrophytes are often much more productive than algae associated with sediments.
13. Productivity of littoral algae is not much greater on a cellular basis than that of phytoplankton, and turnover rates tend to be somewhat slower.
    a. The large surface area available for colonization, however, particularly on submersed macrophytes, can result in very high contributions by attached littoral algae to the total primary productivity of many freshwater ecosystems.
    b. Spatial heterogeneity in rates of production by attached algae is usually very large because of the great variability in littoral habitats within freshwater ecosystems.

c. Community rates of primary production of attached algae commonly follow the annual insolation and temperature curves, with maxima occurring in midsummer.
d. Most lakes of the world are shallow and possess large littoral zones. The productivity of the littoral algae and macrophytes tends to increase in relation to that of the phytoplankton as lakes become enriched. In lakes with a modest development of submersed macrophytes, epiphytic productivity can be very high and dominate total in-lake photosynthetic productivity. Under eutrophic conditions, excessive growth of phytoplankton and epiphytic algae can reduce light sufficiently to cause the decline of submersed macrophytes and attached algae; a consequent overall reduction in total productivity within the lake will then result.

14. Many of the protozoan, other protistan, rotifer, and microcrustacean zooplankton of the littoral zone are sessile on the sediments or macrophytes and are not truly (or are only intermittently) planktonic.
    a. Plant-associated zooplankton are commonly sessile on specific macrophyte types. Population densities of animals feeding on epiphytic microflora and detritus are positively correlated with epiphytic algal density.
    b. Many of the life history, reproductive, and population characteristics of littoral-inhabiting zooplankton are similar to those of their pelagic counterparts.
15. In shallow lakes with a well-developed submersed aquatic plant littoral area, the littoral habitat can function as a refuge for zooplankton from fish and invertebrate predation that prevails in the open water.
    a. Population numbers of common littoral microcrustaceans increase during spring and summer and decrease during summer. Midsummer population minima often result from intense predation by insect larvae and small fishes.
    b. Predatory control of zooplankton by planktivorous fish is reduced markedly where minimally 15–20% of the water volume is occupied by submersed vegetation.
    c. Zooplankton grazing can impact phytoplankton within the littoral and contribute to reduced phytoplankton and improved water transparency.

20 SHALLOW LAKES AND PONDS

I. Origins and Distribution
II. Characteristics
III. Invasion and Growth of Macrophytes
IV. Shifts between Macrophyte and Phytoplankton Dominance
V. Temporary Ponds, Pools, and Streams
VI. Summary

Study of lakes has concentrated almost totally on moderately large lakes in regions of recent geological glacial activity where such waters abound. Although the volume of water in large lakes is appreciable as a percentage of the total fresh water, they represent a very small percentage of the total number of lakes (Wetzel, 1990a). Much less spectacular but important are the millions of shallow lakes, impoundments, and ponds of only a few meters of depth (cf. Fig. 3-2). Many human activities are associated with and dependent upon shallow waters and wetlands. In addition, maximum biodiversity of freshwater ecosystems occurs where wetland and littoral habitat heterogeneity interfaces with pelagic regions (Wetzel, 1999b). In many shallow lakes and ponds, the littoral structure and its productivity completely dominates the ecosystem.

I. ORIGINS AND DISTRIBUTION

Shallow lakes and ponds occur in abundance in lowland areas of very gentle relief. As discussed in Chapter 3, these shallow basins can originate from processes that have caused modest depressions in the landscape. Certainly some processes were major geological disturbances such as glacial movements. Other depressions were formed in relatively flat regions from altered river courses or wind deflation. Hundreds of thousands of small, often temporary, ponds and lakes occur in the flood plains of major river ecosystems. These floodplain impoundments are especially common adjacent to arctic and tropical rivers where large areas of the land are flooded seasonally for several months. Humans have created millions of shallow lakes and ponds, either fortuitously or intentionally, as they modify the landscape by construction and agriculture. The shallow waters may be used for agricultural, industrial, water storage, or aesthetic purposes.

II. CHARACTERISTICS

Such lowland areas tend to accumulate terrestrial organic matter and nutrients, and appreciable amounts of these substances can be transported to shallow lakes. Being of relatively small volume, the loading of nutrients per unit volume can be high. Wetland and littoral macrovegetation that have much higher rates of organic production than do phytoplankton per unit area often dominate production of organic matter within shallow lakes. Hence, the topography of the landscape of shallow lakes and the resulting morphometry of the lake basins tend to be highly irregular and heterogeneous. This heterogeneity leads to large variability in the distribution and productivity of higher vegetation and of the abundant microbiota associated with the surfaces of these larger plants and their particulate detritus. As a result, the growth and interactive metabolic properties of shallow lakes tend to be most variable,

from which generalizations are more difficult than is the case with large lakes.

The importance of loading of nutrients to phytoplankton productivity of lakes, particularly phosphorus and nitrogen, has been discussed in detail (cf. Chaps. 12 and 13). Thermal stratification in these larger lakes is important for losses of phosphorus to the sediments. It was also emphasized that these relationships of nutrient losses and retention in the sediments deteriorate when applied to many shallow lakes. Shallow lakes and ponds tend to have a low percentage, if any, of total water volume in a thermally distinct hypolimnion. In the temperate region, thermal stratification for any appreciable length of time (months) is poor if basin depths are $<5-7$ m. As a result, water commonly circulates for long periods or continuously in shallow lakes.

Not only are the loadings of nutrients proportionally higher in shallow lakes than in deep ones but the losses of nutrients to potential depositories, such as the sediments or outflow, are lower and the rates of nutrient recycling faster in shallow lakes. As a result, factors other than nutrients, such as light availability, frequently regulate both photosynthetic productivity and the growth of organisms that depend on that productivity. Nutrient supply does not always influence phytoplankton productivity in shallow lakes in the manner discussed for large lakes because of the complex competitive interactions of macrophytes, attached microbiota, and phytoplankton.

III. INVASION AND GROWTH OF MACROPHYTES

Earlier discussion of the competition between submersed macrophytes, epiphytic periphyton, and phytoplankton was focused on large lakes with a large depth gradient and thermal stratification. In shallow lakes, the littoral can and often does extend over the entire lake or pond basin. A "***shallow lake***" or "***pond***" is usually defined as a permanent standing body of water that is sufficiently shallow to allow light penetration to the bottom sediments adequate to potentially support photosynthesis of higher aquatic plants over the entire basin. Turbidity from abiotic or biotic sources may prevent light from reaching the sediments, but the lakes or ponds are sufficiently shallow for this potential condition to occur. Commonly, macrophytes colonize only a portion of the ponds and lakes because of the frequent periodicity of high turbidity.

The type of macrophyte colonization is also highly variable. The common depth distribution and zonation of macrophytes in large lakes, as discussed earlier (Chap. 18) can apply similarly in shallow lakes but usually on a greatly contracted depth gradient, simply because light is often rapidly attenuated with depth in shallow lakes. Emergent macrophytes are largely limited to depths <1 m and rooted floating-leaved macrophytes to depths of $<2-3$ m. Submersed macrophytes can form a dominant component of shallow lakes and ponds and markedly influence the biological community structure of these lakes. Much of the following discussion is directed at recent intensive studies that have examined the shifts between dominance by submersed macrophytes to dominance by phytoplankton and what effects these shifts have on overall ecosystem productivity.

IV. SHIFTS BETWEEN MACROPHYTE AND PHYTOPLANKTON DOMINANCE

Nutrient loadings of phosphorus and nitrogen are still important, particularly at the lower concentrations, in shallow lakes. The resulting dominance of photosynthetic communities utilizing these nutrients, however, is coupled to the timing of competition between the macrophyte versus algal communities. Plant-dominated and phytoplankton algal-dominated alternative equilibria can exist over a wide range of nutrient concentrations (Scheffer *et al.*, 1993; Scheffer, 1998). Submersed macrophyte dominance is the prevalent condition, as in large lakes, when nutrient concentrations of the water are low (e.g., 25 μg total P liter^{-1}) with a high N:P ratio ($>>$10:1). In hardwater, calcareous shallow lakes, charophyte macroalgae are common (e.g., Wetzel, 1973; Blindow, 1992) under oligotrophic conditions. Isoetid submersed plants (e.g., *Isöetes, Littorella*, and *Lobelia*) are common in more acidic oligotrophic waters. These submersed plants utilize nutrients from the sediments, are small and growing close to the sediments, and are vulnerable to shading. Shading by phytoplankton communities, however, is generally modest at these nutrient levels.

As phosphorus and nitrogen levels increase, however, this plant community is replaced with larger submersed plants, such as *Myriophyllum* and a number of *Potamogeton* species, as well as increasing densities of water lilies (Nymphaeaceae). The larger submersed plants are much more productive and still derive most of their nutrients from the sediments (e.g., Barko and Smart, 1980; Denny, 1980; Moeller *et al.*, 1988). Although total phosphorus levels may increase further from external loadings, nitrogen is commonly limiting to both submersed macrophytes and phytoplankton because of heavy biological utilization and from losses by denitrification. Further increased loading of phosphorus and nitrogen can often result in a further shift in

the submersed plant community to tall species (e.g., *Myriophyllum spicatum*, certain *Potamogeton* spp., *Ceratophyllum*) as well as water lilies. Although the phytoplankton communities expand and proliferate under conditions of increasing nutrients, they can coexist with certain aggressive, eutrophic submersed macrophytes that grow rapidly and concentrate photosynthetic tissues near the surface.

A. Macrophyte Dominance

Often, however, this submersed macrophyte–phytoplankton "equilibrium" over a wide range of total phosphorus concentrations (<10 to >1000 μg liter^{-1}) rapidly shifts to an alternative condition of dominance by phytoplankton with elimination of submersed macrophytes (Balls *et al.*, 1989; Jeppesen *et al.*, 1991). This shift can occur regardless of the water concentrations of total phosphorus, and obviously other factors than nutrient changes can cause this shift from the submersed plant-dominated state to one of phytoplankton dominance. In shallow lakes and ponds, submersed macrophyte dominance can be maintained by several mechanisms:

1. Geomorphic conditions, such as surrounding hills or trees, that minimize wave action and currents that would resuspend sediments and increase nonbiotic turbidity.

2. Sequestering of phosphorus and nitrogen by submersed macrophytes in excess of nutritional requirements, thereby reducing availability to phytoplankton and periphyton (e.g., Moeller *et al.*, 1988; Stephen *et al.*, 1998). Except for very oligotrophic environments and very hard waters, phosphorus is relatively adequate for submersed macrophytes, particularly from the sediments. Within submersed plant beds, anoxic areas occur near the sediments, which leads to appreciable bacterial denitrification and losses of nitrogen to the atmosphere. Because of the marked uptake of combined nitrogen by submersed macrophytes and especially epiphytic periphyton communities, nitrogen availability can become restricted to littoral phytoplankton (e.g., Fitzgerald, 1969; Howard-Williams, 1981; Van Donk *et al.*, 1993).

3. Submersed macrophytes that provide physical refuges for large zooplankton, such as *Daphnia* and other crustaceans that effectively graze on and reduce phytoplankton, from predation by fish (e.g., Timms and Moss, 1984; Schriver *et al.*, 1995). Small fish commonly inhabit littoral areas as a refuge from predation by piscivorous fish (e.g., Gerking, 1962; Venugopal and Winfield, 1993). Dense submersed vegetation, however, and reduction of light and oxygen in the lower portion of plant beds (cf. Fig. 9-8) can restrict small fish to water at the edges and above the plant beds. These refuges for zooplankton that feed upon and at times control phytoplankton densities are important to the regulation of littoral phytoplankton communities and their biomass (Irvine *et al.*, 1990; Stephan *et al.*, 1998). Clearly, some of the zooplankton migrate upward and out of the submersed plant protective habitat for feeding at night when the visually mediated predation pressure from fish is low. Lateral horizontal migration diurnally by littoral zooplankton (Davies, 1985) is less clear.

4. The large surface area of submersed macrophytes that provides habitat for prolific development of epiphytic periphyton. That development increases with increased nutrient loading and can suppress light availability to and growth of the macrophytes (e.g., Sand-Jensen and Sondergaard, 1981; Losee and Wetzel, 1983). Insect larvae, such as chironomids, and snails can be effective in grazing periphyton and reducing shading to the supporting plants. Again, habitat refuges for the macroinvertebrates from fish predation are abundant within the macrophytes (e.g., Brönmark, 1989; Moeller *et al.*, 1998).

5. Release of organic compounds that suppress the growth of phytoplankton and periphyton (e.g., Wuim-Andersen *et al.*, 1982; Gross and Sütfeld, 1994). This mechanism is constantly cited in the literature but is very poorly studied and is largely suppositional. When these compounds are released, their efficacy can be modified by interaction with natural organic compounds and bacterial metabolism. Suppression of phytoplankton growth by these compounds of macrophytes has not been demonstrated (e.g., Forsberg *et al.*, 1990).

6. The intense metabolism of the submersed macrophytes and epiphytic microbiota, as well as the large deposits of decomposing organic detritus, that frequently causes marked diurnal fluctuations of dissolved oxygen, pH, and other parameters in the littoral waters. Some of these conditions can suppress intrusions of fish and predation on the grazing zooplankton and macroinvertebrates.

B. Phytoplankton Dominance

In shallow lakes and ponds, the shift to phytoplankton-dominated conditions where submersed macrophytes are suppressed or eliminated can result from several mechanisms:

1. The development of prolific phytoplankton communities that compete with submersed plants mainly for light but also nutrients such as inorganic carbon. This condition is particularly effective for the

development of small algal and cyanobacterial species with a high capacity for light absorption and low light compensation points. With the reduction of grazing pressures by large zooplankton, discussed further on, the development of phytoplankton early in the season in nutrient-rich shallow waters of temperate regions can attenuate light markedly and suppress macrophyte development and growth from overwintering propagules or seeds.

2. If the small lakes and ponds are exposed to wind action, the common mixing of the water with resuspension of surficial sediments in the open habitat. As a result, abiogenic and biogenic turbidity increases with a marked reduction of light penetration. The loose, flocculent sediment is also a poor substratum for macrophyte colonization.

3. The absence of submersed macrophytes, which greatly reduces refuge habitat for large zooplankton that are effective in phytoplankton grazing. If a large proportion of small zooplanktivorous fish dominates the fish communities because of a small population of piscivorous fish, the grazing pressure on phytoplankton by large cladoceran and copepod zooplankton is reduced. As a result, the grazing mortality of phytoplankton is reduced. Many piscivorous fish are poorly adapted to lakes without macrophyte habitats and plant-associated food refuges for small fish and macroinvertebrates. Consumption of the larger fish, including cannibalism on their own species, skews the fish to smaller, effective zooplanktivorous fish. Gradually, piscivorous fish reproduction and recruitment can decline.

4. Once established and dominating under conditions of high nutrient loads, dense phytoplankton communities that tend to persist in spite of changing nutrient availability. As we have seen in the discussion of changes in phytoplankton populations seasonally in large lakes (Chap. 15), similar changes occur in shallow lakes and ponds seasonally. At very high phosphorus and combined nitrogen concentrations in the water, green algae can effectively compete with nitrogen-fixing cyanobacteria (e.g., Jeppesen *et al.*, 1994), a well-known and effectively demonstrated sequence in large lakes (cf. Chap. 15). Once the cyanobacterial populations are established, most species are largely inedible and poorly grazed (Gliwicz, 1990; Lampert, 1994).

C. Other Control Mechanisms

It should be noted that a number of other factors could induce the rapid transition from submersed-macrophyte domination to domination by phytoplankton. The introduction of certain large fish and other animals can cause the shift in conditions. For example, the sucking detrital feeding activities of the common carp (*Cyprinus carpio*, Cyprinidae) and the benthivorous bream (*Abramis brama*) remove large portions of sediments as they search for food. The sediment disturbance can markedly increase turbidity in shallow lakes and littoral areas in proportion to the biomass of benthivorous fish (Fletcher *et al.*, 1985; Breukelaar *et al.*, 1994). The large grass carp (*Ctemopharyngodon idella*, Cyprinidae), if sufficiently abundant, can consume submersed vegetation voraciously and completely denude shallow waters of these plants (Chilton and Muoneke, 1992) and often, though not always, result in large increases in phytoplankton biomass (Gasaway and Drda, 1978; Terrell, 1982; Richard *et al.*, 1984).

A number of other vertebrates can impact aquatic vegetation. Herbivorous waterfowl, such as the large Canada goose (*Branta canadensis*) and the mammals nutria (*Myocaster coypus*) and muskrat (*Ondotra zibethica*) are voracious herbivores that consume and disturb large quantities of macrovegetation (e.g, Manny *et al.*, 1994; Taylor *et al.*, 1997). Humans influence submersed vegetation either directly by application of herbicides purposefully for control or accidentally in runoff, by mechanical cutting, or from damage from boat motors or indirectly by excessive fishing removal of piscivorous fish. All of these factors, as well as others, such as selective winterkill of piscivorous fish, may impact the submersed vegetation or phytoplankton abundance sufficiently to induce a shift to dominance by phytoplankton.

V. TEMPORARY PONDS, POOLS, AND STREAMS

Small depressions in impermeable or semipermeable terrain can be filled with water during certain times of the year. Such temporary waters may be astatic seasonally or possess dry periods for longer intervals (Decksbach, 1929). The duration of flooding varies greatly and results in many variations in temporary or semipermanent shallow waters that last only a few weeks or, alternatively, pools that are dry for only short periods over an annual period.

In temperate regions, in spring melting snow and rain fill depressions of these temporary ***vernal pools,*** and these pools remain dry for the remainder of the year (cf. Wiggins *et al.*, 1980; Williams, 1987). Water levels subsequently decline, and the pools are generally without water for many months. The duration of the wet and dry phases varies widely, and the pools can often be inundated again in the autumn (termed *autumnal pools*) and remain inundated throughout the autumn and through the subsequent spring period. Other pools are inundated for a period of one year and may

enter a drought period for months or years before being reflooded.

The marginal vegetation growing adjacent to, or vegetation including trees growing within, temporary pools of course influences the loading of organic matter to the pool ecosystem. Often, the predominant organic loading occurs as dissolved organic matter leached from the surrounding vegetation and soils. Particulate organic matter is frequently also predominantly allochthonous via leaf fall from trees and wetland vegetation. When exposed to appreciable light, autochthonous supplements are common from opportunist macrophytes and attached and planktonic algae/cyanobacteria. As was emphasized in the detailed treatment of the ecology and metabolism of littoral and floodplain environments (Chaps. 18 and 19) and the sediments (Chap. 21), the plankton component contributes only a small portion of the overall pool metabolism (cf., e.g., Cole and Fisher, 1978; Hobbie, 1980). Benthic microbial metabolism totally dominates in these ecosystems.

Temporary pools are essentially closed waters with influents largely from precipitation and runoff. Water losses by evaporation result in the concentration of imported salinity. In arid regions, concentrations of salts can reach extraordinary levels prior to drying and further constrain organisms to a few tolerant species (cf. Chap. 10; W. D. Williams, 1996). In addition, the annual disturbance imposed by the drying period allows more accelerated aerobic degradation and oxidation of organic matter and release of nutrients than would occur in many permanently inundated ponds. As a result, upon reflooding, nutrient availability is high with increased initial productivity.

Organisms living in such irregular, transient habitats must have many structural, behavioral, and physiological adaptations for surviving or avoiding drought. Organisms adapted to temporary pools are few but are a consistent and predictable assemblage. Only a few species of each major freshwater group have adapted to these habitats. Different animal communities can be distinguished on the basis of survival during drought periods and seasonal patterns of recruitment (Fernando and Galbraith, 1973; Wiggins *et al.*, 1980; D. D.Williams, 1987; Neckles *et al.*, 1990; Jeffries, 1994):

a. Animals that are permanent residents capable only of passive dispersal that aestivate and overwinter in the dry pool basin, either as stages resistant to desiccation [certain Turbellaria (cysts and egg cocoons), Bryozoa (statoblasts), Anostraca, Cladocera (ephippia), Copepoda (eggs), and Ostracoda] or while protected, largely as resistant eggs, in the sediments (Oligochaeta, Hirudinoidea, Decopoda, and molluscs).

b. Animals capable of some dispersal (certain Ephemeroptera, Coleoptera, Trichoptera, and Diptera) that oviposit on water in spring and then aestivate and overwinter in the dry basin in various stages of the life cycle.

c. Animals (certain Odonata, Trichoptera, and Diptera) that oviposit as summer recruits in the sediments of the pool basin after surface water has disappeared. Eggs or larvae then overwinter until the next inundation period.

d. Animals (certain Ephemeroptera, Odonata, Hemiptera, Coleoptera, Diptera, and amphibians) that have well-developed powers of dispersal that leave the disappearing pool and pass the dry phases in permanent waters. Some of these animals subsequently return to oviposit in the temporary pool in the following spring.

A requisite for all organisms, and particularly for larger animals, in temporary pools is a rapid rate of development during the wet phase. Development and locating a mate must be completed in a few weeks, often accelerated by rapid changes in physical (e.g., increasing temperatures and ultraviolet intensities), chemical (increasing salinity and increasing dissolved organic matter), and biological (increasing susceptibility to predation) conditions in the receding pools. Additionally, species of temporary pools have a marked seasonality in their life cycles that is coupled to the probability of inundation of temporary pools. Artificial elimination of the flooding–drying periodicity can alter or eliminate needed cues for oviposition, embryonic development, and hatching among dominant taxa.

Temporary or intermittent streams differ markedly from temporary pools in both physical and biological terms. Many organisms, such as benthic invertebrates, are capable of movement and many clearly seek refuge in the interstitial waters of the hyporheic zone as drying of the stream occurs progressively to the sediments and below the surface of the sediments (Williams and Hynes, 1974, 1977). Because of common groundwater persistence in the hyporheic zone, organisms inhabiting these regions are not well adapted to the drought and desiccation of temporary pools.

It may be noted that the water column and part of the sediments freeze solid during winter in certain shallow ponds (e.g., Hobbie, 1980). These ponds contain water at all times of the year and thus would be considered permanent water bodies. Because biological activity essentially ceases during the winter period, these waters have been termed ***aestival ponds*** (Welch, 1952). Organisms of aestival ponds are adapted to tolerate interruption of development by freezing until subsequent thawing periods. The physiological rigors of freezing

without desiccation are less severe than being exposed to a drying temporary pool where both freezing and desiccation can occur (Daborn, 1974).

VI. SUMMARY

1. Millions of shallow lakes and ponds occur in lowland areas of gentle relief and in floodplain regions adjacent to river ecosystems. These shallow waters are rarely thermally stratified and if so, only briefly; water circulation is frequent and often continuous.
2. Loadings of nutrients are proportionally higher, losses are lower, and rates of nutrient recycling are faster in shallow lakes than in deep ones.
3. Complex competitive interactions of macrophytes, attached microbiota, and phytoplankton occur in shallow lakes and ponds.
   a. Light penetration to much of the sediment surface can support invasion and growth of macrophytes over much of the basin.
   b. Submersed macrophyte dominance prevails when nutrient concentrations of the water are low with a high N:P ratio ($\gg$10:1). As nitrogen and phosphorus concentrations increase, transitions occur in submersed aquatic plant communities.
   c. Submersed macrophyte dominance can be maintained by mechanisms (e.g., abiogenic turbidity, sequestering of nutrients by macrophytes, and large zooplankton herbivory) that suppress the development of profuse phytoplankton communities.
   d. A shift to phytoplankton-dominated conditions, where submersed macrophytes are suppressed or eliminated, can result from prolific development of algae or cyanobacteria adapted to competition for light as nutrient levels increase. The phytoplankton increase turbidity, reduce light for submersed macrophytes, and reduce the grazing pressure, because of food particle size, of large zooplankton on phytoplankton.
4. Temporary ponds and pools are shallow waters that are flooded periodically, largely from precipitation and immediate terrestrial runoff, and dry for periods of the year.
   a. Sources of organic matter are largely allochthonous, and benthic microbial metabolism totally dominates in these ecosystems.
   b. Losses of water are largely by evaporation and result in marked, rapid changes in ionic composition, nutrient availability, and desiccation.
   c. The few organisms adapted to living in these irregular, transient habitats have many structural, behavioral, and physiological adaptations for surviving (e.g., aestivation) or avoiding (e.g., dispersal) drought and desiccation. Very rapid rates of development during the wet phase are essential.

VIII. Summary

Many characteristics of sediments of freshwater ecosystems have been analyzed. Thus, sediments of the littoral zone of lakes and of running waters are sorted along a gradient by particle size as a result of water movements and differences in water velocity. Particle size of both inorganic and organic sediments is of major importance to the distribution and growth of many benthic invertebrates (cf. Cummins, 1962) and microbial metabolism. Because of the overriding importance of microbial metabolism in mineralization of organic matter, in biogeochemical cycling of nutrients and in the amount of matter deposited without appreciable further degradation in permanent sediments, the organic composition of sediments in lake systems has received much study.

I. GENERAL COMPOSITION OF SEDIMENTS

Sediments consist of three primary components: (a) organic matter in various stages of decomposition; (b) particulate mineral matter, including clays, carbonates, and nonclay silicates; and (c) an inorganic component of biogenic origin (e.g., diatom frustules and certain forms of calcium carbonate) (cf. Jones and Bowser, 1978; Kelts and Hsu, 1978). In many respects, the organic sediments of lakes are similar to the uppermost A_0 horizon in terrestrial soils (Hansen, 1959a). Heterogeneous humus in particulate form can be divided into two main types, acid humus and neutral humus (sapropel[1]). From a colloid-chemistry viewpoint, acid humus is largely an unsaturated sol whose particles have negatively charged surfaces, while neutral humus is largely a gel in which anions are adsorbed to the surfaces of the humus particles. Acid humus prevails in peat bog systems. Decomposing peat plant materials, such as the moss *Sphagnum*, form unsaturated humus colloids (dopplerite). Aggregations of black, gelatinous dopplerite are very soluble in water unless

[1] True sapropel is bluish-black, contains much hydrogen sulfide (H_2S) and methane (CH_4), and is deposited under anaerobic-reducing conditions.

dried; upon drying, they become insoluble. The nitrogen content of this humic material is very low (≈0–2%).

A. Dy and Gyttja

Two words of Scandinavian origin are widely used in limnology to describe the general character of organic sediments. The terms *dy* (pronounced "de", nasally) and *gyttja* (pronounced "yit-ja") were introduced in the middle of the nineteenth century by von Post (Hansen, 1959a,b). Gyttja is a coprogenous sediment containing the remains of all particulate organic matter, inorganic precipitations, and minerogenic matter. In a fresh state, gyttja is very soft and hydrous, with a dark greenish-gray to black color; it is never brown. In a dry state, some gyttjas are hard and black, while others are more friable and lighter in color, depending upon the main constituent. The organic carbon content of gyttja is <50%. Dy[2] is a gyttja mixed with unsaturated humus colloids. Fresh dy is soft, hydrous, and brown in color. In a dry condition, dy is very hard and dark brown. The organic carbon content of dy and peat is >50%.

Numerous comparative studies of the organic components in sediments have demonstrated that the protein and nitrogen content of acidic humus is low. The C:N ratio of *Sphagnum* peat is about 35; that of pure dopplerite varies from 46 to 52. Hansen concluded that if the C:N is <10, the humus is neutral humus and the sediment is gyttja. If the C:N >10, the gyttja is mixed with acid humus and the sediment is a dy.

The sources of particulate organic matter and their respective rates of decomposition during sedimentation in the pelagic zone were discussed elsewhere (Chaps. 17 and 23). In large oligotrophic as well as large eutrophic lakes in which phytoplanktonic productivity dominates, humic inputs to the sediments will be relatively low. Gyttja sediments would be anticipated in these lakes, and this is generally borne out by empirical observations (cf., e.g., Hansen, 1961). Dy sediments are found in some small lakes dominated by littoral productivity, especially by acid-producing *Sphagnum* mosses, or allochthonous inputs of humic organic matter of terrestrial and wetland plant origins. All sediments contain some humic matter, and there is a broad transition between gyttja and dy.

Comparisons of the changes in chemical composition of pelagic seston while it is sedimenting in the water column were discussed in Chapter 17. Diagenesis of this organic matter is faster within the water column than once it is buried in the sediments. Within the sediments, decomposition rates of organic matter follow the general sequence: carbohydrates-amino acids-amino sugars > humic compounds > lipids (e.g., Kayama *et al.*, 1973; Kemp and Johnston, 1979).

Examination of lipids within sediments showed that bound lipids are relatively stable in comparison to free lipids (Cranwell, 1981; Robinson *et al.*, 1987; Ogura, 1990). Short-chain and unsaturated[3] compounds are readily and preferentially utilized by sediment bacteria. The total lipid content of the sediments is related more to chemical composition than to nutrient availability; total lipid content tends to increase where the biodegradability of the total organic compounds of the sediments decrease.

B. Humic Compounds Originating from Wetland and Littoral Flora

Products formed by microbial degradation of lignin can polymerize as humic compounds (Flaig, 1964; Larson and Hufnal, 1980; Wang *et al.*, 1980). As a result, it would be expected that the wetland and littoral macrophytes, and particularly the highly productive and more highly lignified emergent flora, would be a greater source of humic compounds than submersed hydrophytes or planktonic microflora. Analyses of the successive degradation of macroflora cast some light on the decomposition products and the rates of their formation.

The carbon and nitrogen contents of fractions of (1) fresh, living plant material of *Stratiotes aloides* were compared with those of (2) semidecomposed, dead plant material that was morphologically distinct but undergoing intermediate phases of decomposition, (3) young, thin sapropel formed by partial mineralization, and (4) old, thick, stratified sapropel resulting from nearly complete mineralization and humification (Úlehlová, 1970, 1971, 1976). Results (Table 21-1) showed that the carbon and nitrogen content decreased markedly with progressive decomposition to sapropels, while little change occurred in the C:N ratio. Free humic substances exhibited a loss of carbon in the sapropel phases of decomposition; this loss occurred primarily in the fulvic acid fraction. In the chemically bound humic fractions, carbon content increased with progressive degradation; again, humic acid content increased at the expense of the fulvic acid component. Nitrogen content increased in the semidecomposed stage, and the quantity of old sapropel decreased in the bound humic fractions. Most of the nitrogen was found in the fulvic acid fractions of the humic substances. These results suggest that free humic

[2]Also termed *tyrfopel* in older literature, meaning a *fine-grained peat.*

[3]Alkyl groups containing carbon–carbon double bonds.

substances present in the early stages of decomposition were microbiologically transformed to chemically bound humic substances in later stages of decomposition. As the nitrogen of humic compounds is selectively removed, C:N ratios increase markedly. Slower rates of degradation occur when nitrogen levels decline sufficiently, which then permit some net accumulation of organic matter in the sediments.

II. RESUSPENSION AND REDEPOSITION OF SEDIMENTS

A conspicuous feature of the annual cycle of sedimentation rates of seston among dimictic lakes is a marked increase during periods of spring and autumnal circulation (Fig. 21-1). Much of this greater rate of settling particulate matter results from resuspension of flocculent surface sediments by currents moving across the sediments. The extent of disturbance and sediment resuspension into the water column, transport to different locations, and redeposition is of course variable among lakes of differing morphology, exposure to wind, and other features.

Sediments are resuspended when the bottom shear exceeds a critical shear stress for the sediment materials. Critical shear stress is a function of properties of the sediments, such as water content and grain size, and must be sufficient to disrupt the cohesion of the particles and the forces of gravity. Resuspension occurs during (a) continuous mixing throughout the water column to the bottom sediments, (b) intermittent complete mixing, particularly in monomictic and dimictic lakes with full circulation following periods of stratification, (c) intermittent complete mixing of the epilimnion that intersects shallow sediments (many lakes have over half of their volume in the epilimnion, the base of which is in contact with sediments), and (d) peripheral wave intersection with sediments in littoral areas where the water is shallower than half the wave length (see Chap. 7) (Hilton *et al.*, 1986; Evans, 1994; Bloesch, 1995).

Resuspension occurs episodically in both shallow regions and in deepwater sediments primarily as a function of depth and the distribution of shear stresses as regulated by a combination of wind speed, wave height coupled with effective lake fetch, duration of the disturbance, and lake basin morphometry. In the zone of erosion, material of a size available for resuspension is usually quite small and is moved to the water column over relatively short time periods (Godshalk and Wetzel, 1984; Evans, 1994). The areal extent of resuspension increases with wind speed and is greatly increased during times of complete overturn and circulation of the water column. Deepwater sediments of many lakes are disturbed to depths of several millimeters to several centimeters usually one or more times a year (e.g., Davis, 1968, 1973; Wetzel *et al.*, 1972; Pennington, 1974; White and Wetzel, 1975). In calcareous

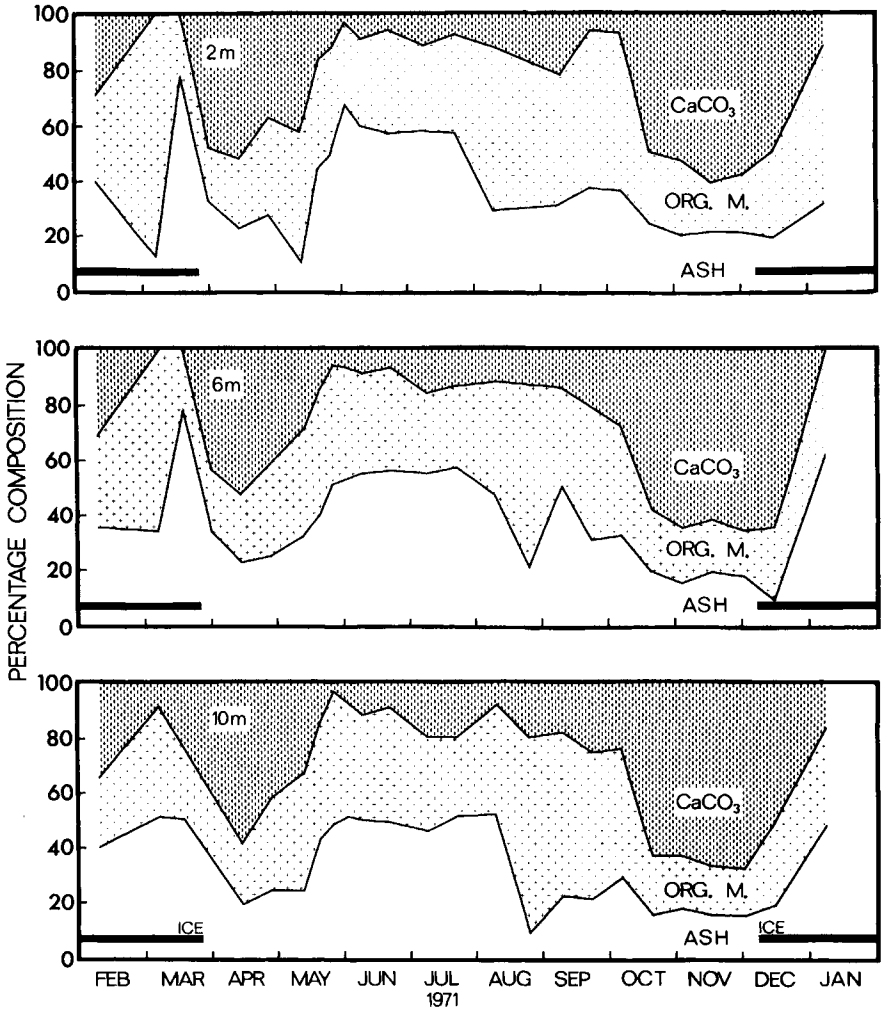

FIGURE 21-1 Seasonal changes in the percentage composition of calcium carbonate, particulate organic matter, and ash sedimenting to 2-, 6-, and 10-m depths. Lawrence Lake, Michigan, 1971. (From White and Wetzel, unpublished.)

lakes, as exemplified in Figure 21-1, resuspended calcium carbonate forms a major constituent of the seston during periods of circulation. This type of maximum resuspension during and at the end of water column circulation is common (e.g., Cobelas *et al.*, 1993), and the increased turbidity has been referred to in local vernacular as the "lake is cleaning itself." This fine-grained particulate matter is swept into the water column where it is subject to additional degradation by bacteria under aerobic conditions both during circulation as well as when it resettles to the bottom.

Differential horizontal sedimentation of particulate matter has been demonstrated in studies of the movement, deposition, and redeposition of pollen grains of different sizes and densities (Davis and Brubaker, 1973). Larger particles with rapid sinking rates are deposited fairly evenly onto the sediments throughout the lake basin. Smaller-sized particles with slower sinking rates in water are kept in suspension in the turbulent waters of the epilimnion, are carried across the lake in wind-mediated water currents, and are deposited preferentially onto littoral sediments. Later, particularly during fall circulation, these fine particles can be resuspended in the littoral areas, mixed in the lake water, and redeposited over the entire basin. Larger particles of organic matter or seston are not extensively resuspended and transported from the littoral to the center of the lake, although they are frequently shifted about in the littoral regions (Wetzel *et al.*, 1972; Godshalk and Wetzel, 1984; Hamilton and Mitchell, 1996). Aquatic plants, particularly emergent aquatic plants, disperse wave energy and ameliorate erosive effects and sediment resuspension (e.g., Moeller and Wetzel, 1988; James and Barko, 1994). The result is a size-selective

sorting and transport of the finest-sized particles from the littoral, which sediment into the quiescent waters below the metalimnion (cf. also Sebestyén, 1949). This resuspension and redistribution of organic matter has important consequences for the rates of decomposition of particulate organic matter deposited in littoral areas from either littoral production or allochthonous matter brought to the lake basin (cf. Chaps. 18 and 23). Resuspension of organic as well as inorganic particles can appreciably reduce light availability for photosynthesis and production of organic matter. For example, in a shallow lake, attenuation of light by resuspended particles was found to be directly proportional to wind velocity to the third power (Hellström, 1991) and the amount of organic matter in the resuspended particles (Blom *et al.*, 1994). In such lakes, total phosphorus content and other nutrients of the overlying water increased markedly during resuspension of the sediments, and phosphorus inputs to the water can be totally dominated by resuspension events (Kristensen *et al.*, 1992; Newman and Reddy, 1992; Reddy *et al.*, 1996).

Clearly, resuspension is greater in shallow lakes, even those that stratify thermally, than in deeper lakes. Although the data available on resuspended sediments as a proportion of the total settling particulate matter are few and variable because of differing techniques used for estimates, the conclusion is similar (Evans, 1994; Kozerski, 1994; Bloesch, 1995). The net sedimentation is small relative to the combined (gross) sedimentation of net sedimentation plus resuspension (Table 21-2). The percentage of suspended solids in the water column at any time originating from resuspension may exceed concentrations of new material by 10–20 times.

As the water levels in lake or reservoir basins change appreciably, the erosive energy of wave action is moved to different sediment strata, sometimes below the growth of littoral communities. Wind-mediated water movements can then cause appreciable resuspension of sediments and increases in nutrient loading to the water (e.g., Gibson and Guillot, 1997; Vernieu, 1997). Sediment resuspension is not limited to surface water movements. A zone of high shear and intense mixing can occur where internal seiches intersect the sediments and internal waves on the seiches break against the sediments and may be circulated within the metalimnion or hypolimnion (Gloor *et al.*, 1994; Pierson and Weyhenmeyer, 1994; Chikita *et al.*, 1995). Concentrations of resuspended particles, largely organic in nature, adjacent to the sediments have been observed to be several times greater than in the water directly above the benthic boundary layer.

III. MICROFLORA OF SEDIMENTS AND RATES OF DECOMPOSITION

A conspicuous feature of microbial populations in lakes is the great increase in numbers in the transition from the overlying water to the diffuse, uncompacted zone of the surficial sediments (Fig. 21-2). Bacteria increase about 3–5 orders of magnitude from the water to the surface sediments and decrease rapidly with increasing depth in the sediments. Expressed in numbers per gram dry weight of sediment, bacterial populations in the surficial sediments can reach 6–7 orders of magnitude greater than in an equivalent weight of overlying water (Table 21-3). Saprophytic bacteria decrease much more rapidly than do total bacteria with increasing depth below the sediment–water interface, which suggests a reduction of readily assimilable organic substrates below the interface.

Bacteria within the surface sediments are unevenly distributed over the lake basin as well (Henrici and McCoy, 1938; Steinberg, 1980a). When the littoral zone is covered with a well-developed macrophyte

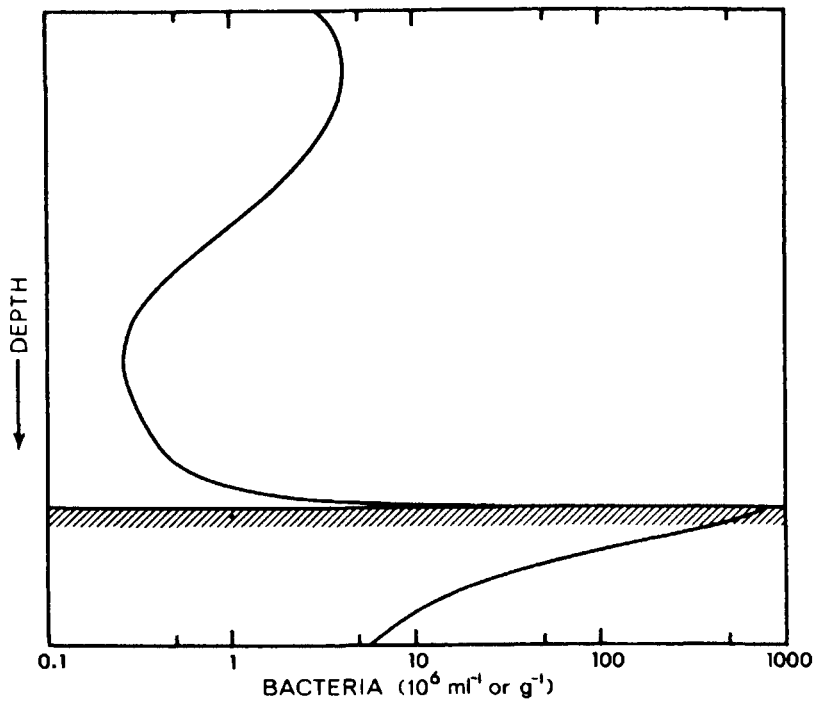

FIGURE 21-2 Generalized relative vertical distribution of bacterial numbers in water and sediments of a moderately productive lake. Depth scale in the water relative in meters and in the sediments in centimeters.

community, bacterial numbers of littoral sediments are much higher by several orders of magnitude than those found in profundal sediments of deepwater areas. Numbers of bacteria in sandy, organic-poor, wave-swept littoral sediments are lower than those in profundal sediments (e.g., Jones, 1980). In eutrophic Blelham Tarn, for example, aerobic respiration and nitrate reduction in the sediments of the littoral were greater than those of the profundal zone, whereas methanogenesis and sulfate reduction were greater in the profundal than in sediments of the littoral zone (Jones and Simon, 1981).

A more detailed analysis of bacterial concentrations in sediments within the macrovegetated littoral zone as compared with those of sediments free of vegetation showed similar relationships (Table 21-4), but with marked shifts seasonally in relation to growth of the macrovegetation. Nitrogen-fixing bacteria *Azotobacter* and the obligate anaerobe *Clostridium* were more abundant in sediments with macrovegetation than in sediments without vegetation or in the overlying water. Similar relationships were found among populations of hydrocarbon- and hydrogen-oxidizing bacteria, cellulose-decomposing bacteria and actino-

mycetes, and fungi. Large numbers of methane-forming and sulfate-reducing bacteria developed under anaerobic conditions in sediments that contain large quantities of decomposition products of higher aquatic plants.

Bacterial numbers and metabolic activities of the deepwater profundal sediments show a weak correspondence with the productivity of the lakes (Table 21-5), as one would anticipate the loading of organic matter and organic nutrients bound within the seston to be approximately proportional to lake productivity. Bacterial numbers in the open water tend to undergo rapid fluctuations and because of nutrient limitations and mortality from grazing and parasitism do not correlate well with lake productivity (cf. Chap. 17; Jones, 1979; Jones *et al.*, 1979). In extremely oligotrophic lakes, total numbers of bacteria of the sediments can be less than the cumulative total of the entire overlying water, which indicates that in these lakes most of the readily decomposable organic matter has been mineralized before the particulate residues reach the sediments (cf. Chap. 17; Bengtsson *et al.*, 1977; Mothes, 1981). Hence, strong positive correlations between bacterial abundance and organic matter in pelagic sediments would not be anticipated (cf. Bird and Duarte, 1989), but certainly increases in littoral areas.

A. Bacterial Activity of Sediments

The relationship of increased bacterial populations and metabolic activity to greater organic matter in sediments may appear obvious, but *in situ* measurements are very few. A significant correlation ($r = 0.93$; $p = 0.01$)

TABLE 21-5 Comparison of Relative Bacterial Numbers (Plate Culture Techniques) of the Profundal Sediments among Several Wisconsin Lakes of Differing Productivity[a]

[a] After data of Henrici and McCoy (1938). The results must be treated in relative terms only because the methods employed likely estimate <5% of bacteria present.

between dehydrogenase activity and organic content of surface sediments has been found in a eutrophic reservoir (Lenhard *et al.*, 1962). These correlations, however, would not be expected to hold in organic-rich sediments in which other conditions, such as acidity as occurs in bogs, depress microbial activity or in sediments where much of the organic matter is chemically recalcitrant.

Data on oxygen consumption by the benthic community of bacteria, algae, and micro- and macrofauna offer some insight into sediment respiration rates, provided that oxygen utilization by these community components can be appropriately partitioned and corrected for abiotic oxygen uptake (Bowman and Delfino, 1980). Under aerobic conditions of shallow ($\bar{z}$ = 2.4 m) Marion Lake, Canada, respiratory oxygen consumption by sediment-dwelling bacteria over an annual period was found to be related primarily to temperature (Fig. 21-3; also Granéli, 1978). The proportion of community respiration resulting from bacterial respiration varied with season (Fig. 21-3) and was lowest during maximal community respiration during the summer period of higher temperatures. This percentage certainly increases under other conditions among lakes; in deep-water sediments, for example, nearly all metabolism is by heterotrophic microbes.

Microbes associated with particulate organic detritus consumed up to 3 orders of magnitude more oxygen per unit dry weight than did those of sand (Hargrave, 1972). Uptake rates were inversely related to particle size and directly related to particle organic content of carbon and nitrogen.

In shallow lakes, water turbulence can frequently disturb and mix sediments to appreciable depths (e.g., to 10 cm; Viner, 1975). After brief reoxygenation by turbulence or the respiratory or feeding activities of benthic animals, community respiration and oxygen consumption rates of highly organic sediments quickly (hours to a few days) return to values similar to those of undisturbed sediments of similar organic content and composition (Hargrave, 1975; Viner, 1975).

Assays of the heterotrophic activity of benthic microorganisms of shallow water sediments by the uptake of labeled glucose, acetate, and glycine demonstrated that the greatest activity occurred in the summer months when the water temperatures exceeded 10°C (K. J. Hall *et al.*, 1972; Toerien and Cavari, 1982). Availability of substrates and slow diffusion rates exerted some control over the uptake and utilization of dissolved organic compounds of the interstitial water. The fraction of the substrate respired as CO_2 varied with the amended compound and was highest (average 63%) with glycine in comparison to glucose (22%) and acetate (13%). Most of the heterotrophic activity occurred in the upper sediment layers, the sites of highest bacterial numbers in the sediments.

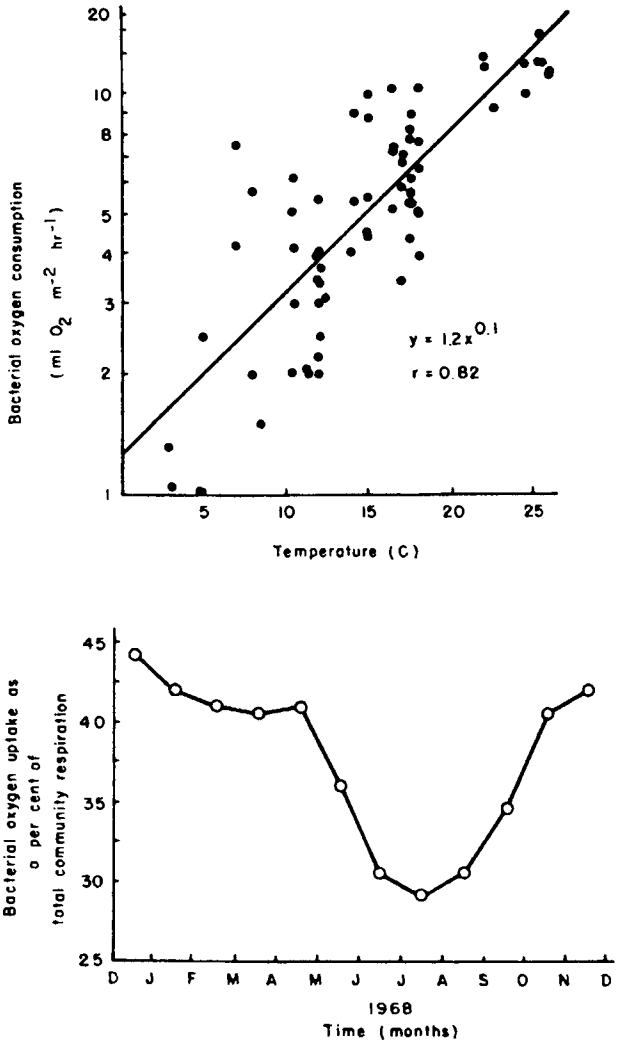

FIGURE 21-3 *Upper*: Relationship of temperature and sediment bacterial respiration; *lower*: bacterial respiration as a proportion of total community oxygen consumption in shallow-water Marion Lake sediments during 1968. (After Hargrave, B. T.: Epibenthic algae production and community respiration in the sediments of Marion Lake. *J. Fish. Res. Bd. Canada* 26:2003–2026, 1969.)

Glucose uptake rates by bacteria of surficial sediments of a small, eutrophic alpine lake were greater in littoral areas than in profundal sediments (Steinberg, 1978b). Similar results were found in a hypereutrophic lake in southern Michigan (King and Klug, 1982b). The turnover times (T_t) of glucose were much more rapid in the anaerobic sediments (0.3–4 h) than in the overlying water column (20–40 h). About 40% of the methane carbon generated in the sediments emanated from the added glucose. Turnover rates were faster in the littoral sediments than in the profundal sediments.

A number of studies have indicated enhanced growth of bacteria in sediments at temperatures greater than usually occur in profundal sediments of temperate lakes (e.g., Inniss and Mayfield, 1978a,b, 1979; Tison and Pope, 1980; Tison *et al.*, 1980). Appreciable adaptation to cold temperatures apparently occurs by selection of bacterial species and by a physiological tolerance of temperature changes by individual species (e.g., Boylen and Brock, 1973; Leduc and Ferroni, 1979).

IV. ANAEROBIC DECOMPOSITION IN SEDIMENTS

Oxygen serves as the universal hydrogen acceptor for biochemical reactions of microbes under aerobic conditions. Under anaerobic conditions, however, the relationships are far more complicated, for various other substances and intermediate metabolic organic compounds become electron (hydrogen) acceptors. Often, the same compound can serve as an electron acceptor or donor, depending on the environmental conditions.

As was described earlier for the water column, when oxygen is utilized more rapidly than it is generated by photosynthetic processes or intrusion from other habitats, anaerobic microbial processes utilize a variety of inorganic and organic compounds as alternative electron acceptors. Specific anaerobic processes occur largely in a fixed sequence reduction of nitrate, manganese, iron, sulfate, and carbon dioxide utilizing organic substrates in methanogenesis (Table 21-6). The occurrence of specific anaerobic processes is dependent on the presence of the appropriate electron acceptor as well as competitive electron acceptors (e.g., review of Laanbroek, 1990). During the succession of anaerobic oxidation processes, the redox potential of the sediments decreases as a result of the reduced products formed (Table 21-6).

Each redox couple has a characteristic redox potential at pH 7. The potentially available maximum amount of energy generated in a redox reaction, assuming H_2 as the electron donor, decreases in the sequence from oxygen to carbon dioxide (Table 21-6). Generally, physiological adaptations have evolved to optimize the energy yield from the total oxidation of organic matter.

Some electron-acceptor compounds, such as nitrate and ferric oxide, can be reduced by the same bacteria. These microbes, however, have a preference to utilize nitrate in the reduction of organic compounds and are approximately mutually exclusive to utilize nitrate until the supply is exhausted before utilizing iron oxides. The reductions of ferric oxide, sulfate, and carbon dioxide are also mutually exclusive but vary because the reduction is performed by physiologically different types of bacteria with different affinities for electron donors such as acetate and hydrogen (Lovley and Klug, 1983b; Newell, 1984; Ward and Winfrey, 1985; Lovley, 1987; Laanbroek, 1990). Ferric oxide reduction occurs preferentially to the reduction of sulfate and carbon dioxide owing to a stronger affinity of ferric oxide–reducing bacteria for these electron donors than the other types of anaerobic bacteria. Similarly, sulfate-reducing bacteria are better scavengers for acetate and hydrogen than are the methanogenic bacteria because methanogens have the lowest affinities for these fermentation products.

The dynamics of nitrogen metabolism and exchanges in sediments is complicated because of numerous pools for nitrogen and the many simultaneously regulating roles of microorganisms on the nitrogen cycle. If light reaches the sediments, the processes and fluxes are further complicated by nitrogen assimilation and/or fixation, storage, and release as organic nitrogen. Because many sediments receive sufficient light to support an intercoupled benthic microalgae and

(Modified from Rysgaard *et al.*, 1993.)

bacterial community on the surface of the sediments (cf. Chap. 19), it is included in the general model presented in Figure 21-4. Nitrogen transformations include assimilation, mineralization, nitrification, and denitrification in sediments (e.g., Rysgaard *et al.*, 1993). Particulate organic nitrogen is mineralized to NH_4^+ in both the oxic and anoxic strata in the sediments. Ammonium can then be oxidized to NO_3^- by nitrifying bacteria in the oxic layer of the sediment, assimilated by benthic algae and other microbes, or diffuse out of the sediment. The NO_3^- of nitrification can under anaerobic conditions be reduced to N_2 by denitrifying bacteria and lost from the environment, or it can be reduced to NH_4^+ by fermentative bacteria or diffuse out of the water. Nitrate and NH_4^+ in the overlying water can also diffuse into the sediment and be cycled as discussed.

As organic matter concentrates in the sediments, decomposition processes release ammonium (NH_4^+) that can be adsorbed to sediment particles (ca. 90% can be adsorbed; cf. Verdouw *et al.*, 1985), assimilated and metabolized directly by biota in the sediments, or nitrified bacterially to nitrate. In addition, NO_3^- can diffuse from the overlying water into the sediments. Denitrification in aquatic sediments, as in anoxic water strata overlying sediments, is a major potential loss of nitrogen from aquatic ecosystems, as it converts nitrate to N_2 that can evade to the overlying water and the atmosphere. A large percentage of the nitrate produced in the sediments is denitrified, and in many freshwater sediments, most (75–>95%) of the organic nitrogen mineralized in the sediments is lost through nitrification and denitrification (Seitzinger, 1990). Some of the highest rates of denitrification have been found in eutrophic river sediments. When benthic algae and cyanobacteria are present and active, much of the NO_3^- and NH_4^+ is assimilated by these microphytes, even for many hours (25–60 h) after darkness (Rysgaard *et al.*, 1993). Under steady-state conditions in the dark, however, as would be the case in profundal sediments, nearly all (≈100%) of the total NO_3^- uptake was by bacterial denitrification.

A. Methanogenesis

Degradation of large quantities of organic matter occurs under anaerobic conditions through methanogenesis in the sediments of lakes, ponds, wetlands, and streams, as well as in waste-treatment facilities (oxidation ponds, anaerobic lagoons, and septic tanks). In the degradation process, organic matter is converted quantitatively to methane and carbon dioxide in two stages (Fig. 21-5). In the first stage, a heterogeneous group of facultative and obligate anaerobic bacteria, termed *acid formers*, converts proteins, carbohydrates, and fats primarily into fatty acids by hydrolysis and fermentation (Deyl, 1961; McCarty, 1964; Zeikus, 1977; Nedwell,

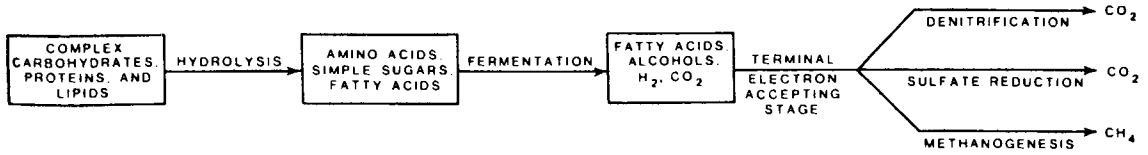

FIGURE 21-5 Stages of anaerobic metabolism of complex organic compounds. (Modified from Wolfe, 1971; Molongoski, 1978; Zehnder, 1978.)

1984). The methane-producing bacteria then utilize the organic acids, converting them to carbon dioxide and methane. Certain alcohols from carbohydrate fermentation can also be converted to methane and carbon dioxide by methane-producing bacteria.

Utilization of organic compounds in suspension or solution by acid-forming bacteria in the first stage results only in the synthesis of bacterial cells and the generation of end-product organic compounds, such as organic acids. Removal of oxidizable organic compounds occurs in the second stage and is directly proportional to the quantity of methane produced. During most anaerobic metabolism, the formation of hydrogen occurs (see later discussion); alternatively, the reduction of inorganic electron acceptors, such as nitrate, nitrite, oxidized iron, and sulfate takes place (described in detail in Chaps. 12 and 14).

The first stage of acid formation results from hydrolysis and fermentation (McCarty, 1964). Proteins are first enzymatically hydrolyzed to polypeptides and then to simple amino acids. Complex carbohydrates such as starch and cellulose are hydrolyzed to simple sugars, while fats and oils are hydrolyzed to glycerol and fatty acids. The amino acids, simple sugars, and glycerol formed by hydrolysis are soluble and are fermented by acid-forming bacteria. In the absence of oxygen, one portion of the organic molecule is oxidized, while another portion of the same molecule (or sometimes another compound) is reduced. These fermentative energy-yielding oxidation–reduction reactions produce reduced (saturated) fatty-acid compounds and oxidized carbon as CO_2. Ammonia is produced as an end product during amino-acid fermentation.

The methane-producing bacteria are strictly anaerobic and consist of four major genera: rod-shaped nonsporulating *Methanobacterium*, rod-shaped sporulating *Methanobacillus*, and the spherical *Methanococcus* and *Methanosarcina*. Species are differentiated on the basis of the substrates they are capable of using.

Methane is formed by two major processes. In the first, carbon dioxide serves as a hydrogen acceptor and is reduced to methane by enzymatic addition of hydrogen derived from the organic acids:

$$CO_2 + 8H \longrightarrow CH_4 + 2H_2O$$

In the second process, acetate, which is a major intermediate produced by the fermentation of complex organic compounds, is converted to CO_2 and methane. In this reaction, the carbon of the methane originates from the methyl carbon of acetate:

$$*CH_3COOH \longrightarrow *CH_4 + CO_2$$

Methane produced during the fermentation of mixed organic compounds originates largely (approximately 70%) via the intermediate, acetate. Much of the remainder of the methane results from reduction of CO_2. Propionic acid, an intermediate compound produced in significant quantities from protein, methanol, methylamines, carbohydrate, glycerol, and other compounds, also can serve as a substrate for methane production (e.g., Naguib, 1982; Lovley and Klug, 1983a). Longer-chain acids are of less importance. Acetate and hydrogen are, however, the major methane precursors.

The concentrations of acetate, H_2, and CO_2, the major *in situ* substrates for methanogenesis, are variable and dependent upon the inputs and rates of fermentation of settling organic matter. Acetate is the preferred substrate for methanogenesis at low partial pressures of hydrogen; as the partial pressure of hydrogen increases, bicarbonate is the preferred substrate (e.g., Winfrey *et al.*, 1977; Strayer and Tiedje, 1978a; Jones *et al.*, 1982; Lovley and Klug, 1982; Lovley *et al.*, 1982; Nedwell, 1984; Rothfuss and Conrad, 1993; Conrad, 1999). Hydrogen should theoretically account for about one-third of total methanogenesis when carbohydrates or similar forms of organic matter are degraded (Fig. 21-6). Many hypolimnetic temperatures are always cold (<12°C), which slows methanogenesis for thermodynamic reasons. Increases of temperature, however, can shift the degradation pathway and increase the role of H_2 as an intermediate substance (Schulz and Conrad, 1996). In methanogenic environments, H_2 is rapidly cycled, and its concentration is the result of simultaneous production by fermentation and syntrophic bacteria and consumption by methanogenic bacteria.

Nitrate, nitrite, oxidized iron, and sulfate in sediment in interstitial water inhibit methanogenesis either directly by metabolic inhibition of methanogens or

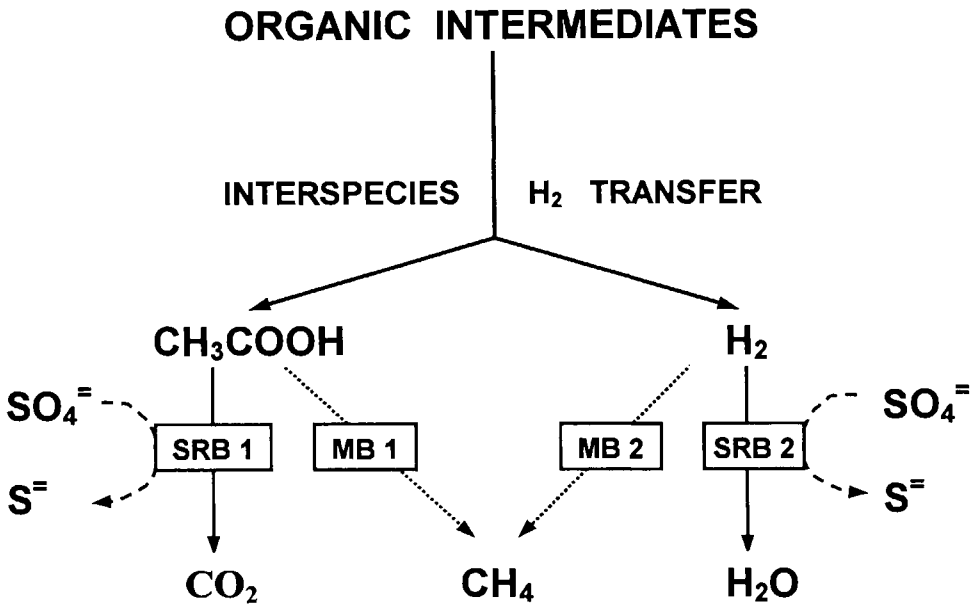

FIGURE 21-6 Competition for H_2 and acetate between methanogenic bacteria (MB) and sulfate-reducing bacteria (SRB). In the presence of high sulfate concentrations, MB are outcompeted for resource by SRB (*broken lines*). MB-1 = Acetate-utilizing MB; MB-2 = H_2 + CO_2-utilizing MB; SRB-1 = acetate-utilizing SRB; SRB-2 = H_2-utilizing SRB. (Modified from Nedwell, 1984.)

indirectly by channeling electron flow from methane carbon precursors to these alternate electron acceptors (Fig. 21-6, Table 21-6) (cf., Chap. 12 and 14, and, e.g., Chen *et al.*, 1972; MacGregor and Keeney, 1973; Cappenberg, 1974, 1975; Winfrey and Zeikus, 1977, 1979; Zeikus, 1977; Zehnder, 1978; Ward and Winfrey, 1985; Roden and Wetzel, 1996). The degree of inhibition depends upon the relative concentrations of alternate electron acceptors. Evidence suggests that certain sulfate-reducing bacteria can function commensally with methanogens: Methanogens ferment acetate released by the sulfate-reducing bacteria (Cappenberg, 1975). When sulfate is not limiting, the lower half-saturation constant of sulfate-reducing bacteria enables them to inhibit methane production by lowering the hydrogen partial pressure below levels that methanogenic bacteria can effectively utilize (Lovley *et al.*, 1982; Robinson and Tiedje, 1984; Ward and Winfrey, 1985; Conrad *et al.*, 1987). However, methanogenic bacteria can coexist with sulfate-reducing bacteria in the presence of sulfate (Fig. 21-6); the outcome of competition at any time is a function of the rate of hydrogen production, the relative population sizes, and sulfate availability. In low-sulfate environments methanogens are more competitive, whereas in high-sulfate environments, sulfate reducers are more competitive, in part because sulfate reducers have a greater affinity for acetate and H_2 (Conrad, 1999). In methanogenic environments, H_2 is rapidly turned over, and its concentration is the result of simultaneous production by fermenting bacteria and consumption by the methanogenic bacteria. The steady-state concentration observed in most methanogenic environments is close to the thermodynamic equilibrium of H_2-dependent methanogenesis to a boundary of ΔG_0 of ca. -96 kcal mol^{-1}.

Rates of sulfate reduction in pelagic sediments generally increase with greater productivity of phytoplankton in lakes (Table 21-7). The intensive sulfate-reduction processes, however, remove sulfate supplies as rapidly as they penetrate sediments from the overlying water, and exceed availability, particularly during stratification where sulfate is eliminated completely from the hypolimnion (Chap. 14). Methanogenesis then dominates in sediments receiving high amounts of organic matter.

B. Methane Oxidation

Methane can be oxidized abiologically by oxidation by hydroxyl radical and by aerobic bacterial oxidation. On a global basis, bacterial oxidation likely exceeds abiological conversions and substantially reduces methane emissions to the atmosphere (King and Blackburn, 1996). Data from many diverse aquatic ecosystems indicate that as much as 90% of the methane produced in sediments is oxidized as it passes into oxic zones within the sediments or water.

Although the production of methane in sediments can be very intense and reach as much as 85% of the

total gas volume formed in the deposits, little of the methane escapes to the atmosphere in low to moderately productive lakes, owing to the presence and activity of methane-oxidizing bacteria in the sediments and overlying water (ZoBell, 1964). Methane oxidation rates are much higher per unit volume in sediments or surface flocs than in the water column (Lidstrom and Somers, 1984; Kuivila *et al.*, 1988; Frenzel *et al.*, 1990; reviewed in King and Blackburn, 1996). In profundal lake sediments, 50–>90% of methane flux is consumed by methane oxidation. Variables include the extent and rates of advection and diffusion of CH_4 and O_2, both of which vary markedly with seasonal stratification, lake circulation, and sediment resuspension. Consumption of oxygen diffusing into sediments usually exceeds inputs within the first 2 mm, so that much of the methane oxidation is maximized in this area where the two gradients meet. Under some circumstances, it is possible that ammonia-oxidizing bacteria can also oxidize CH_4, although it is unclear that this metabolism supports growth (cf. King and Blackburn, 1996). Very high concentrations of ammonia (>5–20 mM) can inhibit methane oxidation in the surface layers of sediments (Bosse *et al.*, 1993).

Methane oxidation is much more variable and ranges from <10–>90% in shallow water and wetland sediments. As discussed earlier, photosynthesis by benthic algae growing on the sediments in shallow water can shift oxygen concentrations within the surficial sediments (1–4 mm) from anaerobic conditions during darkness to supersaturated concentrations during the daylight (cf. Fig. 13-8 and pp. 253). During the transition from light to dark periods, methane flux increases accompanied by a decrease in methane oxidation (King, 1990a). The processes reverse under lighted conditions.

Emergent and floating-leaved but rooted aquatic plants are major conduits for methane exchange with the atmosphere (e.g., Dacey and Klug, 1979; Sebacher *et al.*, 1985; Schütz *et al.*, 1989; King, 1990b; Whiting and Chanton, 1992). Clearly, methane diffuses into the roots of aquatic plants—appreciable amounts (up to 95%) of the CH_4 is oxidized there or in the oxidized microrhizosphere around the roots (e.g., Schütz *et al.*, 1989; King *et al.*, 1990; Bosse and Frenzel, 1997; Calhoun and King, 1997), but collectively large amounts can be transported in the internal ventilation gaseous system of the plants and expelled to the atmosphere. Results generally indicate that >90% of the methane evasion to the atmosphere from wetlands and littoral areas is released from the plants rather than from direct ebullition. That gas flux to the atmosphere is coupled, in part, to rates of metabolism of the plants, increases with increasing emergent plant productivity, and commonly decreases as stomatal conductance decreases (Csermák *et al.*, 1992; Morrissey *et al.*, 1993; Whiting and Chanton, 1993). This release appears to be greater during vigorous plant growth than later during leaf senescence (Stanley *et al.*, 1998). Herbivory on the aquatic plant leaves had little effect on methane release. Although methane evasion to the atmosphere from the pelagic region of lakes is relatively low, these rates increase in shallow lakes and in the littoral areas (Table 21-8). Methane emissions from natural and cultivated (particularly rice) wetlands are appreciable (ca. 170–200 Tg yr^{-1}) on a global basis (Aselmann and Crutzen, 1989; Bouwman, 1991; Bartlet and Harriss, 1993; Sass and Fisher, 1996).

Methane concentrations in rivers can also be significant, and in large rivers the waters are nearly always supersaturated with methane (10–500 nM). Much of the methane evades directly to the atmosphere, with only about 25% being utilized by methane oxidizers (Lilley *et al.*, 1996). Undisturbed forested streams and rivers can contain high natural levels of CH_4 not attributable to pollution (de Angelis and Lilley, 1987; Jones *et al.*, 1995; Jones and Mulholland, 1998). Production can occur in the stream sediments as well as be imported by lateral diffusion and runoff from saturated forest and fertilized agricultural soils. Methane production is commonly greatest in bank sediments that are relatively isolated hydrologically and

[a] Many additional values of methane evasion exist in a large literature on this subject (e.g., reviews of Shotyk (1989), Chanton and Dacey (1991), Harriss *et al.* (1991), Bartlett and Harriss (1993), Bubier *et al.* (1993), Sass and Fisher (1996), Javitt *et al.* (1997), and Segers (1998).

lowest in hyporheic and parafluvial sediments that are interactive with the surface stream water. In large rivers, increased areas of anoxia in sediments and reduced hydrologic exchange with surface water can enhance concentrations of methane.

Methane oxidizers are widely distributed in most natural waters (cf. Higgins *et al.*, 1981; Saralov *et al.*, 1984). Among the best-known of many species of methane-oxidizing bacteria is *Methanomonas methanica*, which, in addition to methane, can oxidize numerous other hydrocarbon compounds. All members of this group appear to be strict aerobes, although they tolerate microaerobic conditions. The overall empirical equation for methane oxidation is

$$5CH_4 + 8O_2 \longrightarrow 2(CH_2O) + 3CO_2 + 8H_2O$$

with a free-energy yield of − 195 kcal per mol.

The distribution of methane-oxidizing bacteria in dimictic lakes indicates that these forms are present throughout the year in significant numbers. The methane oxidizers increase during summer stratification, the highest numbers ($>5 \times 10^2$ ml^{-1}) occurring in metalimnetic and hypolimnetic waters with reduced oxygen concentrations and maximum concentrations of methane (Cappenberg, 1972). During summer stratification, the highest rates of methane oxidation have been consistently found in the lower metalimnion, where oxygen concentrations are reduced to approximately 1 mg $liter^{-1}$ or less (Rudd *et al.*, 1974, 1976; Rudd and Hamilton, 1975; Jannasch, 1975; Panganiban *et al.*, 1979). During the summer, when combined inorganic nitrogen sources in the epilimnion were low in the eutrophic lakes studied, the methane-oxidizing bacteria fixed molecular nitrogen. Methane oxidation in strata

above the metalimnion declined by as much as 40%, because N_2 fixation can be inhibited by the higher concentrations of oxygen occurring there. High rates of methane oxidation, amounting to as much as 95% of the annual quantity of methane oxidized (Rudd and Hamilton, 1975; Heyer and Suckow, 1985), have been found in spring and fall periods of lake circulation. During the periods of lake turnover, combined inorganic nitrogen is available and the dependency of methane oxidation on N_2 fixation found in summer months is alleviated. In shallow but eutrophic lakes that do not stratify and are oxic continuously, methane oxidation is still the dominant methane sink. For example, in a large, eutrophic lake in Japan, methane oxidation consumed an annual average of 74% of dissolved methane in the water column (Utsumi *et al.*, 1998). Under ice cover, high rates of methane oxidation can occur throughout the water column of eutrophic and protected dystrophic lakes, possibly lowering oxygen concentrations or even causing total anoxia (cf. Chap. 9).

Oxidation of methane to carbon dioxide in the absence of oxygen has been observed but only at the sediment surface (Panganiban *et al.*, 1979). The methane-oxidizing organisms and the metabolic pathways involved are unclear but are likely associated with the activity of sulfate-reducing bacteria (cf. Reeburgh and Heggie, 1977; Rudd and Taylor, 1980).

C. Methane Cycling in Lakes

Several recent investigations have attempted to quantify methane cycling in eutrophic lakes in terms of overall carbon cycling and to evaluate its effects on the entire lake ecosystem (reviewed in Rudd and Taylor, 1980). For example, the annual methane cycle was evaluated in Lake 227, a lake in western Ontario rendered eutrophic by experimental fertilization (Rudd and Hamilton, 1978). Lake 227 is small (5 ha.), moderately deep (z_m = 10 m), and during the investigation circulated only for about six weeks in the fall before ice formation. During summer stratification, most methane produced in hypolimnetic sediments accumulated in the hypolimnion. Vertical diffusion of methane from the hypolimnion to the metalimnion was very slow and amounted to 11% of the methane produced in the hypolimnion. Nearly all of the methane that diffused into the metalimnion was converted to bacterial-cell carbon and CO_2 by methane-oxidizing bacteria. Small amounts of methane observed in the epilimnion during summer emanated largely from methanogenesis in epilimnetic sediments. Epilimnetic methane slowly evaded to the atmosphere, since little was oxidized because of low combined inorganic nitrogen concentrations and the inhibitory effects of high oxygen on N_2-fixation by methane-oxidizing bacteria.

Oxidation rates of methane in Lake 227 increased abruptly during fall circulation as hypolimnetic water rich in accumulated methane and inorganic nitrogen was mixed and oxygenated. About 40% of the methane that was transported into the upper strata escaped to the atmosphere. During fall circulation, however, the rates of methanogenesis in the surficial sediments were markedly reduced as the availability of alternative, more efficient electron acceptors, such as sulfate, became available in the sediments for reduction (e.g., Phelps and Zeikus, 1985). Under winter ice cover, methane production in hypolimnetic sediments was similar to that during the summer. Only about 10% of the methane was consumed by methane-oxidizing bacteria at the aerobic–anaerobic interface; the remainder accumulated and extended into the summer hypolimnion, since this lake did not circulate completely in the spring following ice loss.

In Lake 227, the annual methane production, oxidation, and evasion were compared to the annual phytoplankton primary production and total carbon inputs from runoff and the atmosphere. This comparison showed that the amounts of CO_2 and bacterial-cell material produced by methane oxidizers were insignificant in terms of carbon flow in comparison to primary production (Table 21-9). Methane cycling was much more significant, however, when compared with the total carbon input into the lake. During 1974, the amount of carbon regenerated as methane was equivalent to about 55 percent of the total carbon input into the lake (Table 21-9). Methane-oxidizing bacteria recycled about two-thirds of the methane carbon. Similar values

Phytoplanktonic primary production	138
Total carbon inputs	33

[a] After Rudd and Hamilton (1978).

[b] Primary production and total carbon inputs occurred mostly during the summer. The methane production and oxidation year included the succeeding winter since regeneration of methane carbon fixed during the previous summer would be occurring. The large difference between the amount of carbon entering the lake and the amount fixed by phytoplankton presumably resulted from rapid aerobic recycling of carbon within the epilimnion during the summer months.

Lake Washington, WA (Kuivila *et al.*, 1988)	Feb., Oct.	20	ca. 2

[a] Values of particulate loading are based on phytoplanktonic sestonic sedimentation only; inputs of organic carbon from the wetlands and littoral productivity, which are extensive in many of these lakes and could be transported along the sediments to hypolimnetic areas and missed in pelagic sedimentation traps, were not evaluated. Therefore, the methanogenetic values could be overestimates.

have been found in a number of other eutrophic and hypereutrophic lakes during summer periods of thermal stratification (Table 21-10). A general direct relationship has been found between the rates of particulate organic carbon sedimentation and rates of methane release from *pelagic* sediments in eutrophic lakes (Robertson, 1979; Casper, 1992). In oligotrophic lakes where phytoplankton sedimentation to pelagic sediments is low, however, as well as in eutrophic lakes with well-developed littoral areas, methane production rates of the sediments in the littoral zone were found to be much higher than those of the profundal zone (Casper, 1996; Rolletschek, 1997).

The terminal processes involved in the decomposition of organic carbon compounds and electron flow in sediments can be divided into two groups (Fig. 21-7; Table 21-6): (a) those processes requiring electron acceptors (e.g., O_2, NO_3^-, Fe^{+3}, and SO_4^-,) generated or regenerated externally (i.e., from aerobic overlying water) to the zone of anaerobic metabolism in the sediments,

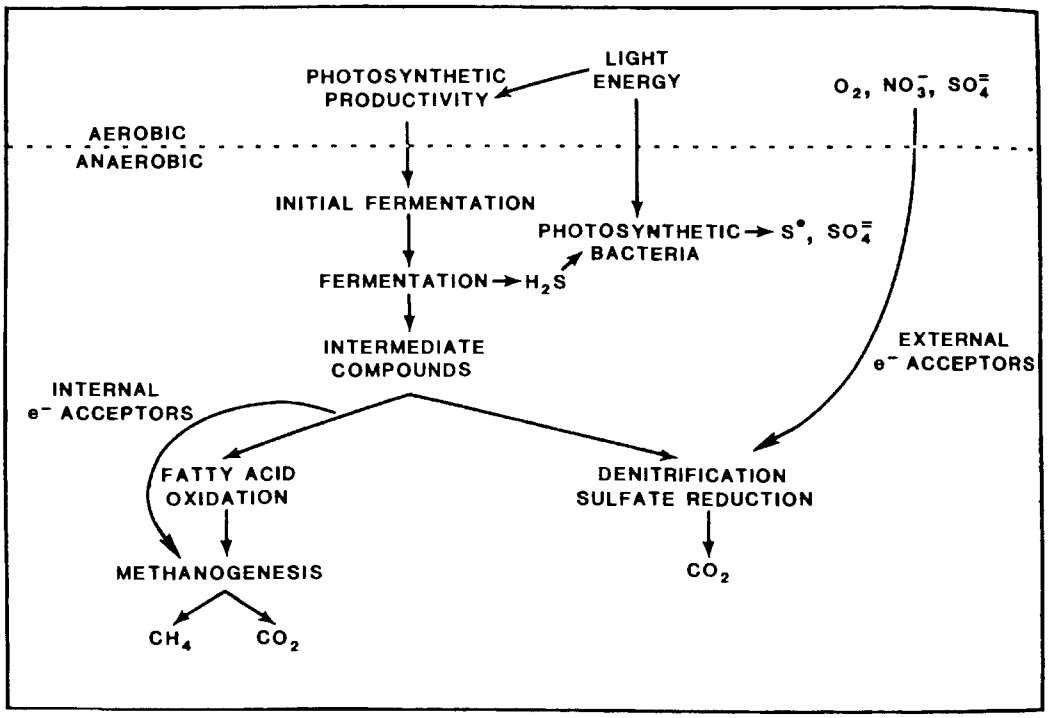

FIGURE 21-7 Relationship of main terminal degradation processes to the available electron acceptors in lake sediments. (Modified from Klug *et al.*, 1982.)

and (b) those processes utilizing electron acceptors (e.g., HCO_3^-), generated or regenerated internally within the zone of anaerobic metabolism (Klug *et al.*, 1982). Denitrification and sulfate reduction are examples of microbial processes dependent upon external electron acceptors. Fermentation and methanogenesis, in contrast, depend upon internally generated electron acceptors.

D. Hydrogen Metabolism

Molecular hydrogen is formed in the sediments, under anaerobic conditions, by fermentative degradation of carbohydrates, cellulose, and hemicelluloses to fatty acids, especially acetic acid. Hydrogen and CO_2 are generated by *Clostridium* from simple carbohydrates and from cellulose by *Achromobacter* and *Bacillus*. Formate serves as the carbon source for hydrogen formation in some species of *Bacterium*.

In sediments, only microorganisms catalyze the oxidation of H_2 coupled to the reduction of nitrate, Mn(IV), Fe(III), sulfate, or carbon dioxide. H_2 concentrations are dependent on the physiological characteristics of the microorganisms consuming the H_2 and utilizing H_2 to maintain lower concentrations in proportion to the availability of electron acceptors (Lovley and Goodwin, 1988). As discussed earlier (p. 639), each terminal electron-accepting reaction has a unique range of H_2 concentrations associated with it, greatest with methanogenesis and least with nitrate reduction. Because hydrogen is oxidized by several pathways, little reaches the surface and escapes to the atmosphere as bubbles. Certain strictly anaerobic sulfate-reducing bacteria of the genus *Desulfovibrio* oxidize hydrogen while utilizing CO_2 to synthesize at least part of their cell substance (ZoBell, 1973):

$$H_2SO_4 + 4H_2 \longrightarrow H_2S + 4H_2O \quad (\Delta G_0' = -73.1 \text{ kcal mol}^{-1})$$

Such sulfate reducers were found to fix an average of 0.24 g CO_2–C per gram of H_2 oxidized, and nearly all of the CO_2–C was accounted for as bacteria biomass. Oxygen for the oxidation is derived from the sulfate. Certain species of all of the major genera of the methane-forming bacteria can oxidize molecular hydrogen.

E. Carbon Monoxide Metabolism

Carbon monoxide results from certain microbial fermentations, but even under exceptionally favorable conditions, it generally does not exceed 3% of the gases formed by bacterial fermentation of organic wastes (ZoBell, 1964, 1973). Carbon monoxide can also be generated in surface waters by ultraviolet photolysis of humic substances (e.g., review of Moran and Zepp, 1997). The chemical reactivity of CO and the relative ease with which various bacteria reduce it to methane or oxidize it to CO_2 probably account for its absence or very low concentrations in most environments.

Aerobic CO-oxidizing bacteria are distributed widely, especially in organic-rich sediments. Species of *Carboxydomonas*, *Hydrogenomonas*, *Bacillus*, and certain methane-oxidizing bacteria oxidize CO (Hubley *et al.*, 1974):

$$CO + \tfrac{1}{2}O_2 \longrightarrow CO_2 \qquad (\Delta G_0' = -66 \text{ kcal mol}^{-1})$$

Additionally, several aerobic bacteria in mixed populations quantitatively convert carbon monoxide into methane in the presence of hydrogen:

$$CO + 3H_2 \longrightarrow CH_4 + H_2O \quad (\Delta G_0' = -46 \text{ kcal mol}^{-1})$$

In the absence of H_2, some anaerobic bacteria (*Methanosarcina*) produce CO_2 and methane:

$$4CO + 2H_2O \longrightarrow 3CO_2 + CH_4$$

F. Effects of Hydrostatic Pressure on Gaseous Metabolism in Sediments

Analyses of the distribution of the gases contained in lake sediments and water show that the total quantity of nitrogen, methane, and hydrogen in lake sediments increases with water depth (Table 21-11; cf. also

TABLE 21-11 Average Content of Gases in Sediments of Several Japanese Lakes in Relation to Gas and Hydrostatic Pressures[a]

[a] After Koyama (1964).

Fig. 12-1). The total pressure of the gases was usually slightly higher than the corresponding hydrostatic pressure (Koyama, 1964).

Experimental investigation of the metabolism of lake sediments under normal pressure demonstrated the following sequence (Koyama, 1955): (a) CO_2 production began immediately at high rates; (b) as the sediments became anaerobic, hydrogen was evolved, followed by increasing rates of methane production. The primary reaction of methane formation was the reduction of CO_2 by hydrogen and hydrogen-donor compounds. Hydrostatic pressures that would be encountered in the sediments of most lakes do not greatly alter bacterial production of gases. Methane production decreased slightly as pressures were increased from 0 to 50 atmospheres (atm) and then increased up to 300 atm, after which gradual decreases in methane production were observed.

G. Production of Gases in Sediments, Ebullition, and Relationships to Lake Productivity

Lakes and rivers are collectors of organic carbon. Total organic carbon within these ecosystems results from autochthonous production augmented by imported allochthonous organic carbon from wetland and terrestrial sources. All of the organic carbon is not mineralized because much is deposited within low redox conditions within sediments. As will be emphasized in the concluding chapters, most of the intense microbial respiration and fermentation is associated with the sediments. As a result, large quantities of CO_2 and CH_4 evade from the sediments. Carbon dioxide is only moderately soluble in water (cf. Chap. 11), and much more is produced by decomposition than can be refixed photosynthetically within the limitations of nutrient and light availability and herbivory. Consequently, large quantities of CO_2 evade to the atmosphere (Table 21-12). Marked seasonality occurs in the evasion of CO_2 to the atmosphere, with the greatest amounts following ice cover during lake circulation and the lowest during periods of highest photosynthesis (e.g., Otsuki and Wetzel, 1974; Anderson *et al.*, 1999). But for most lakes and rivers, a large net evasion of CO_2 to the atmosphere prevails.

Concentrations of fermentation gases within the water column of most productive lakes are very low in

the surface layers and markedly increase in the hypolimnion and near the sediments. If production rates and pressure conditions are such (cf. p. 152ff.) as to permit bubble formation, the gases can rise rapidly to overlying strata. Often these reactive gases are redissolved and metabolized by microflora en route; much of the methane ebullition is redissolved and utilized by methane-oxidizing bacteria.

Bubble release from the water surface occurs in shallow aquatic situations, such as marshes and littoral areas, where intense anaerobic fermentation in the surficial sediments occurs (e.g., Koyama, 1963; King and Wiebe, 1978; Barber and Ensign, 1979; Svensson and Rosswall, 1984). Although methane emissions to the atmosphere from wetlands is largely (ca. 95% or more) through the internal ventilation system of emergent aquatic plants, methane is still released in significant quantities by ebullition from shallow eutrophic waters, particularly from nonvegetated sediments. Not unexpectedly, rates of evasion of methane to the atmosphere are roughly an order of magnitude greater in water above the sediments in shallow littoral areas than from the water column of pelagic areas (Table 21-8). Despite high release rates of CO_2 simultaneously from shallow waters and wetland, methane evasion could account for 50% or more of the carbon flux to the atmosphere. Measurements given in Table 21-8 are approximate, and data exhibit large variability. Some of that variability results from spatial heterogeneity in sediments, vegetation, temperature, and hydrology (e.g., Bartlett *et al.*, 1989), and that from day to day may result from natural variations in ebullition rates, such as marked increases from lakes associated with decreases in air pressure (Mattson and Likens, 1990) or water depth and hydrostatic pressure overlying sediments (Chanton *et al.*, 1989). Also, in polymictic, shallow, eutrophic lakes, ebullition of methane to the atmosphere is highly irregular in relation to mixing events and disturbance of sediments (Takita and Sakamoto, 1993). Ebullition in these waters increases with increasing temperatures in the sediments and overlying water during the active growing season.

As is the case with CO_2, methane also can accumulate greatly under ice (e.g., Rossolimo, 1935; Smith and Lewis, 1992) and evade to the atmosphere following ice loss and lake circulation at much greater rates than during other seasons. Rates of evasion from aquatic plants also vary markedly diurnally and seasonally with changes in physiology during the life cycles of the plants (e.g., Kim *et al.*, 1998).

As lakes become very eutrophic, the anaerobic fermentation of organic matter in the sediments can reach levels sufficient to result in the steady ebullition of gases. For example, Strayer and Tiedje (1978) found that an average of 21 mmole m^{-2} day^{-1} of methane left the anaerobic sediments by ebullition in hypereutrophic Wintergreen Lake, Michigan, during the period of late May through August. Ohle (1958) demonstrated by both chemical analyses and sonar echo sounding that, under stratified conditions in very productive lakes, ebullition is sufficient to induce "methane convection" currents by which sediment particles and dissolved substances of the hypolimnion can be transported to the trophogenic zone.

The return of nutrients from the sediment zone to the zone of primary production represents an ***internal fertilization*** of the system. The ebullition of gases from the sediments is closely related to lake productivity (Ohle, 1978). When the oxygen content of the deeper water is exhausted, ebullition of fermentation gases increases. These gases further reduce the oxygen content of water strata nearer the surface through bacterial oxidation and cyclically generate conditions for further intensification of gas generation and ebullition. The result can be observed in a jumplike increase in eutrophication *(rasante Seen-Eutrophierung)* (Fig. 21-8). The accelerated biogenic response intensifies production and inputs of organic matter to the sedimentary fermentation system and enhances rates of generation of gases.

Ohle (1958) further proposed a symbiotic relationship among the bacterial populations that utilize and generate fermentation gases. Sulfate-reducing bacteria of the sediments can utilize methane as an excellent

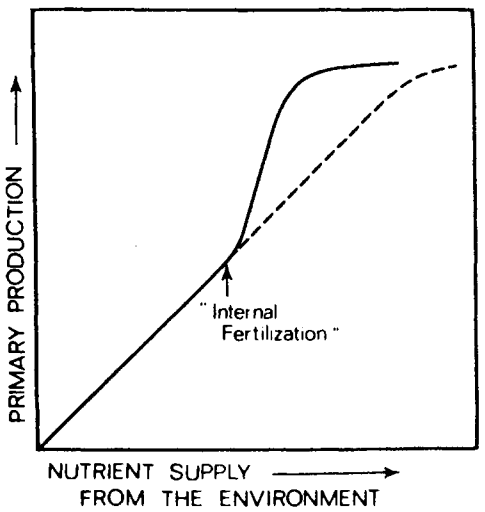

FIGURE 21-8 Accelerated primary production of lakes resulting from "internal fertilization," in part enhanced by ebullition of gases from sediments, during the progression of increasing nutrient inputs from the surrounding environment. (After Ohle, 1958.)

energy and carbon source, but they are strict anaerobes. Their generation of hydrogen sulfide, even though inhibitory to many bacteria, serves as an efficient means to maintain anoxia against intrusions of aerated water.

H. Rates of Bacterial Production and Mortality

Representative estimates of rates of bacterial production on and within the surficial sediments of lakes and streams (Table 21-13) demonstrate the extremely high production rates. In comparison to those rates of production of bacterioplankton within the integrated water column above the sediments, rates of bacterial production in sediments are several orders of magnitude greater. As will be emphasized in the concluding integrating chapter on carbon fluxes and budgets (cf. Chap. 23), decomposition in the sediments is where most degradation occurs in both lakes and streams. Decomposition in the sediments, largely by bacteria, results in a major source of oxidized carbon and contributes to the massive net evasion of CO_2 to the atmosphere from lake and river ecosystems. Lakes and rivers are basically sedimentary repositories for reduced organic carbon; metabolism within these ecosystems results in most being returned to the atmosphere as CO_2.

The highest bacterial carbon production is always found in the upper layers of natural sediments where concentrations of particulate organic matter are also usually highest in the vertical profile of sediments (e.g., Marxsen, 1996). The distribution of bacterial production over depth within the sediments is generally positively correlated with particulate organic matter content. In many studies of bacterial production, only the upper centimeter is evaluated. This stratum often contains most of the bacterial production, but in loose, particularly sandy, porous sediments as in many streams, a significant portion of total sediment bacterial production can extend lower. For example, in a small first-order stream (Marxsen, 1999), bacterial production was significant to much greater depths, even though those of the surficial centimeter usually dominated.

Bacterial production constitutes a large fraction of total secondary production in most aquatic sediments and benthic heterotrophy (cf. review of Kemp, 1990). Feeding by benthic macrofauna is largely restricted to surface sediment, and the macrofauna in most sediments consume directly only a small fraction (<10%) of bacterial production. Estimates of the fraction of bacterial production consumed by meiofauna are more variable but is also largely restricted to surface sediment and considered relatively small. An exception may be among the nematodes, many of which are largely bacterivorous and commonly occur in concentrations of ca. 10^6 m^{-2}. Microflagellates are abundant,

particularly in organic-rich sediments, and are more likely to be important bacterivores. Ciliate bacterivory may be more important in sandy, aerobic sediments, but ciliates are unlikely major consumers of bacteria in organic-rich sediments. The overall trophic efficiency of transfers of organic carbon from bacteria to macrofauna via meiofaunal and protistan links is quite low (Kemp, 1990). Less than 20% of this rich bacterial production would be expected to enter macrofaunal food webs. Most of the bacterial organic carbon is respired and mineralized to CO_2 within the microbial food web.

1. Biotic Alterations of Sediment Redox

Although the direct consumption of bacteria by benthic deposit-feeding macroinvertebrates is a quite small portion of the whole, their feeding activities can significantly alter the gradients within the sediments by physical disturbance (Krantzberg, 1985; Koyama, 1993; Graf and Rosenberg, 1997). As a result, bacterial production can be increased within sediments and result in enhanced generation of respiratory gases. For example, feeding activities of amphipods, oligochaetes, and immature chironomid dipterans at high densities can reduce the steepness of redox gradients of sediments, increase bacterial production, and accelerate oxygen consumption from the overlying water in surficial sediments by factors in the range of 1.4–>4 times (Granéli, 1979; Andersen and Jensen, 1991; van de Bund *et al.*, 1994; Svensson and Leonardson, 1996).

Earlier discussion (Chap. 18) emphasized the major intercellular ventilation system of rooted aquatic plants by which gases are transported and exchanged to meet the respiratory demands of rooting tissues living in anoxic sediments. Oxygen is released from the roots and rhizomes of emergent, floating-leaved, and submersed aquatic plants (e.g., Carpenter *et al.*, 1988; Chen and Barko, 1988; Jaynes and Carpenter, 1988; Wetzel, 1990c; Boon and Sorrell, 1991; Armstrong *et al.*, 1992; Flessa, 1994; Christensen *et al.*, 1997). Appreciable quantities of oxygen are released into the rhizosphere and this oxidation can alter markedly the redox conditions in the immediate (usually <0.5 mm) microrhizosphere.

Fluxes of gases through the plants are mediated by both physical processes, some coupled with photosynthesis. Emergent and floating-leaved aquatic plants in contact with the air have mechanisms (Chap. 18) that allow moderate exchange of internal gases with the atmosphere during periods of darkness. In contrast, the release of oxygen into the rhizosphere from rooting tissues of submersed higher plants is light-dependent, and the release of oxygen from roots is appreciably reduced during darkness. The fluctuating redox conditions in sediments permeated with roots of higher aquatic plants leads to steep gradients within the sediments of increased redox, reduced nutrient availability, and increased organic substrates released by the plants.

Earlier discussion (Chap. 19) also evaluated the importance of attached algae on sediments in relation to their ability to influence nutrient fluxes into and from sediments by direct utilization as well as shifts in redox by the production of dissolved oxygen in excess of that consumed by heterotrophic biota. Photosynthesis of the epipelic algae and cyanobacteria can rapidly shift redox conditions at the sediment–water interface from anoxia to supersaturated concentrations that penetrate several millimeters into the sediment (e.g., Carlton and Wetzel, 1988; Wiltshire, 1993; Berninger and Huettel, 1997). Slow horizontal water movements over the epipelic microbial community at the sediment–water interface enhances the diffusion of photosynthetically produced oxygen out of the sediments.

V. LITTORAL DECOMPOSITION AND MICROBIAL METABOLISM

Evaluations of the horizontal distribution patterns of bacterioplankton in lakes demonstrate that bacterial densities are much greater in the littoral zone than in the open water (e.g., Mühlhauser, 1990). Although comprehensive studies of these spatial distributions are few, examples from both small and large lakes are consistent. The quantity of total bacterioplankton in the littoral zone of Lake Balaton, Hungary, determined by direct enumeration, was found to be 2–3 times greater than that of the open water (Oláh, 1969a,b). Saprophytic bacteria[4] of the littoral zone were 40–120 times more abundant than in the open water. Observed differences were greatest during the spring period of active growth of the emergent macrophyte reed zone (*Scirpus* and *Phragmites)* and in the autumn as portions of the littoral foliage senesced. High numbers of bacteria from the littoral zone extended out into the open water for considerable distances (1500 m) in this large lake during the spring, but they were restricted largely to the macrophyte belt during the summer.

Similarly, the bacterioplankton activity of large, shallow Lake Mekhtev, Russia, was strongly influenced by the aquatic macrophytes and associated sessile

algal flora (Aliverdieva-Gamidova, 1969). Although temperature was strongly correlated directly to bacterial growth on a seasonal basis, and maximal populations and shortest generation times occurred in midsummer (Table 21-14), bacterioplankton were clearly more abundant and on the average grew faster in water among macrophyte stands than in open water lacking littoral flora. Although these studies indicate that large amounts of organic substrates are being released by the macrophytes and their epiphytic microflora during growth and senescence, measurements of actual transfer rates were not available in this study. As we have seen in the detailed discussions of Chapter 19, there is a strong tendency for conservation and retention of released organic substrates and nutrients by the epiphytic microflora on living, senescing, and detrital particulate matter of the macrophytes. This capacity for microbial retention and recycling can be overwhelmed with massive production of macrophytes under hypereutrophic conditions.

When the macrophyte-derived dissolved organic matter (DOM) passes through attached microflora, some of the DOM remains in dissolved and colloidal form and is transported within and out of the littoral areas. Some of the DOM is mineralized by littoral bacterioplankton and some aggregates into large colloidal masses and particles. Experiments with DOM from different macrophytes showed some 23% of the dissolved organic carbon remained in solution, 58% was mineralized by bacteria, and 19% formed aggregates (Alber and Valiela, 1994). The aggregates had low C:N ratios (4–12, depending on the source species) and contained large densities of active bacteria. These values of mineralization are similar to results of other studies (Findlay *et al.*, 1986b; Mann and Wetzel, 1996; Waichman, 1996; Bicudo *et al.*, 1998).

A. Losses of Macrophytic Particulate Organic Matter and Benthic Sediments

Relatively little, usually <5%, of the very high total (above- and belowground) annual organic productivity of wetland and littoral macrophytes is consumed by grazing animals. Most of the high net primary production senesces undisturbed and enters the detrital pool as dissolved and particulate organic matter (Polunin, 1984). Early stages of decomposition are dominated by leaching of soluble organic matter from the senescing tissues. Some of this degradation and leaching can occur while the senescing tissues are standing dead among living emergent macrophytes or after the tissues have fallen to the water. Earlier discussion indicated that the microbial utilization and degradation of dissolved organic matter released extracellularly during active plant growth and by autolysis was rapid and relatively complete (cf. Table 17-5).

In contrast, the degradation of the particulate organic matter of the littoral zone is much slower. Once in the water, microbial colonization, mostly bacteria, is rapid in a succession of forms. These bacteria initially utilize primarily released soluble organic matter (Mann and Wetzel, 1996), and the release of organic substrates influences bacterial growth and activity on leaf litter to a greater extent than does the process of fragmentation of the litter and associated increases in surface area available for bacterial colonization (Gunnarsson *et al.*, 1988). Studies are few and generally employ

approximate techniques (e.g., following the rates of weight loss over periods of time while being incubated in litter bags under experimental or *in situ* situations) (cf. Boulton and Boon, 1991, for discussion of methodological problems).

Emergent macrophytic vegetation generally exhibits very slow rates of degradation in comparison to those of floating-leaved and submersed aquatic plants (Table 21-15). Part of this greater resistance to decomposition is related to the greater quantity of lignified tissue found

in emergent flora (Sculthorpe, 1967; cf. Chap. 18). With adaptation to a largely or totally submersed existence, a conspicuous reduction in lignification of supportive and conducting tissues is found in floating and submersed vegetation. Lignin, consisting of aromatic rings with side chains and -OH and $-OCH_3$ groups, exhibits a high degree of chemical stability. Catabolism of lignin by oxidative depolymerization is dominated by fungi, especially the Hymenomycetales (Basidiomycetes), which possess the inductive exoenzymes for this cleavage (Trojanowski, 1969). Bacteria are also active in the decomposition of lignocellulose macromolecules, often in concert with fungi, as side chains or monomers are detached from the lignin by fungi (e.g., Hackett *et al.*, 1977, Healy *et al.*, 1980; Benner *et al.*, 1984) or ultraviolet photolysis of partially degraded products. Large amounts of paracoumaric esters and lignin derivatives are found to persist during decomposition of emergent macrophytes under different environmental conditions (Boon *et al.*, 1982) and can further retard decay of emergent plants in the littoral zone of lakes. Under conditions of aerobic decomposition, appreciable amounts (to 30%) of the nitrogen can occur in nonprotein nitrogen compounds (Odum *et al.*, 1979). Much of this nitrogen is apparently chitinaceous and of fungal origin; these compounds are also relatively recalcitrant to rapid decay.

As the macrophytes are partially decomposed, appreciable quantities of dissolved organic compounds of relatively high molecular weight (1000–50000 D) are released. Bacterial degradation of these lignocellulose-derived dissolved organic compounds can be appreciable. For example, bacterial mineralization of a macrophyte DOC-pool was initially rapid (12% per day) but slowed to ca. 30% after 30 days (Moran and Hodson, 1989). Some of these macrophyte organic products are resistant to decay, but it can be greatly accelerated by exposure to natural UV light (Wetzel *et al.*, 1995, Wetzel, 2000c).

Planktonic fungi found in the open water likely originate mainly from wetland and littoral areas (Willoughby, 1965; Novotny and Tews, 1975), although some (e.g., many chytrid species) are highly specialized parasites of planktonic algae (cf. Chap. 15). Fungal propagules are transported in the water directly or in association with inflowing particulate plant debris. Little is known about their metabolic activities once the material becomes sestonic in the pelagic zone.

The sources of accumulated organic matter in the littoral zone are variable among lakes in relation to basin morphometry and production by the littoral algal and macrophyte components. In most situations, a majority of the particulate organic matter originates from the macrophytes (approximately 90%), most conspicuously from the emergent forms. Lesser quantities are derived from attached algae, loosely attached littoral algae, and windrowed planktonic algae. Rates of decomposition of the littoral particulate organic matter are quite variable in relation to conditions of accumulation (Table 21-16). In the example from Mikolajskie Lake, decomposition rates were lowest among plant material in the emergent part of the eulittoral zone on

the surface of the sediments. Senescence and death of submersed species in the submersed littoral site was slow and delayed decomposition; when dead and decaying submersed plants occurred in pools and among reed heaps, decomposition was very rapid. Filamentous algae and accumulations of planktonic cyanobacteria in the littoral decayed much more rapidly (>95% in 3–10 days) under comparable conditions (Pieczyńska, 1970).

B. Degradation Patterns of Littoral Flora

Lignified tissue of emergent hydrophytes is degraded slowly by a succession of fungal flora. For example, it has been observed that the mycoflora of the cattail *Typha latifolia* passes through early stages that are similar to those of terrestrial plants, with primary colonization by leaf-surface fungi, followed by a secondary phase in which many species of *Leptosphaeria* dominate moribund leaves (Pugh and Mulder, 1971). The succession is associated with aging of plant material and substrate changes. Final stages of decomposition are accompanied by a dominance of fungi predaceous on nematodes. Similar successional patterns have been found on analogous substrates (Sparrow, 1968; Mason, 1976). Fungi generally very poorly colonize senescent or dead roots and rhizomes.

Lignin is not biodegraded anaerobically to any appreciable extent (cf. excellent review of Kirk and Farrell, 1987). As a result, much of the decomposition, fragmentation, photoalteration, and other degradation processes of the lignin components of the large lignocellulose mass of higher plants occurs under aerobic or intermittently aerobic conditions. Once permanently interred in anaerobic sediments, lignin is extremely recalcitrant to biomineralization.

Leaves of the emergent rush *Juncus effusus*, a plant common to many littoral areas and wetlands of lakes and streams, senesce from the leaf tip to the base at an exponential rate (90–225 days), the rate of which is greater with increasing temperatures seasonally (Kuehn and Suberkropp, 1998a). The leaves of *Juncus* remain standing while dead, a feature common among emergent macrophytes. Even though fungal biomass constitutes 3–8% of total detrital mass, decomposition is slow ($k = 0.40$ yr^{-1}), and the senescent leaves lose about half of their biomass in two years. Availability of water was a major factor affecting rates of fungal respiration in standing dead plant litter of this emergent macrophyte (Kuehn and Suberkropp, 1998b). Rates of CO_2 evolution from the plant litter increased precipitously in the evening with increasing relative humidity (>90%) and plant water potentials (>−1.0 Mpa). Fungal respiratory rates were manifoldly higher during night and early morning hours than during the daytime on clear days.

The movement of fine organic detritus particles of decomposing macrophytes from the littoral zone to the open water can occur by water movements and currents returning from the littoral to the pelagic zones, both along the surface and near the sediments (cf. Schroder, 1973, 1975; Gaudet, 1976; Kistritz, 1978; Rho and Gunner, 1978). In addition to these fine particles, nutrients, particularly phosphorus, are transported from the littoral flora to the open water. The maximum phosphorus inputs from the littoral occur in the summer period when the phosphate concentrations in the open lake water are minimal. The prevailing situation, however, is for the littoral community of macrophytes and microbial communities attached to living and detrital particulate matter to conserve and retain nutrients, especially soluble components released from the living and senescing macrophyte organic matter (cf. Wetzel, 1990a, and summary in Chaps. 18 and 19).

Very fine-sized (<100 μm) particles of the emergent reed *Phragmites* were studied as they underwent decomposition in lake water (Oláh, 1972). The successional patterns of bacterial populations in the water containing leached dissolved organic matter from the particles and on the particles correlate with progressive utilization of organic substances (Fig. 21-9). Within a few hours, large rods dominated the liquid phase, presumably utilizing the leached dissolved organic substrates of the detritus. A large population of small cocci

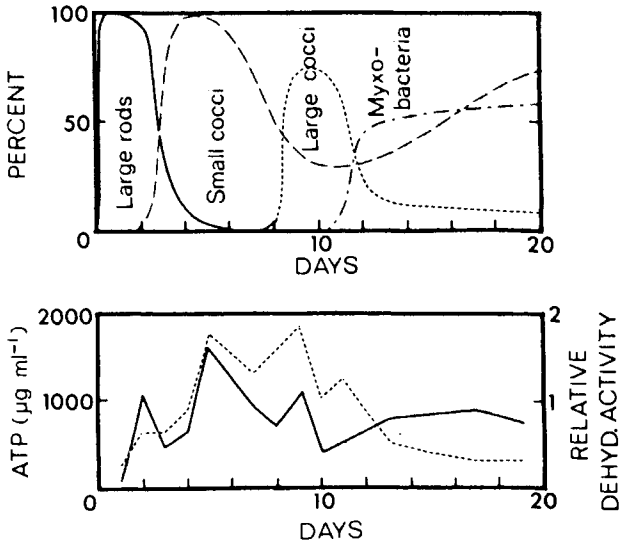

FIGURE 21-9 *Upper*: Bacterial populations; *lower*: activity associated with decomposition of fine particles of *Phragmites* detritus. —— = ATP biomass carbon; - - - - = relative dehydrogenase activity. (Drawn from data of Oláh, 1972.)

succeeded these bacteria; a few days later, the cocci were displaced by large cocci. Both of the coccal types were associated with the liquid phase and populated the surfaces of the small *Phragmites* fragments. Myxobacteria, well-known decomposers of living and dead particulate organic matter (Ruschke, 1968), colonized both the large cocci and the residual, stabilized detrital particles. Maximal bacterial biomass, measured as ATP content, coincided with the maximal development of the bacterial population succession and corresponded to the time of the mass development of small cocci (Fig. 21-9). Bacterial metabolism, determined by dehydrogenase activity, behaved similarly and decreased after about 10 days. The decrease was related to a stabilizing condition of decreasing quantities of easily assimilable organic substances in the residual particulate detritus. Analogous sequences of microbial succession were found during the decomposition of emergent reeds (*Typha, Phragmites*, and *Sparganium*), floating-leaved plants, and submersed macroflora (*Ceratophyllum, Myriophyllum, Najas*, and *Potamogeton)* (Gorbunov, 1953; Krasheninnikova, 1958; Casper *et al.*, 1988). Degradation rates were greater for the submersed flora under similar conditions than for emergent flora.

Intensive investigation of the decomposition of the particulate organic matter from several species of emergent, floating-leaved, and submersed macrophytes and of dissolved organic matter leached from them was undertaken under different conditions of temperature and oxygen availability (Godshalk and Wetzel, 1978a–c). Resistance of particulate tissue to microbial decomposition was strongly influenced by the chemical composition of the plant species. The floating-leaved species decomposed faster than the submersed plants, which decomposed more rapidly than the emergent species. Decay rates were related to initial nitrogen and fiber contents, with high-nitrogen, low-fiber plants decomposing most rapidly. Unlike the leached dissolved organic matter of the plants (whose rate of decomposition was found to be mostly influenced by oxygen and nutrient availability), primarily temperature, tissue nitrogen, and fiber content regulated the rate of conversion of particulate organic matter to carbon dioxide and/or dissolved organic compounds.

The relative rates of decomposition, k, of aquatic macrophytes have been variously defined mathematically (see Godshalk and Wetzel, 1978b; Carpenter, 1980; Belova, 1992) and are controlled by factors of the plant itself and the environment within which it is decaying (Godshalk and Wetzel, 1978c):

$$k \propto \frac{T \times O \times N}{R \times S}$$

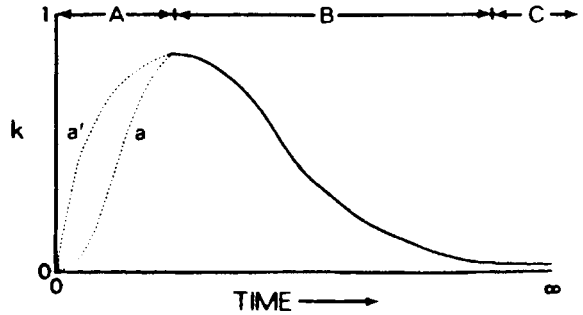

FIGURE 21-10 Generalized sequence of decay rates of dissolved and particulate organic matter with three phases of decay (see text). The logistic S-curve (line a) is found among plants beginning to decompose under natural conditions where decay is initially slow and is followed by increasing cellular senescence. Line a′ is found in laboratory studies using predried plant material at the start of experimental assays (cf. Rogers and Breen, 1982). (After Godshalk and Wetzel, 1978c.)

where T = temperature, O = dissolved oxygen, N = mineral nutrients necessary for microbial proliferation (e.g., Waite and Kurucz, 1977; Almazan and Boyd, 1978; Andersen, 1978; Carpenter and Adams, 1979), R = initial tissue recalcitrance, and S = particle size (i.e., particle volume/surface area). The relative rate of decomposition, k, can be summarized graphically (Fig. 21-10) versus undefined units of time; in this case, k is defined as the amount of detrital dissolved and particulate organic carbon metabolized (e.g., POM → DOM, POM → microbial cellular material, DOM → CO_2, et cetera) per unit time. Although decomposition is a continuous process, the *rate* of decomposition varies with time, and can conceptually be viewed as three distinct phases.

Phase A (Fig. 21-10) is a period of increasing biomass loss from leaching and/or autolytic production of dissolved organic matter (DOM). Much of this DOM is rapidly (hours) metabolized, and the quantity and quality of DOM that persists are influenced by temperature and oxygen availability. Following the maximum rate of weight loss, decay rates decrease to varying degrees during the next phase (B, Fig. 21-10) of decomposition, which can last from several days to many months. Microbial activity and nitrogen content of the particulate detritus increase in the initial phases; factors controlling decay rates have their greatest influence in this phase. The relative resistance of the remaining particulate organic matter continually increases as the more labile compounds are metabolized. In phase C, the rate of decomposition of the residual resistant particulate matter approaches an asymptotic limit of zero and is limited mostly by the high recalcitrance of the particulate detritus. Some of this matter can enter the anaerobic sediments and become buried; if so, decay

rates become so slow that, for all practical purposes, decomposition ceases.

If particulate detritus from aquatic plants is colonized by epiphytic algae as well as bacteria and fungi on the sediments, there is a potential for a synergistic coupling between the photosynthesis and metabolic products of the algae, enhancing the metabolism of the heterotrophic microbiota that could influence and increase degradation of the macrophyte tissue. For example, the decomposition of cattail (*Typha latifolia*) detritus was accelerated moderately (5–10%) by the positive interactions between epiphytic algae and heterotrophic decomposers (Neely, 1994; Neely and Wetzel, 1997).

VI. DEGRADATION OF PARTICULATE ORGANIC MATTER IN SEDIMENTS OF RUNNING WATERS

An enormous literature exists on the inputs of particulate organic matter into stream and river ecosystems and the microbial degradation and utilization of this organic matter once it is in the sediments. Disproportionately intensive study and evaluation have resulted because of (a) the major loading of particulate organic matter seasonally in many low-order streams from leaf abscission of canopy vegetation in temperate regions, (b) the major importance of the macroinvertebrates in the food-web structure and energetics between the microbes and higher trophic levels, and (c) the many highly specialized feeding strategies that have evolved among immature and adult macroinvertebrates that spend much of their life histories in these habitats. Because terrestrial vegetation along river courses shades many low-order streams and results in low rates of photosynthesis within these streams (cf. Chaps. 15, 18, and 19), heterotrophic metabolism is highly dependent on dissolved and particulate organic matter that falls into the water channels or is imported with ground water and surface water. Similarly, large rivers are dominated by decomposition of imported organic matter because photosynthetic production is often limited by reduced light availability as a result of high turbidity.

Many river ecosystems of low elevational areas flood with predictable periodicity, as is common in many tropical and subtropical areas. Flood plains are periodically inundated by the lateral overflow of rivers or shallow riverine lakes. In many backwater areas, wetlands are particularly effective in sediment accretion, where prolific macrophyte growth both collimates and disperses flow as well as contributes directly through high productivity of organic matter (e.g., Rybak, 1980; Phillips, 1989; James and Barko, 1990; Feijoó *et al.*, 1994; Callaway *et al.*, 1996). Depending on the severity of flooding events, the wetlands typically serve as both short-term sediment sinks and long-term sediment storage sites.

These flood plains can be classified according to amplitude, frequency, predictability, and the source of flooding (Junk *et al.*, 1989; Junk, 1997a,b). For example, flood plains of large rivers have a predictable monomodal flood pulse of large amplitude and long duration (months) (e.g., the Amazon and Orinoco rivers of South America). Flood Plains of small creeks and streams are characterized by unpredictable polymodal flood pulses of highly variable amplitudes and duration. During these flooding events, large amounts of dissolved and particulate organic matter of various sizes are imported to the river channel sediments.

Detrital particulate organic matter associated with sediments in streams and rivers is commonly separated into size classes: (a) coarse particulate organic matter (CPOM, >1 mm), which consists of large woody debris, leaves, needles, and foliage of terrestrial and aquatic vegetation, and animal parts, and (b) fine particulate organic matter (FPOM, range, 0.5 μm–1 mm), which consists of fragmentation pieces of CPOM, imported terrestrial and wetland organic matter, and aggregated dissolved organic matter. Dissolved and colloidal organic matter is of a size <0.5 μm.

Much study has addressed the rates of decomposition of CPOM detritus of stream sediments mostly derived from terrestrial leaves that fall into small forested streams in the autumn of temperate regions. The rate of loss of mass of CPOM in streams follows approximately a simple exponential model (Petersen and Cummins, 1974; Webster and Benfield, 1986):

$$W_t = W_0 e^{-kt}$$

where

W_t = ash-free dry mass at time t in days
W_0 = initial ash-free dry mass
k = rate coefficient of breakdown loss rate of leaf mass vs. time, day^{-1}
t = elapsed time (days).

This model has been expanded to include a second independent variable, degree days or accumulated temperature, which improved data analyses slightly and is useful for examining differences influenced by temperature among different sites and seasons (Hanson *et al.*, 1984; McArthur *et al.*, 1988). The improvement by this modification over the simple negative exponential model is very small, however (Campbell *et al.*, 1994).

Allochthonous CPOM is often the largest source of particulate organic matter inputs to many streams. For example, in several Appalachian Mountain streams, >86% of the particulate organic matter loading was as CPOM (Wallace *et al.*, 1995). Movement of CPOM is

often restricted by debris dams, where the CPOM is caught and accumulates against relatively immovable objects of the substratum or projections from the banks (e.g., Webster *et al.*, 1994). When discharge is at low base levels, CPOM settles relatively randomly onto the surface of the sediment (Jones and Smock, 1991; Shaddon *et al.*, 1992). During high discharge, however, backwater areas and debris dams can become primary retainers of CPOM. Because of the reduction of retention devices in higher-order streams, less CPOM is retained on the sediments and a greater percentage becomes suspended (Wallace *et al.*, 1982).

Because water is moving past the detrital CPOM on the sediments, fragments of FPOM derived from partial fungal degradation and the feeding activities of detritivorous invertebrates can be exported downstream from the CPOM. In many streams and rivers, particularly in low elevational gradient waters, most export of particulate organic matter is as FPOM. For example in several Appalachian Mountain streams, >96% of the particulate organic matter was exported as FPOM (Wallace *et al.*, 1995). Hence, the observed loss rates in streams are a combination of decomposition (respiratory CO_2 and CH_4 to the atmosphere), fragmentation, and export losses of dissolved (DOM) and fine particulate (FPOM) organic matter.

Very little is known about the fungal and bacterial decomposition of FPOM. In small headwater Appalachian streams, bacterial productivity was greatest per ash-free dry mass in the 106–250 μm fraction of FPOM, but differences were small (Peters *et al.*, 1987, 1989). The proportion of more recalcitrant organic compounds (lignin and cellulose) increased per unit organic mass as the size of the FPOM particles decreased in the range of 500–10 μm. Although productivity was positively correlated with temperature, no changes in bacterial productivity associated with FPOM were induced by amendments of nitrogen or phosphorus in these river ecosystems.

Rates of decomposition of CPOM in streams vary greatly with the chemical composition of the plant material, environmental variables, particularly temperature and nutrients, and the feeding activities of benthic invertebrates. After the initial leaching of large quantities of dissolved organic matter, the rates of decomposition of leaves from nonwoody plants are much faster (mean half-life of ca. 65 days; range, 15–200 days; breakdown rates, 0.3–4% day^{-1}) than rates of leaves of woody plants (mean half-life of ca. 200 days; range, 70–450 days; breakdown rates 0.2–1% day^{-1}) (Petersen and Cummins, 1974; Webster and Benfield, 1986). Nutrient availability is critical for microbial degradation of leaf materials. For example, decomposition rates and fungal productivity of leaves in moderately productive streams were doubled by enrichments of dissolved nitrogen and phosphorus (Meyer and Johnson, 1983; Suberkropp, 1995; Suberkropp and Chauvet, 1995).

As particulate organic matter falls into streams or is imported with runoff water from the flood plains, it is transported downstream for varying distances before being lodged in debris dams or deposited on or in sediments. Leaching of DOM occurs rapidly (e.g., Table 17-9) and within the first few days most loss, commonly 25% of initial ash-free dry mass of small particles, of immediate, nonbiologically mediated leaching occurs. Of the DOM leached from these materials, the more labile components are very rapidly metabolized by attached bacteria and bacterioplankton, whereas the more recalcitrant DOM compounds are metabolized more slowly. For example, carbon and nitrogen labile compounds of leachate from hickory and maple leaves in a small hardwater stream exhibited a half-life decomposition rate of 2 days, whereas bacterial decomposition of the more recalcitrant polyphenolic fraction had a half-life of 80 days (Wetzel and Manny, 1972b).

Leaf litter, fungal biomass, and fungal production per area of sediments is highly seasonal in woodland streams. For example, in a small woodland stream in Tennessee, leaf litter ranged from < 5 g AFDM m^{-2} in summer to 249 g m^{-2} in November after primary leaf fall (Suberkropp, 1997). Fungal growth rates averaged 2.6% day^{-1} over the year. Annual production of leaf-decaying fungi was 34 g m^{-2} (ca. 17 g C m^{-2}) within a daily production rate range of 0.006 (summer) to 0.49 g m^{-2} day^{-1} (November maximum), with an annual production-to-biomass ratio (*P/B*) of 8.2.

If the POM remains senescent as leaves on trees before abscission or is standing dead aerially as is common among emergent aquatic plants or was deposited on terrestrial soils before being transported to the river, the organic matter would be exposed to long periods of leaching by precipitation. Losses of labile dissolved organic matter by leaching of aerial senescent tissue can be large (e.g., Mann and Wetzel, 1996). Once in the stream or river, colonization of the POM by microbes proceeds rapidly by bacteria growing on the surfaces and by fungal hyphae growing on the surface and internally. Fungal growth has been observed to be at least 10 times greater than that of bacteria on the surfaces of newly introduced leaves (Bengtsson, 1992). Rates of decay of the POM vary greatly, in part related to the nutrient, especially nitrogen, content of the tissues (e.g., Kaushik and Hynes, 1971) and of the water. Decay rates are lower among POM sources of higher lignin content and polyphenolic compounds, some of which can competitively inhibit enzyme activities. Nitrogen content of decaying POM commonly increases as a

percentage of ash-free dry mass, in part because nitrogen compounds bound to structural tissue compounds and contained in humic compounds decomposing at slower rates than other constituents and in part because of microbial biomass increases (Suberkropp *et al.*, 1976). Cellulose, hemicellulose, and lipids are mineralized at rates about the same as POM mass, whereas rates of lignin decomposition were slower and increased as a percentage of the residual organic mass. Under well-oxygenated conditions, most of the decomposition of POM in streams is by fungi, primarily hyphomycetes, during the early stages of decomposition over several months (Kaushik and Hynes, 1971; Bärlocher, 1982; Suberkropp, 1992). Bacterial degradation of these recalcitrant plant tissues is relatively minor during this period but increases and usually dominates in the later stages of the POM decomposition processes.

The heavy colonization of detrital POM by fungi and bacteria results in alterations in the texture and physical integrity of the POM tissues, as well as increases in the nutritional quality of the collective detrital mass and attached microbiota. Fungal metabolism renders leaf organic matter more palatable and nutritious for invertebrates by catalysis of leaf substrates to digestible subunits and by providing increased microbial biomass (Bärlocher, 1985). Some 5–10% of the total leaf litter mass can be of fungal hyphae biomass (Suberkropp, 1997). Detritivorous invertebrates feed actively on this detrital POM, and in the process, fragment the CPOM into smaller pieces. The maceration process reduces particle sizes and increases surface areas for microbial enzymatic activity and simultaneously nutrient-enriched feces. Both processes increase the rates of microbial decomposition of the POM. If macroinvertebrate feeding on decomposing POM is restricted by exclosures, such as in litter bags, or removed from the environment by selective poisons, rates of decomposition of the POM decrease significantly (Table 21-17). Decomposition of POM is clearly accelerated (5–25%) by the presence of macroinvertebrate detritivores (Petersen and Cummins, 1974; Polunin, 1984; Mulholland *et al.*, 1985b). Even though the efficiency of degradation within the invertebrate gut is low (usually much $< 50\%$), this direct heterotrophic utilization is a significant part of the whole. The maceration and fragmentation of the POM indirectly accelerates microbial rates of degradation, generation of FPOM, and leaching of DOM from the residual POM.

Decomposition of POM can be markedly suppressed if the conditions of decomposition shift to anoxia (Pattee and Chergui, 1994). Some bacterial degradation of lignified wood occurs under anaerobic conditions, but rates are very slow (Holt and Jones, 1983). As a result, the rates of decomposition slow greatly in backwater areas of streams and can lead to accelerated sedimentation in these areas.

If one examines the inputs and transformations of allochthonous organic matter, very few studies have dealt with the complete dissolved and particulate organic loadings and exports. In forested headwater streams of low stream order, leaves of terrestrial plants can constitute a major (e.g., ca. 70%, Iversen *et al.*, 1982) input of allochthonous *particulate* organic matter. The proportion of inputs into the stream sediments of coarse particulate organic matter (CPOM) of the total tends to increase as the size (width) of the streams decrease. The duration of retention of the CPOM in the stream sediments depends on the number of snags, the sinuosity of the river channels, and particularly the changes in the water discharge. Similarly, the retention capacity of fine POM in the sediments varies with the physical composition of sediment, and retention increases with roughness and substratum complexity (Webster *et al.*, 1987). FPOM is frequently deposited, resuspended, transported, and redeposited in a series of advection–dispersion movements governed by discharge and leading to constant resuspension and further export (Cushing *et al.*, 1993). The export downstream of FPOM increases with increasing water discharge and invertebrate feeding activities (Wallace *et al.*, 1991). In

TABLE 21-17 Decomposition Rates (Half-life, Days) of Dead Terrestrial Leaves in a Small Woodland Stream in Which Invertebrate Detritivores Had Been Removed[a]

Leaf species	*Reference stream (days)*	*Treated stream (days)*	*Increase in decay rate by invertebrates (%)*
Dogwood (*Cornus florida*)	41.0	65.4	160
Red maple (*Acer rubrum*)	50.2	135.9	271
White oak (*Quercus alba*)	64.2	173.3	270
Rhododendron (*Rhododendron maxima*)	128.4	577.6	450

[a] After data of Wallace *et al.* (1982). The stream section treated with insecticide removed about 90% of the macroinvertebrates.

larger streams and rivers, most of the allochthonous organic matter inputs to the river sediments are as dissolved organic matter retained by flocculation and bacterial uptake and fine particulate organic matter. Aquatic plant and terrestrial vegetation inundated by flooding can form a major source of organic matter in tropical river ecosystems (e.g., Walker, 1992). Outputs are largely as evasion of carbon gases (mainly CO_2, CH_4) by biological heterotrophic metabolism and photolysis and downstream export of dissolved organic matter and fine particulate organic matter.

Woody debris can constitute a major source of particulate organic matter in sediments of small streams and riverine wetlands. In rivers of very low elevational gradient, large woody debris can constitute the most stable portion of the river sediments and, in contrast to finer fragments, is seldom moved downstream except during uncommon floods (e.g., Wallace and Benke, 1984). Ranging in size from branches to large tree trunks, the rates of decomposition are generally very slow. Obviously, the wood tissue contains a high content of cellulose and lignin, is poorly penetrable to water, nutrients, and microbes and invertebrates, and has only a small surface area exposed to the enzymatic activities of microbes (Harmon *et al.*, 1986; Ward *et al.*, 1994). Nonetheless, wood serves as a persistent substratum that is actively degraded by many types of fungi in addition to aquatic hyphomycetes (Shearer, 1992). The low rate of decomposition is related to low surface-to-volume ratio and high density, which limits oxygen diffusion and microbial penetration into water-saturated substrates.

Depending upon the type of wood, small pieces <1 cm in diameter could require a decade for degradation if not fragmented by molar action of turbulence, ca. 50 years for branches 5–10 cm in diameter, and 100–300 years for larger tree trunks (Anderson *et al.*, 1978; Maser and Sedell, 1994). Examination of the rates of benthic respiration by consumption of dissolved oxygen per unit area per time by different types of CPOM revealed that microbial respiration associated with woody sticks nearly always made up <10% of the total (e.g., Tank *et al.*, 1993). Most of the benthic respiration was associated with smaller detritus, particularly from decaying leaves. Frequently, woody debris is partially buried in sediment by river turbulence during spates. Channel width and sinuosity are dominant factors that control the importation, storage, and effects on hydrology within the stream of woody debris (Nakamura and Swanson, 1994). The amount of coarse woody debris and the number of pool-forming pieces of wood are relatively high in wide, sinuous reaches of the river, particularly in association with a braided channel pattern. In wetlands, as areas are inundated (e.g., by beaver activity), trees are killed and fall into the sediments. Under anoxic conditions in the sediments, rates of decomposition are slowed even further to rates that are ecologically negligible.

VII. DEGRADATION OF DISSOLVED ORGANIC MATTER IN SEDIMENTS OF RUNNING WATERS

In addition to water flows in the open stream channel, water also flows through sediment interstices. In this subsurface region of sediments in streams and rivers, water exchanges with the overlying water of the channel. Flow also moves laterally into bank and floodplain sediments and then can reenter the flowing water of the stream channel at some point further downstream. This hyporheic zone is a transitional zone between surface water in the stream and ground water in the deeper zone in alluvium that holds ground water; the hyporheic zone connects these surficial sediments with water held and moving in surrounding floodplain sediments.

Bacterial mineralization processes, both aerobic and anaerobic, frequently occur as a result of intrusion of water both from the overlying channel water and with the lateral surficial and hyporheic water contained within the flood plains (cf. Chap. 18). The division between the hyporheic zone and the ground water is the interface region where <10% of the subsurface water originated from the channel water (Triska *et al.*, 1989). Because light penetrates poorly if at all into the hyporheic zone and is inadequate to support appreciable benthic photosynthesis, any biotic activity within the hyporheic zone must be supported by imported organic matter in the form of fine particulate or, predominantly, as dissolved organic matter.

If the sediments of a stream system contain abundant hydrous aluminum and iron metal oxides, an appreciable amount (ca. 40%) of dissolved organic carbon (DOC) can be removed from solution by sorption onto the oxides as they precipitate (McKnight *et al.*, 1992). DOC with greater contents of aromatic moieties, carboxylic acid groups, and amino acid residues were sorbed preferentially over DOC with fulvic and hydrophylic acid components.

From the perspective of bacterial activities within the sediments of streams, the sediments fall into two primary groups: (a) depositional in debris dam and backwater areas of very slow flows, as was discussed briefly earlier, and (b) porous sediments within which channel water can enter and leave by advection and connect with underlying ground water, if present. Although highly variable, with specific substrata and

hydrologic conditions, advective flows commonly carry water into surficial sediments during which some chemical and mineralization can result in zones of microbial enrichment and increased bacterial productivity (review of Hendricks, 1993, 1996; cf. Chaps. 12 and 13). Nutrients and dissolved organic matter of interstitial water are enriched in comparison to those of surface water, often from water passing from lateral floodplain soils into the hyporheic zone (e.g., Valett *et al.*, 1990; Wainright *et al.*, 1992). Dissolved organic carbon is enriched in the upwelling zones of the sediments, emanating in part from enhanced anaerobic processes of denitrification, nitrate reduction, ammonification, sulfate reduction, and methanogenesis. Aerobic processes of respiration nitrification, sulfide oxidation, and methane oxidation are much more prevalent in the downwelling zone within the hyporheic sediments. Total heterotrophic bacterial productivity is appreciably greater in downwelling zones than in upwelling areas of the hyporheic sediments.

Rates of nitrification were found to be an order of magnitude greater in downwelling regions of the hyporheic sediments of streams in comparison to those in upwelling regions (Jones *et al.*, 1995a). When the sediments were disturbed, as following spates and flood-scouring events, nitrification rates were reduced appreciably and gradually increased as the microbial communities reestablished in subsequent succession. Because oxygen penetration can extend throughout surficial and deeper sediments of the hyporheic zone of the main channels of streams, denitrification rates are relatively low in these areas (Duff and Triska, 1990). Denitrification within sediments increased with increasing distance from the stream channel into hydrosoils of wetland and vegetated bank areas.

Population turnover times are rapid among natural communities of bacteria attached to sediments of streams. For example, in four small, temperate streams, estimated bacterial generations ranged from 67 to 375 per year (Bott and Kaplan, 1985). As appears to be true among the bacterioplankton, many of the attached bacteria of sediments are dead or dormant. In these four small streams mentioned, <25% of the bacteria were actively respiring.

Natural variations in loadings of dissolved organic matter to streams are large in response to precipitation events, snow melt runoff, deciduous leaf fall, and other seasonal changes in the flood plain and streams. Sediment microflora retain an ability to readily metabolize different sources of DOM that reach the communities at irregular intervals (Kaplan and Bott, 1985). In order to utilize naturally occurring pulses of carbon and energy, sediment bacteria must be enzymatically prepared and induced when the pulses occur. Within limits, bacterial metabolism is then roughly proportional to the availability of organic substrates.

Dissolved organic matter concentrations tend to be appreciably lower in ground waters and the hyporheic zone of sediments as the distance from a stream or river channel per se increases. In addition, the bioavailability of the organic carbon tends to become more recalcitrant to utilization by bacteria the greater the distance within the hyporheic zone from the main river channel (Ellis *et al.*, 1998). Bacterial production tends to be low in the lateral hyporheic zone and alluvial aquifers and decrease further with increasing distance from the river channel. Closer to the stream channel or within the stream sediments, however, bacterial utilization of DOC from terrestrial and floodplain wetland sources is much more rapid, even though rates differ from these with DOC from various higher plant species and sources (e.g., McArthur and Marzolf, 1986; Meyer *et al.*, 1987; Benner *et al.*, 1995; Bano *et al.*, 1997). Much of the DOC occurs as humic substances (60–80%), but even these relatively recalcitrant compounds are metabolized at rates of ca. 0.5% per day, with bacterial growth efficiencies of ca. 20–30% or more. Higher bacterial growth efficiencies often coincide with high water periods, which suggests that substrates imported from floodplain regions have increased bioavailability. In contrast, simple carbohydrates and amino acid compounds are rapidly immobilized by attached bacterial assimilation and a portion is respired (Fiebig, 1992; Marxsen and Fiebig, 1993). For example, in sandy sediments of a first-order stream, 99% of dissolved amino acids in ground water were immobilized, with some 14–25% respired.

As in lake sediments, by far the greatest bacterial production and metabolism occur in the sediments in comparison to that of the bacterioplankton in the overlying water. For example, bacterial respiration of the sediments of a low-gradient blackwater river was estimated to be about 97% of the total and at least 80% of that occurred in the sediments of the main channel rather than in backwater areas (Edwards *et al.*, 1990). Similarly, in a first-order blackwater stream, 70% of the respiration of the stream occurred in the hyporheic zone, and <1% occurred in the water column (Fuss and Smock, 1996). Many studies of benthic respiration rates, usually based on rates of oxygen consumption per unit area, have examined variations under different sediment conditions and spatial and temporal variability. Most of the findings would be anticipated from what is known from more detailed studies in lakes. For example, respiration per unit volume of hyporheic sediment was inversely related to the diameter of the sediment particles, which indicates that respiration is

affected by substratum surface area and area available for microbial colonization (Jones, 1995). Respiration per unit of surface area on sediments, however, was positively correlated with sediment particle diameter, which indicated greater metabolic activity of microbes on larger particles and that conditions conducive to bacterial metabolism can be reduced among very fine particle-sized sediments.

The ratios between aerobic and anaerobic decomposition in the sediments of running waters vary greatly. Clearly, most stream and river ecosystems are predominantly heterotrophic and metabolize largely allochthonous dissolved and particulate organic matter. Bacterial metabolism within the sediments is influenced by such a large array of rapidly changing physical, chemical, and biotic factors that changes in metabolism also can shift rapidly both spatially and temporally within a river as the hydrology, loading of organic matter, and other parameters change. Rapid changes in nutrient and dissolved organic matter content within the sediments occur, often associated with changes in particle size. Large-scale interannual changes in discharge flow act as a general set-point mechanism that defines the prevalent particle-size composition and chemistry of the river sediments (Chambers *et al.*, 1992; Wondzell and Swanson, 1996). Flow changes of short duration have a less predictable effect on the chemistry of the sediments. Even though the overall pattern of subsurface flow changes little over the course of a year, the relative flux of advected channel water and ground water change among seasons and during storms.

Some generality about sediment metabolism in rivers is commonly observed, however. First, the consistent release of much greater amounts of CO_2 from benthic respiration than the amount of oxygen consumed in benthic respiration indicates, as in lake sediments, a predominance of anaerobic metabolism utilizing alternative electron acceptors (Dahm *et al.*, 1991). The ratio of aerobic to anaerobic metabolism in the sediments tends to increase with increasing size and stream order (e.g., Starzecka and Bednarz, 1994). Even if the metabolism of the surface microbial community is highly productive photosynthetically and appears as an autotrophic system, when the community metabolism of the hyporheic sediments and their large heterotrophic metabolism of allochthonous organic matter are included, as they must be in any three-dimensional evaluation of an ecosystem (Grimm and Fisher, 1984; Dahm *et al.*, 1987), the stream ecosystems are predominantly heterotrophic. Second, most of the benthic metabolism is microbial. For example, ca. 96% of the benthic community respiration of hyporheic sediments of a third-order stream was associated with organisms of a size <100 μm (Pusch and Schwoerbel, 1994).

VIII. SUMMARY

1. Sediments of inland waters are sites of major biological activity.
   a. Lake sediments are the major sites of microbial degradation of detrital organic matter and biogeochemical recycling of nutrients.
   b. Sediments of running waters and shallow areas of lakes are size-sorted in relation to velocity of water movements. Inorganic and organic particle size markedly influences the distribution and growth of many benthic invertebrates.
2. Sediments are composed of organic matter in various stages of decomposition, particulate mineral matter, and an inorganic component of biogenic origin (e.g., diatom frustules, photosynthetically induced precipitation of $CaCO_3$).
3. Particulate organic matter formed in the pelagic zone is decomposed more readily and completely during sedimentation than is the more recalcitrant structural tissue of littoral flora. As senescing littoral plants are decomposed and fragmented by successive communities of fungi and bacteria, redistribution often occurs. The partially degraded material is displaced widely among both littoral and pelagic sediments.
4. Resuspension of surficial sediments (0.5 to several cm) occurs episodically in both shallow and deepwater sediments, most frequently in lakes during complete water circulation (overturn) after periods of stratification. Resuspended particulate matter constitutes a major, often dominant, portion of the total sedimenting materials that reach the bottom on an annual basis.
5. Bacterial populations and metabolic activity in surficial sediments are several orders of magnitude larger than those in the overlying water column.
   a. Bacterial populations and metabolic activity decrease precipitously from the sediment–water interface to lower depths within the sediments.
   b. Bacterial numbers and metabolic activities of deepwater profundal sediments are often positively correlated with lake productivity and the quantity of particulate organic matter reaching the sediments. Bacterial activities are usually much greater in sediments of the littoral areas than in profundal sediments.
   c. Respiratory rates of sediment-dwelling bacteria are commonly inversely related to the surface area of particles (particle size) and directly related to organic nitrogen content.
6. Most sediments contain significant amounts of organic matter, and oxygen intrusions are limited. Bacterial metabolism rapidly produces anoxic,

reducing conditions. Under anaerobic conditions, rates of mineralization are slower than under aerobic conditions.

a. Under anoxic conditions, various substances and intermediate metabolic compounds function as electron acceptors and are reduced to yield energy instead of molecular oxygen. Reduced products formed by bacteria in sediments occur along a succession of anaerobic oxidation processes of reduction of nitrate, manganese and iron oxides, and sulfate (Table 21-6). Often, the same compound can serve as a hydrogen acceptor or donor, depending on the environmental conditions.
b. Large amounts of organic matter are anaerobically degraded by methane fermentation. Organic matter is converted to methane and CO_2 in two stages (Fig. 21-5).
c. Facultative and obligate anaerobic bacteria ('acid formers') convert proteins, carbohydrates, and fats primarily to fatty acids (especially acetate) by hydrolysis and fermentation.
d. Obligately anaerobic methanogenic bacteria then convert the organic acids to CH_4 and CO_2; alternatively, they can reduce CO_2 to CH_4 by enzymatic addition of hydrogen derived from the organic acids.

7. Methane generation can be very intense in anaerobic sediments. Methane diffuses into anaerobic overlying hypolimnetic waters of productive lakes. At the aerobic–anaerobic water interface (sediment–water interface or in the metalimnion overlying an anoxic hypolimnion), much of the methane is converted to CO_2 by aerobic methane-oxidizing bacteria.
   a. During summer stratification, the highest rates of methane oxidation often occur in the lower metalimnion, where oxygen concentrations are reduced (<1 mg liter^{-1}). For the lake as a whole, the total quantity of methane oxidized is often low during summer, however, because the bacteria are limited by the available combined inorganic nitrogen, and because oxygen present in the epilimnion is inhibitory to N_2 fixation. Nonetheless, little dissolved methane is found in the epilimnion, and relatively small amounts evade to the atmosphere at this time.
   b. High rates of methane oxidation (amounting to as much as 95% of the annual oxidation) occur in periods of lake circulation, especially during fall turnover. Considerable amounts of methane can diffuse and escape to the atmosphere during these periods.
   c. Under ice cover, high rates of methane oxidation can occur throughout the water column of eutrophic lakes. Methane oxidation under ice cover can contribute to reduced levels of dissolved oxygen or even total lake anoxia.
   d. Appreciable methane passes through emergent and floating-leaved aquatic plants and evades to the atmosphere. Methane emissions from natural and cultivated wetlands are appreciable on a global basis (ca. 20%).
   e. The amounts of CO_2 and bacterial-cell material production are usually insignificant in comparison to primary production. In relation to the total carbon inputs from the atmosphere and runoff, however, methane cycling can be significant in eutrophic and hypereutrophic lakes as well as in streams and rivers. An amount of organic carbon regenerated as methane equivalent to as much as 60% of the total carbon inputs has been found in several very productive lakes; methane-oxidizing bacteria can recycle about two-thirds of this carbon.
8. As lakes become very productive, anaerobic fermentation processes can evolve large quantities of gases, mainly CO_2, CH_4, and H_2. The quantities produced can exceed microbial oxidizing capacities and hydrostatic pressure constraints, which allows the formation of gas bubbles that rise to the lake surface and escape to the atmosphere.
   a. In relatively shallow hypereutrophic lakes, a steady ebullition of gases can result.
   b. Rising gas bubbles can generate small currents that are effective in redistributing hypolimnetic nutrients and degradation products to overlying water strata. These ebullition currents can enhance nutrient availability and primary productivity in the epilimnion and thus represent a positively reinforcing, internal fertilization process.
9. Most of the very high bacterial production of sediments is mineralized and respired as CO_2 and CH_4 within the microbial food web and evades to the atmosphere. Less than 20% of this rich bacterial production would be expected to reach higher trophic levels in either lake or river ecosystems.
10. The terrestrial vegetation adjacent to lakes and rivers, wetland vegetation, and higher aquatic plants of littoral and floodplain zones constitute a large source of organic matter.
    a. Senescent plant tissues decay during initial stages largely by fungal degradation.
    b. Within water, an appreciable portion (25% or more) of the tissue is leached as dissolved organic matter, some of which aggregates back to

particulate organic matter physically or by sediment microbial assimilation.

c. Particulate organic matter forms a major organic loading to sediments. Decomposition rates are initially rapid but decline with time as more labile organic constituents are decomposed. Rates vary greatly with differences in chemical composition of the particulate organic matter, particle size, nutrient availability, and temperature, among other factors.
d. In woodland streams, leaf fall from terrestrial vegetation can constitute a major seasonal input of particulate and dissolved organic matter. In larger rivers, external dissolved and particulate organic matter is derived largely from the flood plains and ground waters from adjacent terrestrial sources.
e. Loss rates in streams result from a combination of decomposition with evasion of respiratory CO_2 and CH_4 to the atmosphere, fragmentation of particulate organic matter by turbulence and macroinvertebrates, and export losses of dissolved and fine particulate organic matter. Fragmentation of coarse particulate organic matter by feeding activities of immature macroinvertebrates can increase markedly rates of microbial degradation.

11. In sediments of both lakes and rivers, much greater amounts of CO_2 are released from benthic respiration than the amount of oxygen consumed, which indicates a prevalence of anaerobic metabolism utilizing alternative electron acceptors. Most of the benthic metabolism is microbial, associated with organisms of a size <100 μm.

X. Summary

I. BENTHIC ANIMAL COMMUNITIES

The distribution, abundance, and productivity of benthic organisms are determined by several ecological processes: (a) the historical events that have allowed or prevented a species from reaching a habitat, (b) the physiological limitations of the species at all stages of the life cycle, (c) the availability of energy resources, and (d) the ability of the species to tolerate competition, predation, and parasitism (Reynoldson, 1983; Hutchinson, 1996). We should examine briefly characteristics of the diversity of benthic invertebrates that inhabit inland waters.

Analyses of the complex interrelationships among the benthic animals of fresh waters have focused to a large extent on descriptions of species and their distributions within lakes and streams in relation to environmental variables. Although such analyses are essential to initial evaluations of the communities, physiologically oriented experimental analyses of regulating environmental parameters have not been utilized among benthic communities to nearly the extent that they have been in studies of planktonic communities. The population, productivity, and trophic interrelationships of the benthic fauna are poorly understood in lakes; they are somewhat better known in running waters (e.g., Hynes, 1970).

The distribution of the diverse fauna within lakes and streams is extremely heterogeneous, which is in part a product of variable requirements for feeding, growth, and reproduction. These requirements are influenced strongly by changes in the substratum and

overlying water on a seasonal basis (e.g., changes in oxygen content and in the inputs of living and dead organic matter for food). The benthic organisms either possess adaptive mechanisms to cope with these changes, enter relatively dormant stages until more physiologically amenable conditions return, move, or die. The adaptive capabilities of the benthic animals to the dynamics of environmental parameters are basic to their distribution, growth and productivity, and reproductive potential.

Several major problems must be overcome in order to analyze benthic animal communities effectively. First is the difficulty of obtaining quantitative samples. Substrata heterogeneity leads to a patchy, nonrandom distribution that requires extensive replicated sampling according to procedures that depend on the organisms and bottom substrata involved (cf. detailed discussions of sampling methods in Edmondson and Winberg, 1971; Holme and McIntyre, 1971; Brinkhurst, 1974; Elliott, 1977; Benke, 1984; Downing, 1984; Peckarsky, 1984a; Wetzel and Likens, 2000). Organisms must be separated from samples obtained with benthic grabs, dredges, or cores, which retrieve organisms together with the substrate in which they live. The taxonomy of many animal groups is confusing to the nonspecialist; some groups are still very incompletely described. Emigration and immigration of members of the populations of certain groups, especially among the insects, necessitates more elaborate sampling methods. In spite of these problems, careful and detailed analyses of some populations provide insight into the controlling environmental and biotic interactions within benthic animal communities.

Benthic animals are extremely diverse and are represented by nearly all phyla from protozoans through large macroinvertebrates and vertebrates. This fact, together with their heterogeneous characteristics of habitats, feeding, growth, reproduction, mortality, and behavior, makes it exceedingly difficult to treat these animals in an integrated, functional manner. In the brief space available, we can only point out some of the major groups, giving examples of their population and production dynamics in relation to freshwater ecosystems. Important characteristics of the sediments have been discussed elsewhere in relation to oxygen (Chap. 9), redox (Chap. 14), microbial metabolism of organic matter (Chap. 21), and organic composition of different sediments (Chaps. 21 and 23).

A. Protozoa and Other Protists

Perhaps the least understood groups of benthic animals that occur in massive numbers on and in surficial sediments are the protozoa and related protists and the ostracod crustaceans. General characteristics of the protozoans and related protista and particularly their many modes of nutrition were discussed earlier among the planktonic populations (cf. Chap. 16, pp. 396–412; cf. also the excellent summary of Taylor and Sanders, 1991).

In spite of the abundant information that we have on protozoan morphology, physiology, genetics, and behavior, very little is known concerning their population dynamics and contributions to productivity in the sediments. Temperature, availability of dissolved oxygen, and characteristics of the substratum markedly influence the distribution and productivity of protozoa. Most protozoa are attached to substrata, and they are particularly abundant in habitats of active oxidative decomposition. Ciliate protozoans are particularly important in the metabolism of dissolved and particulate organic matter of sewage-treatment facilities and organically polluted streams (Cairns, 1974), and their community composition has been used extensively as part of a system for classifying the water quality of aquatic habitats (Sládeček, 1973; Foissner, 1988).

The diversity of species of protozoa, their possession of wide ranges of tolerance to environmental extremes and varied feeding capabilities (including algae, bacteria, particulate detritus, and other protozoa and protists), and their large population densities on aerobic, organic-rich sediments, all point to a significant metabolic role in freshwater ecosystems. Because of their low collective community biomass, it generally has been assumed that their contributions are small. However, their short generation times and rapid turnover under the optimal trophic conditions of the sediments indicate that the protozoa contribute appreciably to the degradation processes in lakes, just as they do in the pelagic and littoral zones.

Flagellates clearly dominate in many benthic communities, and have been found to range from 100 to 180,000 cells cm^{-3} of sediment, whereas ciliate numbers ranged from 26 to 11,000 cells ml^{-1} (Gasol, 1993), although much higher estimates were found in sediments of small temperate streams (Bott and Kaplan, 1989). Most of the protozoans occur in the upper 1 cm of sediment. The number of species within sediments of a lake can be very large (50–150; e.g., Webb, 1961; Laminger, 1973; Finlay *et al.*, 1979; Finlay, 1990). Although coexistence in the same habitat is common, microspatial differences in distribution exist, and species separation by differences in food utilization, reproduction, and timing of population development within community succession on substrata are also common (Goulder, 1971, 1974a,b; Taylor and Berger, 1980; Jax, 1997).

Many factors affect the distribution and growth of free-living protozoa (cf. reviews of Noland and

Gojdics, 1967; Laybourn-Parry, 1984, 1992; Taylor and Sanders, 1991), but dissolved oxygen is of paramount importance. The protists are sufficiently small that cellular exchange by diffusion is adequate without the necessity of organelles to increase surface area. Few species can tolerate the anaerobic conditions of the sediments for any appreciable period. Microaerophilic protists, however, can tolerate very low oxygen tensions, and these habitats can provide a refuge from competition and predation by larger animals. Protozoa are distributed in environments of widely ranging temperatures (0–50°C), but with a Q_{10} of about 2.0, rates of growth are most efficient below 25°C.

The distribution and abundance of chlorophyll-bearing forms, often microaerophilic ciliates with endosymbiotic green algae, are regulated to a large extent in ways analogous to the regulation of algae, such as by inorganic and organic nutrient availability and by light. Among heterotrophic protozoa, the distribution and quality of dissolved and particulate organic matter for food are important. Although the nutritional requirements of only a few species are known, there is a tendency for species living in unpolluted waters to feed on microalgae, while those of more polluted waters ingest predominantly bacteria. The significance of vitamins and other growth substances to protozoan population dynamics is just beginning to be appreciated.

Most species of protozoans are intolerant of low oxygen concentrations and reducing conditions in sediments, but some species tolerate reducing conditions much better than others (e.g., Goulder, 1971, 1980a; Laminger, 1973; Finlay, 1980). As a result, protozoan species are often segregated vertically in lake sediments along a depth gradient. These depth distributions may change seasonally, owing to changes in oxygen concentrations of overlying water. Many species migrate to sediments in shallower areas as anoxia develops in the hypolimnion, or the populations gradually assume a different depth distribution as reproductive rates change. Some species are negatively phototactic and avoid high light intensities within epilimnetic sediments.

Many of the benthic protistan populations exhibit pronounced summer maxima (Finlay, 1980, 1990; Bark, 1981; Rogerson, 1981). These changes have been positively correlated with summer increases in temperature, day length, and abundance of organic matter and microflora serving as food in the surficial sediments. Other studies found maxima in winter with decreases in nanoflagellates in the summer and autumn (Starink *et al.*, 1996). The importance of predation upon the benthic flagellates in summer by other meiobenthic invertebrates is unclear. As oxygen is depleted in the hypolimnion, many populations migrate upward to metalimnetic and epilimnetic regions; this migration also contributes to seasonal increases in the protozoan populations in these areas.

Although competition among protistan species has been demonstrated in cultures, most of the evidence for competitive species interactions is indirect under natural conditions (e.g., Cairns and Yongue, 1977). Both heterotrophic flagellates and benthic ciliates are estimated to consume only a small fraction (<2–5%) of the daily bacterial production in sediments (Kemp, 1988; Alongi, 1991; Starink *et al.*, 1994) and consume many other food materials, such as microalgae, particulate organic detritus, and other protists. Benthic bacterivory was in the range of 10–70 bacteria protist^{-1} h^{-1}, and somewhat higher for ciliates. Similarly, herbivory of benthic algivorous ciliates on attached diatoms was estimated to be <5% (Balczon and Pratt, 1996).

Predation upon protists is common by other protozoan species and by micrometazoa, particularly rotifers and some cladocerans and copepods. For example, experimental introduction of micrometazoa reduced the abundance of larger protists, mostly ciliates and certain algae (McCormick and Cairns, 1991). Benthic heterotrophic flagellate abundance increased under these conditions, in part related to declines in ciliates that prey and compete with the smaller flagellates. As was discussed among the planktonic protists (Chap. 16), changes in body size, feeding behaviors, and growth rates also occur among benthic protists, although much less is known about these interactions.

B. Porifera—Sponges

Few sponges occur in fresh waters; most species are marine. Although some species endemic to Lake Baikal grow to magnificent lobed structures of about half a meter in size, most are small, inconspicuous, and morphologically variable. The flagellated chambers create weak currents with water that enters through many pores (ostia), passes through the internal canals and chambers, where bacteria and particulate detrital material are trapped for intracellular digestion, and then collects and leaves through larger channels and openings (oscula) (reviewed in Frost, 1980, 1987, 1991). Filtration of water for feeding can be high (ca. 6 ml h^{-1} per mg dry mass of tissue). Zoochlorellae, ingested algae that persist inter- and intracellularly in the tissue, can grow and metabolize appreciably within certain sponges (Gilbert and Allen, 1973). The photosynthate produced can contribute significantly to the energy budget of the host, in the range of 2–22% of the animal respiration (Frost and Williamson, 1980; Sand-Jensen and Pedersen, 1994; Frost *et al.*, 1997). Rarely do sponges occur at depths in excess of the

Secchi disc transparency (Hutchinson, 1993), a depth equivalent of ca. 10–15% of surface illuminance. Although such symbiotic relationships between the organisms are common, the zoochlorellae are not essential to the survival of the sponge, at least not for *Spongilla* and a number of other genera.

Sponge growth occurs by proliferation of the tissue over the substratum with the addition of new chambers. Growth rates and energy demands generally increase progressively seasonally and reach a maximum in midsummer (e.g., Melão and Rocha, 1998). In mild climates, sponge populations can persist for many years without appreciable change (e.g., Pronzato and Manconi, 1995) until a major disturbance occurs, such a flooding. Under unfavorable conditions, such as in autumn in the temperate zone, tissue is reduced by partial or total deterioration. Highly resistant resting structures termed *gemmules*, usually less than a millimeter in diameter, are formed in many species (Gilbert, 1975; Gilbert and Simpson, 1976a). Some species, particularly those in sublittoral environments of muted seasonality, do not form gemmules; instead, sexual reproduction continues into the autumn (Gilbert and Allen, 1973; Simpson and Gilbert, 1974; Gilbert and Hadzisce, 1975, 1977). Major predation upon sponges by other animals is rare. Spicules and likely organic compounds can function as deterrents to predators. A number of animals, particularly certain immature insects, live within sponges, perhaps to find a refuge from predation. The relationships have been shown to be obligatory in only a few cases.

Gemmules contain undifferentiated mesenchymal cells and have an outer layer of compacted siliceous spicules within a tough sclerotized membrane. They can withstand freezing and desiccation. After a diapause of one to several months at colder temperatures, germination of the gemmules is usually associated with warmer temperatures >15°C in the early spring (Harrison, 1974; Gilbert *et al.*, 1975). Motile larvae move to appropriate substrata, attach, and develop. Syngamic sexual reproduction also occurs in warmer periods of the year. Sponges are usually dioecious, and the sex ratio is about 1:1 in natural populations. A common freshwater sponge, *Spongilla lacustris*, exhibits a type of alternate hermaphroditism, in which a sponge may be exclusively male or female during the period of sexual reproduction 1 year and the opposite sex the next year (Gilbert and Simpson, 1976b). This form of sexuality may facilitate larval production and thus dispersal following colonization of a new habitat.

Sponges are among the few animals requiring large amounts of silica for spicule development. Spicules occur in many types and species-specific forms and are bound together by collagens to form an inorganic skeleton. Sponges are restricted largely to waters of moderate silica content (>0.5 mg liter^{-1}) (Jewell, 1935). Species distribution is also directly correlated with the calcium content of the water but declines in very hard waters (Jewell, 1939; Strekal and McDiffett, 1974; Hutchinson, 1993); although causal mechanisms for this relationship remain obscure, they are probably related to food abundance rather than to a direct demand for calcium.

Freshwater sponges, which usually occur only in relatively clear, unproductive waters, rarely become a major component of benthic communities. Their significance in benthic productivity is minor in most situation, but has been found to constitute a significant portion of the total benthic productivity in certain conditions [e.g., 40% in the River Thames (Mann *et al.*, 1970) and in a *Sphagnum* bog pond (Frost, 1978)].

C. Cnideria (Coelenterata)

The hydroids and "jellyfish" of the class Hydrozoa belong to a predominately marine group that is poorly represented in fresh waters. The common *Hydra* occurs only as the tentacled polyp stage, while the rare *Craspedacusta* or freshwater jellyfish undergoes metagenesis with alternation between medusoid and polyp stages that is common to the marine Hydrozoa. During the life cycle of *Craspeducusta*, both medusa and polyp states feed on a variety of zooplankton, but because of low densities, they likely do not influence zooplankton densities (DeVries, 1992).

Epidermal cells contain nematocysts or stinging cells that function in capture of prey; food particles are then moved to the mouth orifice by the tentacles. The hydroids are sessile and are almost exclusively carnivorous on zooplankters. One species of green hydra (*Chlorohydra*) contains unicellular green algae in a symbiotic relationship, and the algae live intracellularly in gastrodermal cells. About 10% of the carbon photosynthetically fixed by the algae is released and assimilated by the *Hydra* (Muscatine and Lenhoff, 1963). This photosynthate is clearly of nutritional significance to the *Hydra* (Pardy and White, 1977; Phipps and Pardy, 1982).

Development in quiet waters is rapid in spring, and greatest densities usually are found in early summer and late summer (Miller, 1936; Cuker and Mozley, 1981). Growth rates decrease markedly when populations are crowded (Thorp and Barthalmus, 1975). Hydroid densities usually do not become great, however, and their contribution to total benthic productivity is usually, although with poor foundation, considered negligible. Under some conditions, populations of *Hydra* can become very large (to 30,000 m^{-2} among

submersed macrophytes) and significantly reduce population sizes of small zooplankton by predation (Cuker and Mozley, 1981) and larval fish by both ingestion or mortality after being stung by nematocysts (Elliott *et al.*, 1997).

D. Turbellarian Flatworms

The dominant free-living members of the Platyhelminthes are the turbellarian flatworms. These organisms are acoelomate with only a single opening to the digestive tract (they lack an anus). Most members of the group, the tapeworms (Cestoidea) and the flukes (Trematoda), are entirely parasitic. Many free-living flatworms are small (<1 mm), but the triclads usually exceed 10 mm in length. Flatworms generally require a firm substratum and possess abundant cilia that assist them in movement over the substrata of shallow lakes and streams. When the animal encounters small invertebrates or detrital organic matter, the ventral pharynx is extruded through the mouth to incorporate the material (Young, 1973). Some of the rhabdocoels contain symbiotic zoochlorellae in their parenchyma and cells of the gastrodermis.

Reproduction is either asexual, by budding or fission (Pattee and Persat, 1978), or sexual. In the latter case, sex organs usually develop over winter and egg capsules are released in the late winter or spring in permanent bodies of water. Nearly all flatworms are hermaphroditic, with both sex organs occurring in the same individual. The eggs are encapsulated or sometimes enclosed in a stalked shell. Winter eggs are heavily encapsulated and are able to withstand low temperatures, but do not survive well to desiccation. Development is strongly temperature dependent in both the egg and immature stages; no larval stages are found in most species (e.g., Pattee, 1975; Folsom and Clifford, 1978). A few species are univoltine, but most species are multivoltine, with the number of generations correlated with the availability of habitat and food (cf. especially Harrmann, 1985).

Most flatworms, especially the triclads, are negatively phototactic and occur in shaded areas among debris, rocky substrata, and macrophytes. Among four species of lake-dwelling triclads studied extensively by Reynoldson (1966), all occupied the same general substratum in the shallow littoral zone and fed on the prey organisms there. Feeding mechanisms of all the species were similar, and a wide overlap existed in the type and size of prey eaten by young and adults of each species. The species populations exhibited restricted fluctuations in numbers and lived under conditions of food shortage for long periods of the year. Flatworms are able to avoid starvation because they can resorb and then regenerate tissues by reductions in size and metabolic rate (Calow, 1977) and because of low predation pressure by other organisms.

The distribution and abundance of individual triclad species are determined primarily by interspecific competition for food (Reynoldson and Bellamy, 1971, 1975; Reynoldson and Sefton, 1976; Reynoldson and Pearce, 1979; Adams, 1980; Reynoldson *et al.*, 1981; Young, 1981; Reynoldson, 1983; Armitage and Young, 1990a). All studies of lake populations indicate that they are food-limited and that severe intraspecific competition occurs. Despite the great overlap of food prey species, each triclad has been found to feed on a particular kind of prey to a greater extent than others. Thus, the competition depends largely on the pattern of distribution and abundance of important types of prey, such as gastropod mollusks, chironomids, stonefly and mayfly nymphs, amphipods, and oligochaetes, each of which represents the dominant prey of particular triclad species.

The coexistence of several species of triclads as well as leeches in lacustrine habitats is common even though both triclads and leeches are food limited and there is much overlap in their diets (e.g., Seaby *et al.*, 1996). Partitioning of food resources apparently occurs because the leeches are more efficient in capturing prey food items than are triclads. In contrast, the triclads can exploit damaged prey, including incapacitated, live, or recently dead animals that are leaking body fluids, better than do leeches. In contrast, the microturbellarians feed on bacteria, attached algae, protozoa, rotifers, and very small cladocerans, copepods, and oligochaetes (cf. Heitkamp, 1982). Predator–prey relations also exist among carnivorous microturbellarian species. Stream triclads reduce potential competition by spatial separation along the stream based on different responses to water temperature and stream gradient. Some evidence exists for interspecific competition for food among stream populations as well (Reynoldson, 1983).

Some species, particularly of the tropical planktonic turbellarian *Mesostoma*, can reach densities of 1000 m^{-3} and are occasionally significant (to 4 individuals day^{-1}) predators of cladoceran zooplankton, especially *Daphnia* and *Ceriodaphnia* (Rocha *et al.*, 1990). These flatworms produce and release a toxin that functions as a neurotoxin when cladoceran zooplankton encounter mucus released by the flatworm (Dumont and Carels, 1987). Capture and ingestion of the prey is assisted by this mechanism.

Although a number of invertebrates and vertebrates may consume triclads, free-living flatworms constitute a minor component of the diet of their predators (Davies and Reynoldson, 1971; Reynoldson, 1983).

Triclads are preyed upon only by a few predators such as dragonfly nymphs and newts. The chemical protection afforded triclads by rhabdites is apparently effective. The incidence of sporozoan, ciliate, nematode, and trematode parasitism is high, but mortality effects appear to be low (Armitage and Young, 1990b).

The abundance of these triclad species has been directly correlated with the general productivity of the waters and amount of food available in the littoral zone, which in turn has been directly related to concentrations of calcium and total dissolved matter (Reynoldson, 1966, 1981). As a result, unproductive lakes receiving low nutrient loading support smaller populations and fewer species, owing to competition for food, than lakes of higher productivity, in which both the diversity and abundance of food species increase. As food supply is reduced, short-term reproductive effort generally increases (Callow and Woollhead, 1977).

Similar relationships have been found among stream-dwelling flatworms (Chandler, 1966). Shallow streams exhibit wide fluctuations in temperature, which influence triclad feeding activity, reproductive capacity, and acclimation capacity. The distribution of individual species is widely separated as a result. Additionally, triclad abundance is inversely related to velocity of water flow. The shifting substrates of rapidly flowing streams and wave-swept littoral zones create an unfavorable habitat for flatworms and many additional benthic animals. Although adults may be able to tolerate the mechanical abrasion associated with shifting substrata, eggs or immature stages often cannot.

Turbellarian abundance in lakes is variable within a range of ca. several hundred to 80,000 m^{-2} (Heitkamp, 1982). For example, in mesotrophic Mirror Lake, New Hampshire, mean turbellarian densities were 27,000 m^{-2}, and decreased from 40,000 m^{-2} in shallow littoral areas to nearly zero in the profundal zone (Strayer, 1985). Although the turbellarians constitute a significant portion of the total meiobenthos productivity, their significance to the entire energy budget of lakes is less clear. Densities in streams are generally lower, with an upper end of the range <5000 m^{-2} where predation, particularly of triclads by a few species of stonefly nymphs and caddisfly larvae, is more effective than in lakes.

E. Gastrotricha

The gastrotrichs are a very small group of diminutive (50–800 μm), pseudocoelomate animals of or closely related to the nematodes of the Aschelminthes. Gastrotrichs occur in high densities in both aerobic and anaerobic sediments and in the periphyton of littoral areas of lakes and streams and in the hyporheic sediments of running waters. The gastrotrichs commonly attach the posterior end of their spindle-shaped body with adhesive tubes to a substratum. Rows of ventral cilia allow the animals to move by gliding.

Gastrotrichs feed on bacteria, algae, protozoans, and small detrital particles. The digestive system is a simple, relatively undifferentiated tubular gut with an anterior mouth and posterior dorsal anus. Little is understood of predation upon gastrotrichs by known predators of amoebae, cnidarians, and midge larvae.

Upon hatching from eggs, young gastrotrichs contain developing parthenogenetic eggs that can develop rapidly (e.g., 2 days), are quickly laid, and hatch (e.g., 1 day) under favorable conditions (Strayer and Hummon, 1991). This parthenogenesis allows rapid population development under favorable environmental conditions, with growth rates of 0.1–0.6 per day. Some of these gastrotrichs age longer and develop into hermaphrodites, and meiotic sexual eggs are produced with genetic recombination. A second type of parthenogenetic egg, a resting egg, is thick-shelled, very resistant to freezing and desiccation, and likely aids in dispersal.

Among the few population analyses, seasonal trends in gastrotrich abundance show species differences among the same sediment habitats. Generally, abundances are greatest in the spring for several species (range 10–50 cm^{-2}) on organic-rich lake sediments; other species reach greater population densities in the winter months (Kisielewska, 1982; Strayer and Hummon, 1991). Gastrotrich densities can be extremely high, within a reported range of 10,000–2,600,000 m^{-2}, and are generally more abundant in the littoral zone (Nesteruk, 1993, 1996). Densities within the sediments are concentrated within the uppermost 2 cm, although they have been found at much deeper depths, 10–15 cm, and among many sediment grain sizes, particularly more coarse particles (>0.5 mm) (Strayer, 1985; Nesteruk, 1991; Fregni *et al.*, 1998). Strayer estimated the secondary production of gastrotrichs in Mirror Lake, New Hampshire, at ca. 100 mg DM m^{-2} yr^{-1}, which was <1% of the total production of the zoobenthic community in this lake.

F. Nematoda—Roundworms

The Nematoda or roundworms, a class of the pseudocoelomate phylum Aschelminthes, are a significant component of the benthic fauna. Although most of the many nematode species are parasitic, the many free-living species are distributed widely in all types of freshwater habitats. The taxonomy of this group is difficult, incomplete, and has contributed to the relative paucity of understanding of the ecology and productivity of nematodes.

The external proteinaceous cuticle of nematodes is noncellular and layered and is molted four times during their life (Malakhov, 1994). This ridged cuticle is interfaced with longitudinal muscle cells that permit active, snakelike movements along and through sediments. Nearly all free-living freshwater nematodes are <1 cm in length.

Feeding habits are very diverse among the nematodes. Some members are strictly detritivores, feeding solely on dead plant or animal particulate matter, or both. Some species are bacterivorous and are prolific on surfaces among organically polluted saprobic conditions (Schiemer, 1983). Others are herbivorous and have specialized mouth parts for chewing living or dead plant material or for piercing and sucking cytoplasm from plants (Prejs, 1977a). Mouth parts are more specialized among carnivorous nematodes, enabling them to seize, rasp, and macerate small prey animals such as other nematodes, protozoans, gastrotrichs, tardigrades, oligochaetes, and small immature insects.

Reproduction is variable. Some species are parthenogenetic or hermaphroditic. Most species, however, are dioecious and syngamic, with separate females and males (Malakhov, 1994). Fertilized eggs, usually laid outside of the body, develop rapidly (1–10 days) and hatch into young, which are nearly fully developed except for the reproductive organs. Reproduction and egg laying by adults are more or less continuous. Little is known of the fecundity of free-living nematodes under natural conditions, but it is apparent that much of their productivity is diverted into reproduction in a normal life cycle. The reproductive phase is extended under habitat conditions of high and predictable food supply (Schiemer, 1983). Several hundred eggs with a biomass several times greater than that of the producing female are apparently common. The duration of the life cycle is also variable, from about 2–40 days. Most species, however, require 20–30 days for development and reproduction.

Nematode populations of the sediments of a typical dimictic, relatively oligotrophic mountainous lake were concentrated at depths of 3–4 cm in the sediments (Bretschko, 1973). Few penetrated below 6 cm into the sediments. Similarly, Traunspurger and Drews (1996) found most (89%) nematodes in the first 5 cm of sediment, although considerable spatial separation was observed among different species vertically within the sediments. Although the four molting instars could not be separated, analyses of the seasonal population dynamics of the 10 species demonstrated three generations per year. The first hatched in September–October and matured in November–December just after ice cover formed. The second generation was the most productive and reached maximum abundance and biomass in January (Table 22-1). The maximum relative abundance of adults of this generation occurred in April. Offspring of the winter generation formed the third generation, with a maximum in biomass and abundance in May (about 50% of that peak in January). As the ice cover was lost in May and the lake circulated, the entire community of nematode populations collapsed for unknown reasons. Over a 2-year period, the average population density was 235,000 m^{-2} under ice cover but only 60,000 m^{-2} during the ice-free period.

The greatest densities of nematodes are found in oligotrophic lakes (Prejs, 1977b,c). Nematode densities decrease in profundal sediments of eutrophic and dystrophic lakes; presumably low oxygen concentrations are a primary limitation in these lakes. Some species tolerate anoxia, at least for short periods, of the hypolimnion in mesotrophic lakes (e.g., Strayer, 1985).

Most studies have examined community dynamics of nematodes in profundal sediments, where densities can range between 30,000 and 750,000 m^{-2} (Traunspurger, 1996). In the littoral zone and in wetlands, however, nematodes can reach very high densities among the attached algae of dense emergent and submersed macrophytes. In a detailed study of the seasonal dynamics of nematode populations in the littoral zones of several lakes, Pieczyńska (1959, 1964) found that maxima occurred in May and June, when the populations numbered over one million individuals per square meter of substrate surface, a level brought about by mass reproduction of the dominant species. The same species reproduced throughout the year, although not as intensely. During the other seasons of the year, the nematodes occurred in lower, more or less constant densities. Variations in the development of the spring maximum from year-to-year were correlated with warming temperatures of the water and the duration of ice cover in the littoral. Species of *Prochromadorella* and *Punctodora* dominated in littoral substrata, especially among shoots of higher aquatic plants, to which they attached readily by the secretion of an adhesive substance from their caudal glands and by their ability to become entangled in colonies of littoral algae. Littoral ice cover was found to be especially destructive to the substrata and nematode populations. Wave action, in contrast, caused little mortality and was found to facilitate dispersal and subsequent rapid colonization of newly growing algal and macrophytic surfaces. The densities of nematodes were correlated directly with the development and density of attached algae.

Nematode species distribution and biomass production were strongly correlated with the type of substratum (Table 22-1). Over 80% of production occurred in the deeper zone of deep, fine sediments where gravel was scarce and boulders were absent within an oligotrophic mountainous lake. Within this zone, 90%

TABLE 22-1 Production of Nematodes Seasonally and along Depth Gradients in Two Lakes of Austria[a]

[a] Summarized from data of Bretschko (1973, 1984) and Pehofer (1989). Dry weight estimated from fresh-weight values given by a factor of 20%; totals do not sum parts exactly because of rounding. The Finstertalersee has subsequently been modified extensively by damming of the valley and inundation for a reservoir.

of the biomass production was by one species of *Tobrilus*. The reasons for the observed high productivity in early winter are unclear but presumably were related to good food conditions that followed the ice-free period of higher primary productivity and to reduced predation by fishes and possibly by certain predacious cyclopoid copepods. Similar distributions and production of nematodes in distinct sediment habitats were found in a more productive lake (Table 22-1). Annual production-to-biomass ratios of three dominant nematode species, constituting most of the nematode production, were in the range of 4–7.5 (Table 22-2).

TABLE 22-2 Total Annual Production by Three Dominant Species of Profundal Nematodes and Their Production (*P*)-to-Biomass (*B*) Ratios[a]

Nematode species	*Production (mg m^{-2} yr^{-1})*	*Annual P/B ratio*	*Source*
High mountain lake, oligotrophic			
Monhystera stagnalis (semivoltine)			Bretschko (1984)
1968/1969	31.2	ca. 4

Ethmolaimus pratensis	110	6.5	
Total mean (6–13.5 m sediments)	700	—	

[a] Extracted from data of Bretschko (1984) and Pehofer (1989).

Clearly, the small size of the nematodes belies their high production rates—in terms of densities per unit area and production, the nematodes are a major component of the benthic invertebrates.

G. Nematomorph—Horsehair Worms

Horsehair worms (phylum Nematomorpha; Gordian worms) are common in many fresh waters. Horsehair worms, evolutionarily distinct from other animals, are free-living as adults but as larvae are obligate parasites of insects and other invertebrates (Poinar, 1991). Larvae readily parasitize immature caddisflies, dragonflies, crustaceans, and leeches, although host specificity is not well documented. Often, sterility or death of the host is induced, and heavy parasitization may affect the population dynamics of the host species.

Adult free-living horsehair worms are common among littoral vegetation of shallow lakes, streams, and wetlands and can attain 1 m in length but are usually <3 mm in diameter throughout their body length. These worms are dioecious, and males are smaller than females. Sexual reproduction occurs during the warmer periods of the year. Eggs are laid in prodigious numbers (millions) in long gelatinous strings among vegetation and particulate detritus. Incubation is temperature-dependent and varies between 15 to 80 days. After hatching, larvae encyst on substrata and may be subsequently ingested by host animals. Internal metamorphosis occurs over several weeks, and juvenile worms emerge from hosts to mature. Emerging horsehair worms require water for maturation.

Very little is known about the feeding habits, population dynamics, and general ecology of these worms. Although the free-living nematomorphs may have relatively little impact on material and energy fluxes within most habitats, their commonly destructive parasitism in larval and juvenile stages could alter the population dynamics of host animals.

H. Bryozoans

The colonial bryozoan members of the primarily marine Ectoprocta are rarely of quantitative importance in freshwater ecosystems. These sessile forms, however, occasionally form massive colonies that can become conspicuous members of shallow eutrophic lakes and open areas of swamps for brief periods. The microscopic zooids possess ciliated tentacular crowns that project into the water and create water currents. Particles as large as rotifers, very small microcrustaceans, and small algae (<20 μm) are directed into the lophophore and mouth (Kamiński, 1984). Many zooids aggregate in colonial masses as a single structure. Some bryozoans contain many algae throughout the matrix that are attached to surfaces enclosed by the colonies (Joo *et al.*, 1992). Cyanobacteria dominated (90%) on surfaces enclosed by the colonies but were minor components of the attached algae on surfaces not colonized by bryozoans.

Although hermaphroditic sexual reproduction occurs in summer, bryozoan zooids are capable of asexual reproduction by budding new individuals from the midventral wall of the mother zooid. Budding permits rapid proliferation on the outer edge of the colonies, which occasionally form amorphous ball-like masses one-quarter of a meter in diameter. These colonies are common in small farm ponds in water less than a meter in depth, and their growth is influenced by fish predation (Dendy, 1963). When protected from fish predation, colonies were branched and more productive; when exposed to fish predation, unbranched, cropped colonies persisted. A large number of invertebrate animals, from protozoans to large insect larvae, particularly chironomids, live within the colonies of bryozoans. Predators of the bryozoans consume these coinhabitants as well as the bryozoans.

Under unfavorable environmental conditions, many bryozoans encapsulate dormant buds, termed *statoblasts*. Statoblasts have a thin outer chitinous shell that encloses yolk material and germinal tissue and can remain dormant for years under desiccation and freezing conditions. Statoblast viability, however, has been observed to be low (<10%) (Brown, 1933; Smyth and Reynolds, 1995). Statoblasts, particularly floating types, assist in dispersal; their production is approximately proportional to the size of the colony (Karlson, 1992).

Extensive studies of 12 species of bryozoans in 122 lakes, streams, and shallow waters of Michigan showed correlations of species distribution with several general limnological parameters such as pH (7–9), current, and substratum type (Bushnell, 1966; cf. the detailed review of Bushnell, 1974; Ricciardi and Reiswig, 1994). Some bryozoan species were associated with particular macrophyte substrata, and others were distributed more ubiquitously. Live colonies were found under ice at water temperatures <2°C. Growth was often erratic, but luxuriant colonies of *Plumatella* were found to grow rapidly, doubling in 3.4–4.9 days in summer and in 4.0–7.4 days in the spring. Growth ceased when temperatures decreased <9°C. Most mature colonies broke up and died after a period of growth, for reasons not completely understood. Predation on actively growing colonies was often very high, especially by caddisfly larvae and snails. *Plumatella* longevity ranged from 4 to 53 days; the death rate of individuals of the colony (the polypides) was highest

(80%) between 21 and 36 days after statoblast germination, and few lived longer than six weeks.

I. Aquatic Worms—Oligochaetes and Leeches

Two major groups of the annelids, or segmented worms, are represented in fresh waters. The first of these, the Oligochaeta or aquatic "earthworms," often form a major component of the benthic fauna, particularly of lakes. The other group, Hirudinea or leeches, is a diverse class of annelids of much biological interest. Although the significance of leeches as a component of total benthic animal productivity is unclear at this time, their predatory habits can materially influence the population dynamics of other benthic organisms, especially oligochaetes. By far the most comprehensive study of the aquatic oligochaetes is the work of Brinkhurst and Jamieson (1971). While largely a global taxonomic work, much of the presently rather limited knowledge of oligochaete anatomy, embryology, distribution, and ecology is reviewed in this book (cf. Learner *et al.*, 1978; Brinkhurst and Cook, 1980). A third minor group, the Branchiobdellida, consists of leech-like ectosymbionts living only on freshwater crustaceans, primarily on astacid crayfish (Brinkhurst and Gelder, 1991). This latter group is of much evolutionary interest but is a minor component of freshwater ecosystems and will not be discussed further here.

1. Oligochaete Worms

Oligochaetes are typically segmented, bilaterally symmetrical, hermaphroditic annelids with an anterior ventral mouth and a posterior anus. Size ranges from <1 mm to about 40 cm (maximum >200 cm), but most freshwater forms are <5 cm in length. Each segment, except for the first and a few terminal segments, bears four bundles of setae. Swimming occurs by rapid rhythmic movements in helical body wave cycles (to 12 s^{-1}) that pass from the anterior to posterier ends of the worm, thus propelling the worm forward (Drewes and Fourtner, 1993). Sexually mature Oligochaeta possess an anteriorly located thickened region in the body wall that is glandular and produces a cocoon at oviposition. Sexual reproduction predominates in many species under poor environmental conditions (Loden, 1981). Asexual reproduction is more common during favorable environmental conditions (e.g., McElhone, 1978).

Much of the information on oligochaete populations focuses on geographical distribution, habitat selection, and effects of organic pollution. Several species usually are found in each habitat, and these species differ little between streams and lakes of the same region. The number of species is often greater in larger lakes, perhaps because of the greater number of different microhabitats. Some species are restricted to relatively oligotrophic waters, while others are distributed widely in lakes of greatly differing productivity, from oligotrophic to extremely eutrophic (see, e.g., Milbrink, 1973a,b, 1978; Lang and Lang-Dobler, 1980; Särkkä and Aho, 1980). Obviously, a number of interacting parameters influence species distribution within the physiological tolerances of individual species. Some of these factors are discussed here.

The distribution of oligochaetes in sediments at different depths within a lake also indicates that a large number of species coexist in the same substrata. Individual species, however, do reach maximal abundance at different depths (Fig. 22-1). Although differences in the composition of the sediments were not analyzed critically in this study of a eutrophic lake, a number of studies suggest that the particulate composition and organic content of the sediments are correlated with the distribution and abundance of oligochaetes (Timm, 1962a,b). In a large, oligotrophic Italian lake, the number of oligochaetes was generally less in sediments of relatively large particle size (0.11–0.12 mm) than in more organic-rich sediments of finer particle size (0.07–0.08 mm) (Della Croce, 1955). A similar relationship has been found in relation to the total organic content of the sediments (Brinkhurst, 1967; Wachs, 1967). Experimental studies on the ubiquitously distributed *Tubifex tubifex* verified these general relationships. Nutrition and the availability of food are primary factors influencing distribution and abundance of oligochaetes.

Oligochaetes ingest surficial sediments containing organic matter of autochthonous and allochthonous origins colonized with bacteria and other microorganisms. Some species actively graze attached microorganisms growing epiphytically on macrophytic vegetation. Other oligochaetes actively ingest epipelic algae (e.g., Moore, 1978, 1981). Detailed analyses of the gut contents and feeding habits of oligochaetes living in the same habitat indicate that resource partitioning occurs by differences in worm morphology and by selective feeding on food items, particularly algae (Streit, 1977; McElhone, 1979). In studies of sediment feeding by this group (reviewed in Brinkhurst and Jamieson, 1971), it has been found that the organic carbon, caloric, and total nitrogen contents of the ingested sediments were only reduced slightly. However, critical experiments with mixed species cultures failed to demonstrate any reduction in the percentage of organic matter, nitrogen, or caloric content in feces as opposed to that in sediment provided as food (Brinkhurst *et al.*, 1972; Brinkhurst and Austin, 1979). These and other experimental studies on the utilization of bacterial species in sediments indicated that one species of

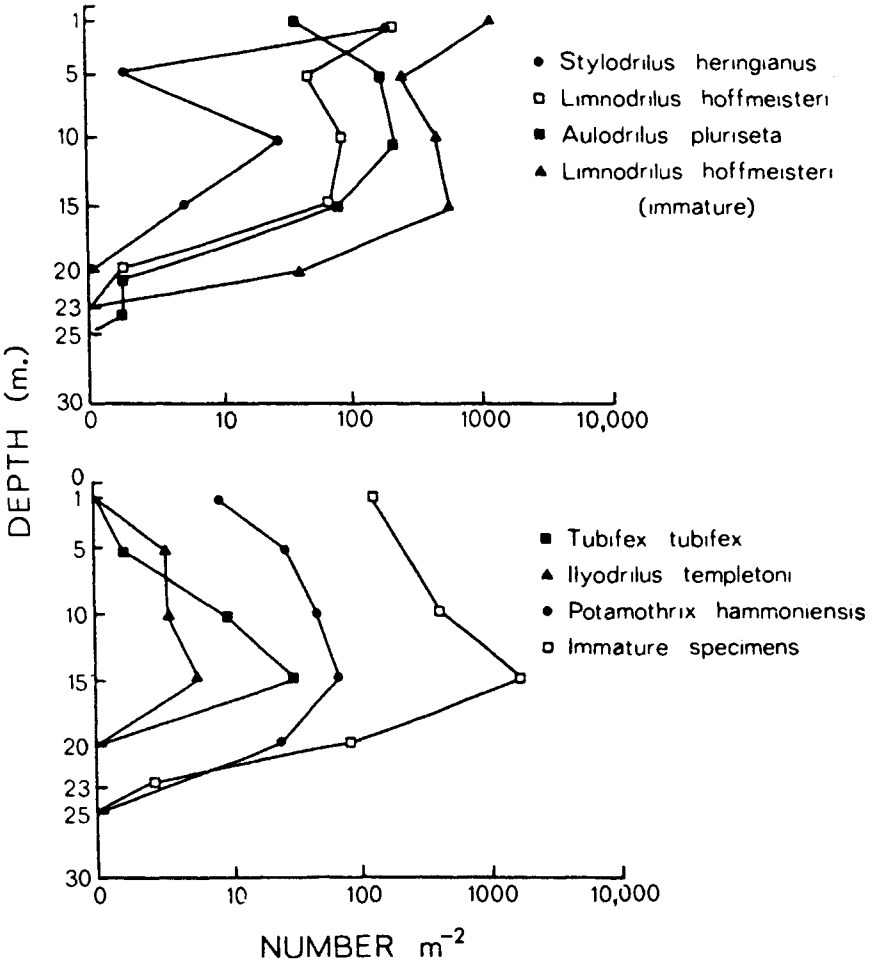

FIGURE 22-1 Distribution of various species of oligochaetes in relation to depth in hypereutrophic Rostherne Mere, southern England. The lake was devoid of oxygen below a depth of 25 m. (Drawn from data of Brinkhurst and Walsh, 1967.)

oligochaete may be able to selectively utilize different microbial components of the sediment (Brinkhurst and Chua, 1969; Wavre and Brinkhurst, 1971; Harper *et al.*, 1981).

As lakes and streams become organically polluted, it is common to find an abundance of tubificid oligochaetes (Brinkhurst and Cook, 1974; Milbrink, 1980). Associated with such organic enrichment is the acute reduction or elimination of dissolved oxygen. Acute reduction of oxygen is lethal to a majority of benthic animals. The number of species of tubificid worms also decreases with higher productivity and increased organic pollution. However, if some oxygen is available periodically and if toxic products of anaerobic metabolism do not accumulate, the combined conditions of a rich food supply and freedom from competing benthic animals permit rapid growth of oligochaetes adapted to these conditions.

Many oligochaetes, especially the tubificids, burrow headfirst into the sediments but leave their caudal ends, which contain most of their gills or respiratory appendages, projecting and undulating in the water above the sediment–water interface. The caudal respiratory movements increase in frequency and vigor as the oxygen content of the water decreases. In general, tubificids are able to adjust their respiration to decreasing oxygen concentration down to a critical level in the range of 10–15% saturation, values below which hemoglobin can no longer be loaded with oxygen. Below this critical level, feeding and defecation are then greatly reduced or cease (cf. Brandt, 1978). Many tubificids can tolerate anaerobic conditions for at least a month or longer but survive only if they are exposed intermittently to some oxygen, since they cannot respire anaerobically for any appreciable length of time. Water movement is apparently an important

factor in removal of toxic metabolic wastes, since anaerobic conditions can be tolerated longer in moving situations than when the water is stagnant. The species of oligochaetes, both those inhabiting littoral areas as well as profundal sediments, exhibit relatively specific distributions in waters of differing productivity, organic loading, and tolerances to low dissolved oxygen. Therefore, the distribution of oligochaetes along gradients of oligotrophy to eutrophy and waters of high organic pollution (e.g., receiving pulp mill wastes) have been used as indicators of trophy and eutrophication. Such indicator organisms may be of some value at the extreme ends of the trophy spectrum but must be used with caution and in conjunction with other parameters because the distribution ranges of the species are quite large (cf. Särkkä, 1987).

Reproduction in oligochaetes varies seasonally, and even when more or less continuous, some periodicity in breeding intensity is common. Oligochaetes lack discrete age classes and production is often approximately continuous. The limited data from natural populations suggest that maturation requires as long as a year in some species and up to 2–4 years in others. Variation is great, however, within the same species, and even from site to site in the same body of water. Breeding intensifies in late winter and spring as temperatures increase above about 10°C. Most adult oligochaetes die after sexual reproduction. Selective predation by other animals as a factor in species coexistence has been studied very little in natural populations. However, it is clear that selective breeding and metabolic adaptations by oligochaetes permit cohabitation. For example, when three species were combined, the population respiration of mixed cultures decreased about 35%, while increasing the population density of a single species proportionately had no such effect (Brinkhurst *et al.*, 1972). More energy was used for growth when the three species were mixed than when they were maintained separately in single-species culture, and the rate of respiration decreased in the mixed populations. Isolated single species spent more time burrowing and searching for their preferred food, which is feces of other oligochaete species, than they did in feeding (Chua and Brinkhurst, 1973; Brinkhurst, 1974). Such interspecific interactions are probably causal factors in the frequently observed clumped distribution of several species of oligochaetes.

In the deep profundal sediments of the Danish eutrophic Lake Esrom, some tubificid *Potamothrix hammoniensis* can first reproduce at 3 years of age, but most do not until they are 4 years old (Jónasson and Thorhauge, 1972). The lifespan of this species can reach 5 or more years. Mature *Potamothrix* in this lake laid eggs in May–July, and this process was related to moderate increases in sediment temperatures. From 2 to 13 embryos hatched from each cocoon about 2 months later, in August. Growth was most rapid in the autumn and spring, and no weight increase occurred during the summer period of stratification. Numbers of this species varied between 10,000 and 25,000 m^{-2} over a 6-yr period. In spite of these large numbers, biomass varied between 0.75 and 1.80 g dry weight m^{-2} but usually was >1.0 g m^{-2}. These values are similar to those observed in other lakes (Table 22-3).

Similar or higher densities (>30,000 m^{-2}) of aquatic oligochaetes were found in the littoral zone of mesotrophic Lake Esrom in Denmark (Lindegaard *et al.*, 1990, 1995). Despite the relatively high annual net production of the two dominant species (*Stylodrilus heringianus*: 3.1 g AFDM m^{-2} and $P/\bar{B}$ of 3.2; and

Marionina southerni: 1.0 g AFDM m^{-2} and $P/\overline{B}$ of 2.5) and moderate net production efficiencies of ca. 43 and 26%, respectively, they constituted only a small portion (<1%) of the estimated mean zoobenthic production in the littoral zone from 0- to 2-m depth in Lake Esrom. Mortality in the Lake Esrom populations was clearly related to natural death following reproduction. However, predation by the dipteran larvae of *Chironomus anthracinus*, studied in great detail in this lake, also caused significant reduction of the oligochaete populations. The reproduction of the oligochaete populations was depressed severely every second year as a result of the 2-yr life cycle of the *Chironomus* larvae (see also Loden, 1974).

Few other estimates of production rates of oligochaete populations exist (Brinkhurst, 1980). Detailed evaluations of the egg development times, mortality, cohort structure, and population dynamics of two dominant species of a reservoir in northern Italy demonstrated marked differences between the seasonal population characteristics of these oligochaetes (Bonomi, 1979; Adreani *et al.*, 1981). *Tubifex* had higher fecundity and shorter generation times and was nearly twice as productive as *Limnodrilus* (Table 22-4). However, the annual production-to-biomass ratios (turnover times) of the two species were very similar.

Oligochaete species frequently segregate vertically within the sediments. Naidid oligochaetes are concentrated at the sediment–water interface, rarely >2–4 cm below the surface (Milbrink, 1973c). Tubificid oligochaetes are most dense between 2 to 4 cm of sediment depth and occasionally penetrate as deep as 15 cm. The movements of benthic organisms within the sediments are important because their activity can disrupt temporarily the oxidized microzone of the sediment–water interface and thereby alter rates of chemical exchange between the sediments and overlying water. Experiments with tubificids have shown that their activity can alter the stratigraphy of surface sediments (Davis, 1974; McCall and Fisher, 1980), which is of interest in micropaleontological work (Chap. 24). As was discussed in Chapter 21, it appears that the intensive microbial activity at the sediment–water interface is sufficient to reestablish redox conditions almost immediately after periodic disturbances. However, if oligochaete populations such as *Tubifex* are present in high densities (e.g., 50,000 m^{-2}) in sediments, water exchanges can double rates of oxygen consumption, increase denitrification of water-phase nitrate by three times, and greatly increase ammonium ion efflux from the sediments (Pelegri and Blackburn, 1995).

2. *Hirudinea—Leeches*

Excellent general summaries on the structure, physiology, and ecology of leeches are given by Mann (1962), Sawyer (1986), and Davies (1991). Many leeches are ectoparasites that intermittently consume blood and body fluids of vertebrates greatly in excess of their own body weight. Leeches then enter a period of fasting, during which the consumed food is utilized over a period that can be as long as 200 days, with progressive loss of body weight. Other leeches are predatory on invertebrates such as oligochaetes, amphipods, snails, and chironomid larvae and consume their prey entirely (Elliott, 1973a; Green, 1974; Davies and Everett, 1975; Bradley and Reynolds, 1987; Proctor and Young, 1987; Toman and Dall, 1997).

Most predaceous leeches have an annual or semiannual life cycle, breed once, and then die. Reproduction is usually initiated in the spring or early summer and apparently is governed by temperature, the density of the populations, and age. Many leeches breed at 1 year of age and die after breeding, although some pass through two or more generations in 1 year (Tillman and Barnes, 1973; Davies and Reynoldson, 1975; Davies, 1978; Malecha, 1984). Other species live 2 years, overwinter and breed in the second, and die soon thereafter (Elliott, 1973b). High postreproductive mortality is associated with both significant metabolic

[a] After Mann (1962), from several sources.

costs incurred during gametogenesis and the high energetic costs of reproductive output (Davies and Dratnal, 1996). All leeches are hermaphroditic and commonly exhibit protandry, but gametogenesis is not always by the same individual (cosexual). After fertilization, eggs are deposited into a cocoon that is usually subsequently laid on or attached to substrata.

Predation on flaccid cocoons by invertebrates, particularly beetles, and fish can be appreciable but usually is not considered as regulatory to population dynamics of leeches as is mortality of the young (Young, 1988). In the first 3 months after hatching there is heavy mortality of the young (approximately 95% see Table 22-5) from predators (carnivorous invertebrates, particularly odonates and beetles, amphibia, many fish, and birds). Thereafter mortality lessens but is still severe (e.g., Spelling and Young, 1987; Young, 1987). Swimming activity of leeches in search of food is much greater during, but not restricted to, darkness, presumably to minimize access by visual predators (Davies *et al.*, 1996; Angstadt and Moore, 1997) or to follow the diurnal vertical migration of pelagic amphipod prey (Blinn and Davies, 1990). When population densities become high, population size can be regulated by high mortality of the eggs, which are consumed by adult leeches (Elliott, 1973a). There is also considerable evidence for common food limitation that can result in a high mortality (to 98%) of recruited young (Martin *et al.*, 1994; Young *et al.*, 1995). The young are unable to locate damaged food in a spatially heterogeneous environment because of a poorly developed chemosensory system. If low food conditions persist for long periods of time, energy partitioned to growth and reproduction declines as leeches allocate more energy to lipid storage, which increases survival (Smith and Davies, 1995).

Parasitism of leeches and mortality associated with parasites is poorly understood. Prevalence levels of microsporidian and trematode metacercariae parasites are low (<10%) (Spelling and Young, 1986a,b). High levels of trematode infestation reduced egg production slightly (<10%) and were not considered to regulate lacustrine leech populations significantly.

Among blood-consuming leeches, the time required for individuals to attain maturity is dependent upon the number and frequency of blood meals that are consumed (Davies and Wilkialis, 1980; Wilkialis and Davies, 1980). A seasonal migration has been found in some species, in which populations move into shallow water areas, where encounters with vertebrates would be more probable, during the ice-free period and then back into deepwater zones during the period of ice cover. Leeches are able to tolerate considerable periods of anoxia but the duration is strongly influenced by temperature (>50 days at 5°C, <10 days at 20°C) (Davies, 1991). Leeches move to shallower regions as oxygen is depleted in the hypolimnion during summer stratification (e.g., Peterson, 1983).

The abundance of leeches is highly variable among different habitats of lakes and streams. A general direct correlation exists between leech abundance and lake productivity. This relationship probably is associated with the increasing diversity of substrate types among the macrophytes and sediments, with correspondingly greater amounts of invertebrate food sources for the predacious leeches and birds and other vertebrates for the blood-consuming leeches (Sander and Wilkialis, 1972). Growth and production rates are quite variable in the littoral areas, however, because of the heterogeneity of habitats and associated prey items. In general, however, leech productivity is highest in the upper littoral zone reaches. For example, in the most detailed study of the growth and production rates of 10 leech species of Lake Esrom, estimates of mean annual production among five littoral locations varied between 288 to 1721 mg AFDW m^{-2} yr^{-1} (Dall, 1987). Both

abundance and production rates of individual species of leeches were manifold higher in the shallow areas than in midlittoral reaches (Table 22-6).

Estimates of the production rates of leeches of running waters are rare. The figures cited in Table 22-7 are for moderately productive stream waters and emphasize some of the population characteristics. Production of the *Erpobdella* leech species varied considerably between years and year-classes. Production was always greatest in the first year of the life cycle, even though the mean biomass was very similar in both years of the life cycle. The rate of production was most rapid during March to July, after which production declined sharply. Feeding rates are usually maximal in the spring and summer and decline sharply in the autumn.

Overwintering leeches of the species *Helobdella stagnalis* were found to reproduce in May in a shallow, eutrophic reservoir in South Wales (Learner and Potter, 1974; cf. Davies and Reynoldson, 1975). These postreproductive adults then died. The spring generation grew rapidly, and about one-third of this generation reproduced in July. The nonbreeding portion of the spring generation overwintered with the summer generation; both reproduced at the same rate in the following spring. The mean biomass was 96 mg DW m^{-2} in 1970 and 393 mg DW m^{-2} in 1971. Production was

estimated to be 310 mg DW m^{-2} yr^{-1} in 1970 and 1190 mg DW m^{-2} yr^{-1} in 1971, with production-to-biomass ratios of 3.2 and 3.0 in the respective years, similar to those found elsewhere (Table 22-6).

J. Tardigrades—Water Bears

The Tardigrada, or water bears, are a group of small (100–500 μm) arthropod-like organisms with a bilaterally symmetrical body and four pairs of legs that usually terminate in claws. Although most tardigrades inhabit wet terrestrial habitats, a number of species occur in fresh waters. The origins and systematics of the Tardigrada are unclear because they share traits of deuterostomes, pseudocoelomates, and coelomate protostomes, but they likely are intermediary forms along the evolutionary progression from the annelids to the arthropods (Kinchin, 1994). The tardigrades have been separated into an individual phylum with detailed systematic analyses (Ramazzotti, 1962, 1972; Ramazzotti and Maucci, 1983).

Some tardigrades are bisexual and fertilization usually occurs within the female (reviewed by Nelson, 1991; Kinchin, 1994). Many tardigrades are hermaphroditic, with male and female gamete production by the same individual. Parthenogenesis is very common among tardigrades. Highly ornamented eggs gestate on substrata or are held within cast exuvia of the adults; development times vary widely between 5 and 40 days. Periodic molting, which requires 5–10 days, continues throughout the life of tardigrades. The pharyngeal apparatus is expulsed periodically, during which time feeding ceases, and the buccal apparatus is regenerated. The claws are also reformed during each molt.

Very little is known about the population dynamics and productivity of freshwater tardigrades. Some direct correlations have been observed between tardigrade population fluctuations and attached bacteria and algae, and inversely with prey nematodes (Kinchin, 1994). No detailed evaluations of the comparative productivity of tardigrades exist for freshwater ecosystems. Although it is improbable that these interesting animals constitute a major benthic component of ponds, lakes, and rivers in comparison to other benthic organisms, conclusions are unwise on the basis of existing information.

K. Water Mites

Water mites are a collective group of animals emanating from five unrelated groups; the Hydrachnida form the largest and most diverse group of freshwater Acari (Gledhill, 1985; Smith and Cook, 1991). The group is extremely diverse, with >5000 species, and is often found in abundances of >5000 m^{-2} and consisting of >50 species in both lake littoral areas and stream riffles and in interstitial waters of the hyporheic sediments (to 50 cm of sediments).

Their complex development begins with hexapod larvae that emerge from eggs and become ectoparasites on insects in or close to the water, from which they extract fluids while being passively transported and dispersed. Upon release from the host, the mites commonly enter a resting stage during which development occurs to form an octopod, actively swimming deutonymph stage. Although predaceously feeding and growing at this stage, the mites are not sexually mature. The mites then enter a second resting stage from which, after further development and metamorphosis, they emerge as active, mature adults. After mating and fertilization, eggs are laid in masses in a gelatinous matrix attached to substrata.

Analyses of dominant water mite populations within a complex community of many species in a eutrophic lake in the Netherlands indicated relatively constant populations densities of up to 1000 m^{-2} throughout the year, with the highest densities in shallow littoral areas (Davids *et al.*, 1994). Nymphs were abundant from spring through late autumn and declined precipitously in the winter. The growth rates of nymphs and adult mites increased with rising temperatures, and the duration of resting stages decreased with increasing temperatures (Butler and Burns, 1995).

The parasitic larvae and predaceous deutonymphs and adults of water mites have direct effects on the size and structure of insect populations in certain habitats. Larval water mites often parasitize 20–50% of natural populations of aquatic insects (Smith, 1988). This parasitism impairs the vitality, growth, mobility, and fecundity of host insects. Deutonymphs and adults of free-living species of mites are voracious predators of eggs of insects and fish, larvae of many diptera and other insects, ostracod, cladoceran, and copepod crustaceans (Böttger, 1970; Gledhill, 1985). Little is known of predation upon mites. Although many species are found in fish, others are specifically rejected by fish as distasteful. Practically no studies treat comprehensively the production of water mites.

L. Ostracods

The ostracods are small, bivalved crustaceans usually <1 mm in size that are widespread in nearly every aquatic habitat. Their size, distribution in the surface sediments with few planktonic species and difficult taxonomy have all contributed to a very poor understanding of their ecology, population dynamics, and productivity in fresh waters. Their valves, which

superficially resemble clam shells, are held apart when undisturbed. Cladoceran-like appendages protrude between the open valves and are used for locomotion. Most ostracods move about on the sediments by beating movements of the antennae and the caudal ramus. Some species (e.g., *Cypridopsis*) are associated with periphyton on macrophytes and particulate detritus and feed voraciously on attached microflora (Mallwitz, 1984; Roca and Danielopol, 1991).

Ostracods are omnivorous and, similar to many cladoceran microcrustacea, they feed on bacteria, algae, detritus, and other microorganisms by means of filtration. Grazing rates increase in a linear function with rising food concentrations and then decrease precipitously at high food concentrations (Grant *et al.*, 1983). Very little is known of the effects of ostracods on the turnover and metabolism of benthic microflora. The large population numbers of ostracods, commonly in excess of 100,000 m^{-2}, suggest that their role in the metabolism of surficial sediments could be considerable.

Ostracod reproduction is usually parthenogenetic for much of their life cycle. In some species, males have not been found; in others, sexual reproduction is common. The time required for egg development is variable, from days to months, and is strongly temperature dependent. The larva hatches as a nauplius with a reduced number of appendages, and then undergoes a series of growth and molting stages; usually eight molts are needed to reach the ninth, adult stage, during which morphology becomes more complex and appendages develop.

Little is known of the population dynamics of ostracod populations, although many exhibit distinct seasonal periodicity. Some species exhibit a single generation per year; others two or three per year (e.g., Mallwitz, 1984). The detailed study of the reproductive potential and life history of a species of *Darwinula* in a deep, dimictic, temperate lake illustrates some of the characteristics of this group (McGregor, 1969). *D. stevensoni* was abundant throughout the littoral sediments of this mesotrophic lake and reached a maximum density at a depth of 6 m throughout the year. Most individuals occurred between depths of 3 and 6 m, and densities decreased markedly between 6 and 9 m. Only a few individuals were found below a depth of 9 m, and none <12 m. More than 95% of the adults and juveniles present in the sediments occurred in the upper 5 cm.

The reproductive period of this *Darwinula* species in this Michigan lake began in May and was effectively completed by October (Fig. 22-2). The number of young per individual increased from a maximum of 3 in May to 15 in August. Although the reproductive potential of a given individual was correlated strongly with temperature and varied somewhat with depth, most adults produced only one brood per year of about 11 young per individual at depths of 3–6 m (13 at 9 m).

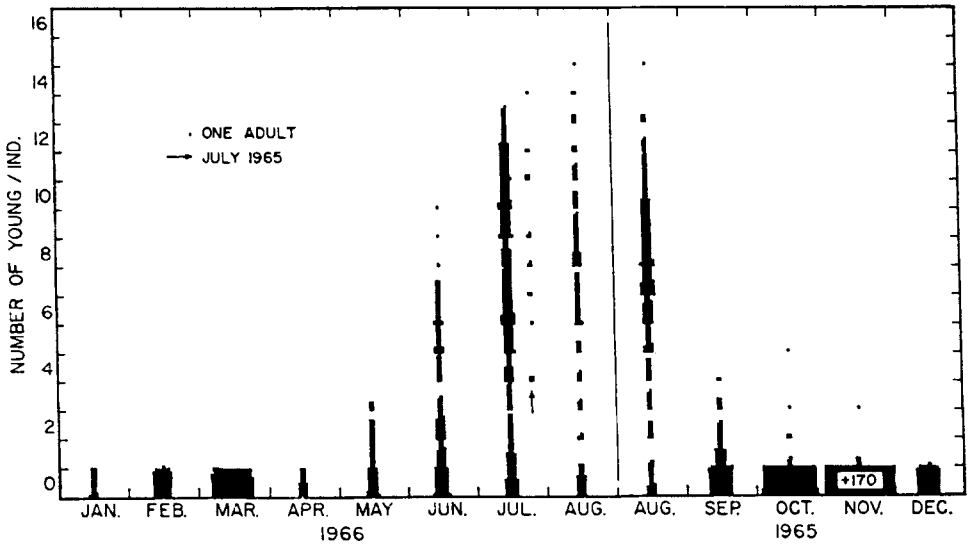

FIGURE 22-2 Annual reproductive cycle and reproductive potential of the benthic ostracod *Darwinula stevensoni* in Gull Lake, southwestern Michigan. (From McGregor, D. L.: The reproductive potential, life history and parasitism of the freshwater ostracod *Darwinula stevensoni* (Brady and Robertson). *In* Neale, J. W. (ed.): *The Taxonomy, Morphology and Ecology of Recent Ostracoda*, Edinburgh, Oliver & Boyd, 1969.)

Eggs of *Darwinula* are released into and develop within the carapace of the parent (McGregor, 1969). Juveniles produced by first and second reproductive season adults are released during the summer and early autumn and overwinter as juveniles. These young mature and reproduce the following summer. Surviving members of this age class overwinter as adults during the second winter and reproduce again the following summer. Most adults of the second reproductive year die following the release of young and are replaced by overwintering juveniles entering their first reproductive period. Thus, a nearly complete turnover of the adult portion of the population occurs each year. Similar population dynamics have been found with other lacustrine ostracod species (e.g., Strayer, 1988a).

Although much of the *Darwinula* population was parasitized by ectoparasitic rotifers, this did not appear to affect the reproductive potential. The population consequences of predation by other benthic invertebrates and bottom-feeding fish are unclear in this and other species. Ostracods alter their feeding and locomotion behaviors in response to chemical compounds released from fish predators and thereby reduce predation efficacy (Uiblein *et al.*, 1996).

Evaluations of densities of ostracod populations are few and range from an average of 57 m^{-2} in oligotrophic Great Slave Lake in the Canadian subarctic (Tressler, 1957) to about 10,000 m^{-2} of the *Darwinula* in mesotrophic Gull Lake. Much higher population densities of >50,000 m^{-2} are common in more productive lakes (e.g., Mallwitz, 1984), but densities decrease, and species diversity is reduced, in hypereutrophic lakes (e.g., Delorme, 1978). Given the common univoltine life cycle, low turnover rates, and long periods of nongrowing adulthood, productivity is likely moderate to low in comparison to other benthic invertebrates. Much greater study is needed.

M. Malacostracean Crustacea

Of the many species of the malacostracean crustaceans, four groups have distinct freshwater representatives of considerable interest and importance. All malacostraceans have a definite and fixed number of body segments.

1. Mysids–Opossum Shrimps

The mysids, or opossum shrimps, are morphologically similar to crayfish; they can attain a maximum length of about 3 cm. Their appendages, however, are elongated, contain abundant setae, and generally are greatly modified for active swimming. Their mode of feeding is by filtration of small zooplankton, phytoplankton, and particulate detritus via setose appendages, particularly two pairs of maxillipeds.

Aggregations of food particles are carried anteriorly to the mouth by water currents set up by movements of the appendages. Gut analyses of *Mysis relicta* showed that at night adults were voracious predators, feeding on *Daphnia*, other cladocerans, and the rotifer *Kellicottia* during their vertical migration (Lasenby and Langford, 1973). *Mysis* had a purported assimilation efficiency of about 85% when feeding on *Daphnia*, but this efficiency dropped to zero when the animal fed on debris from mosses growing in the lake. Several studies have shown that mysids are size-selective in their predation of zooplankton (Bowers and Grossnickle, 1978; Cooper and Goldman, 1980; Langeland, 1981; Murtaugh, 1981a,b). Large mysids prefer large-sized prey (*Daphnia* and *Epischura*) consistently, while small mysids select the smallest zooplankton available. The bivoltine life history of mysids in many lakes results in seasonal variations in population size structure (Murtaugh, 1983). These size changes influence the amount and quality of predation inflicted upon its zooplankton prey. Mysids will consume algae and detritus but are preferentially carnivores.

Freshwater mysids consume prey over a broader size range than most other invertebrate predators. When mysids are introduced into lake ecosystems as a food source for fish, however, size-selective predation pressure can lead to marked alterations in the zooplankton community (e.g., Richards *et al.*, 1975; Langeland, 1981; Cooper and Goldman, 1982; Nero and Sprules, 1986; Northcote, 1991). Selective predation on larger microcrustaceans by mysids can lead to the enhanced development of smaller species because of relaxed competition for food resources. Marked reductions or elimination of some large zooplankton species can thus result, contrary to intentions, in reductions of abundance and growth of some fishes.

The freshwater mysids are distinctly stenothermal, cold-water forms and in stratified lakes are restricted to hypolimnetic strata of <15°C. Reproduction occurs only during the colder periods of autumn, winter, and early spring. There are as many as 40 eggs per clutch, and the eggs are kept within the female brood pouch (marsupium). After hatching, juveniles are retained within the female for considerable periods of time (up to 3 months); hence, the name *opossum shrimps*.

A comparison of the life history, growth, and respiration of *Mysis relicta* in an arctic lake (Char Lake, Northwest Territories, Canada) and a temperate lake (Stony Lake) of southern Ontario is most instructive (Lasenby and Langford, 1972). In the arctic lake, *Mysis* takes 2 years to reach maturity, while those of the temperate lake mature in 1 year. *Mysis* from both lakes

exhibited a trimodal distribution of size classes. In the arctic lake, the population consisted of 8- to-9-month-old immature mysids, 20-month-old adult males and females, and 32-month-old females. In contrast, in the temperate lake, the cohorts consisted of 2-month-old immatures, 1-year-old females, and a few 2-year-old females. Respiration measurements showed no differences between *Mysis* from the two lakes over their environmental temperature range. Over a 2-yr-period from hatching to maturity, the energy used by the arctic population in growth and reproduction was approximately 68% of that used by the temperate mysids in growth and reproduction over a 1-yr period from hatching to maturity (Table 22-8). Of much interest is the finding that the amount of energy (200 cal) used by each mysid for growth and respiration in order to become a reproducing adult was about the same for the arctic population in 2 years as for the temperate population in 1 year. Similarly, size–frequency distributions of *Mysis relicta* of the Superior, Huron, and Ontario basins of the Great Lakes showed differences in life cycles in the three lakes (Carpenter *et al.*, 1974). In the colder Lake Superior, the generation time appeared to be 2 years, while in lakes Huron and Ontario the generations matured in 18 months. When lake productivity is relatively high, the life cycle of mysids takes from 1 to 2 years, but when productivity is low, it may last up to 4 years (Morgan, 1981). Similar variation has been found in Scandinavian lakes (e.g., Kjellberg *et al.*, 1991).

[a] Based on data of Lasenby and Langford (1972).
[b] Based on ingestion = growth + reproduction + respiration + egestion, when $0.85I = G + R$. An assimilation efficiency of 85% is likely an overestimate under natural conditions.

Lacking gills, mysids respire by exchange through a thin carapace. The high respiratory demands for oxygen and the requirement for cold temperatures restrict their distribution to oligotrophic lakes in which the oxygen content of the hypolimnion is not reduced appreciably.

Members of the two major genera, *Mysis* and *Neomysis*, all exhibit distinct, rapid diurnal migrations. During the day, the mysids are on the sediments or in the strata immediately overlying the sediments (Beeton, 1960; Herman, 1963). *Mysis relicta* ascends when surface light intensities decrease to about 3–0.2 μmol quanta m^{-2} s^{-1} (160–10 lux) and migrates into or below the metalimnion, in which temperatures are well below 15°C. This species rarely migrates into warmer surface waters. Descent occurred in populations of the Great Lakes when surface light intensities were increasing from 0.0002 to 0.002 μmol quanta m^{-2} s^{-1} (0.01–0.1 lux). Rates of the upward and downward migrations were similar at 0.5–0.8 m per minute over distances of at least 75 m and represent the fastest rates known among small invertebrates (see Table 16-16). *Mysis relicta* is very well adapted to the photic environment of these relatively clear, oligotrophic lakes in which light in the range of 490–540 nm penetrates the deepest. The peak photosensitivity of *Mysis* is to light at 515 nm, with a threshold response of at least 1.8×10^{-6} μmol quanta m^{-2} s^{-1} (0.00009 lux) (Beeton, 1959). This low irradiance is well within the light intensities at 100 m in lakes of low extinction coefficients even late in the daylight period. Moonlight can inhibit ascent of *Mysis* at night (Bowers and Grossnickle, 1978). Langsby and Langford (1972) indicate that the respiratory expenditure of energy for the daily migration is very small, about 3% of the total over a lifespan of 2 years.

Despite the avoidance of lighted zones, predation on mysids by planktivorous fish can be very high (e.g., Chicbu and Sibley, 1998). The mysid population structure can be appreciably decreased during abundant year classes of these fish species.

2. *Isopods—Sowbugs*

The isopods or sowbugs are largely marine or terrestrial; occasionally isopods become a significant part of the benthic community of lakes and streams. These

small organisms (<2 cm) are flattened dorsoventrally and are well adapted to living on substrata exposed to water movements, as in streams or the littoral of lakes. Their seven pairs of walking legs are well developed. The first is modified for grasping particles. Isopods are omnivorous feeders on both plant and animal matter (Marcus *et al.*, 1978; Willoughby and Marcus, 1979), and for one species (*Lirceus*) both fungi and especially bacteria were determined to be variable and usually minor sources of organic carbon (Findlay *et al.*, 1984, 1986). Isopods are generally not active predators on other benthic fauna.

Reproduction is more common during periods of warmer temperatures but otherwise is similar to that of the mysids. The number of eggs per female is fairly high (to several hundred), and both eggs and young are retained in the brood pouch for about a month. Relatively little is known about their life cycle and population dynamics; generation time is about 8–12 months but quite variable. In an English lake, gravid females of *Asellus* were present in late winter–early spring and again during late summer. These females gave rise to spring and autumn cohorts (Adcock, 1979). Large *Asellus* of the spring cohort reproduced in the autumn, and the remainder in the following spring. The bimodal population growth characteristics showed that growth was faster, and productivity greater, in the overwintering spring cohort than was the case among the smaller individuals of the autumn cohort. Annual production (P) of the population was 3.01 g m^{-2} yr^{-1} from a mean biomass ($\bar{B}$) of 0.76 g m^{-2}. The $P/\bar{B}$ ratio of 4.0 was double that found for the same species in colder Swedish lakes (Andersson, 1969). Reynoldson (1961) has shown a strong direct correlation between the distribution of *Asellus* and the concentrations of calcium and total dissolved matter. This isopod was usually absent in soft, unproductive waters (<5 mg Ca $liter^{-1}$; <70 mg $liter^{-1}$ of total dissolved matter). Isopods are common among the benthic invertebrates of saline inland waters and can tolerate high salinity (see, e.g., Eriksen, 1968; Ellis and Williams, 1970).

3. Decapods—Crayfish and Shrimps

The decapod Crustacea, of which the lobster is a familiar example, are largely marine. The few freshwater crayfish and shrimps are characterized by their approximately cylindrical body, heavily sclerotized translucent shell, and laterally compressed rostrum. Their 19 pairs of appendages include well-developed antennae and five pairs of large walking legs, the first three of which are clawed and the first greatly enlarged with a strong pincer claw used for crushing food. While the few shrimps are more or less continuous swimmers, the crayfish move slowly over the sediments and can move backward quickly by flexing the abdomen. Crayfish are omnivorous but herbivorous on algae and larger aquatic plants; occasionally, they are scavengers (Momot, 1967a, 1995; Jones and Momot, 1981). Some river species (*Orconectes*) acquire about two-thirds of their growth and production from allochthonous carbon sources and about a third from benthic invertebrates (Whitledge and Rabeni, 1997). Generally, however, crayfish can ingest large amounts of herbaceous and detrital materials while searching for and ingesting animal protein, but growth rates are best on a mixture of animal protein with other diets. Crayfish can become major competitors with fish for benthic invertebrate food sources. As sources of animal protein are exhausted, crayfish become facultative herbivores. Crayfish shift rapidly between herbivore/carnivore to scavenger/detritivore in response to food availability, a strategy that allows crayfish to maintain high production despite fluctuations in food resources.

Recently hatched juveniles of crayfish exploit lake littoral and stream riffle areas for food and shelter (Gowing and Momot, 1979; Momot 1984, 1995). Rapid growth of young of the year juveniles compensates somewhat for the high rates of predation, largely from fish. Commonly, larger juveniles migrate to deeper water as they develop and return to littoral and riffle areas as adults. As adults, much of the energy is diverted from growth to reproduction among several cohorts per year.

The lifespan of crayfish is generally fixed, although rapid growth and shorter lifespan occur among crayfish in lower latitudes (Momot, 1984). Longevity varies up to 16 years among the astacid crayfish, and commonly sexual maturity occurs during the third year and many become part of the breeding population during the fourth year. Crayfish occurring at higher latitudes and colder environments usually live longer and mature later (4–16 years). Development is more rapid among the cambarid crayfish and breeding can occur in the first year but mostly occurs in the second year (cf. Momot, 1984; Hobbs, 1991, for general details of life histories). Most species expend about 3–10 times more of ingested energy for maintenance than is expended for growth. Crayfish tend to have a high juvenile mortality with reduced adult mortality, and size-specific predation by fish on crayfish species of different sizes can lead to the eventual elimination of one of the species (DiDonato and Lodge, 1993).

Because crayfish are of some minor economic importance, considerable examination of disease and parasitic mortality has occurred (cf. Lodge and Hill, 1994; Momot, 1997). Although many bacterial and fungal disease organisms attack crayfish, many are nonlethal. Some fungal endemic and epidemic outbreaks have

[a] Data of Momot (1967a) with corrections for computational errors that appeared in the original publication (Momot, personal communication). West Lost Lake has an area of 1.5 ha and a maximum depth of 13.4 m (mean depth, 8.5 m).

eliminated species populations with nearly total mortality. Under natural conditions, however, evidence suggests that predation mortality, largely by fish, of the young stages is most severe.

The population dynamics and productivity of a common crayfish of temperate lakes have been studied in some detail (Momot, 1967a) and are exemplary for this group. In the crayfish population of a hardwater lake, the age structure exhibited a year-class fluctuation, and males had a higher growth rate than females. After the second year, mortality rates for females were greater than for males. Both sexes matured after the midsummer molting in the second year, then mated until early autumn. Eggs were laid the following spring. The average number of eggs carried by females in the spring, a measure of the reproductive capacity, was 58% of the eggs carried in the preceding fall. Within the maximum lifespan of 3 years of this species, *Orconectes virilis*, 2-year-old females produced most (92.5%) of the eggs. Young remained in shallow water after hatching in spring or early summer, but adult females molted and then migrated to deeper waters (3–7 m), where most remained all summer. Adult males also migrated, somewhat later than females, to deeper water. Population size appeared to be regulated by natural mortality at molting and cannibalism of both males and females on each other at high population densities. Predation by fish was not an important population control mechanism in this and other lakes (Momot, 1967b; Momot and Gowing, 1977a; Gowing and Momot, 1979) but can be particularly important in stream environments, as in pools, where refuge is difficult (e.g., Englund, 1999). A number of pollutants of lakes and streams, particularly those that reduce oxygen content or alter the substratum, cause changes in the population distribution or seasonal migrations (Hobbs and Hall, 1974). The successive year-class estimates of the crayfish biomass of this hardwater lake are given in Table 22-9. Seasonal changes in biomass were small because of compensatory changes among age groups. The estimated net production of the crayfish population was 12.7 g m^{-2} between the summer of 1962 and that of 1963.[1] These values are about intermediate within the range of biomass values found among crayfish populations studied in other waters (cf. Table 22-10).

In many lakes, crayfish can dominate the annual production of the benthic animal biomass, at times reaching 100–140 g m^{-2} and densities of 15 m^{-2} (Momot *et al.*, 1978). The rate of population growth, reproductive capacity, age at maturity, and lifespan are primarily density-dependent. Populations often regulate their development by control of brood stock size. Highest production rates are achieved by species with low mortality rates that coincide with the period of greatest growth (early age/size groups) (Momot, 1984). The annual production of crayfish populations ranges from one to several hundred g m^{-2} yr^{-1} in natural environments, but despite high biomass, low growth rates result in modest to low production (Table 22-10). In high-energy, high-nutrient environments or under artificial conditions where predation is minimized, much higher values can be obtained among species with short life cycles, high fecundity, and fast growth. Turnover

rates, estimated from the ratios of production to mean biomass, are mostly around 1, but vary from 0.3 to 7 (Table 22-10).

The feeding and predatory activities of crayfish can have complex, multitrophic-level effects on food webs of streams and lake littoral areas where dense populations develop. For example, dense crayfish can significantly reduce other benthic invertebrates that graze on periphyton, and the reduction of grazing pressure can result in marked increases in periphyton primary production (Charlebois and Lamberti, 1996). In other cases, large attached algae, such as *Cladophora*, can be fed upon directly by the crayfish, which results in altered habitat for benthic invertebrates (Creed, 1994). The grazing activities of crayfish on submersed macrophytes and seedling stages of emergent and floating-leaved macrophytes, either directly or by damaging the plants during predation on macrophyte-associated invertebrate prey, can suppress macrophyte abundance appreciably (Lodge and Lorman, 1987; Nyström and Strand, 1996; Nyström *et al.*, 1996). At very high densities of crayfish, some species of macrophytes can be eliminated. There is some circumstantial evidence for macrophyte species selectivity by crayfish.

4. Amphipoda—Scuds

The amphipods or scuds, also chiefly marine, are represented in fresh waters by a few important species. With the exception of *Monoporeia*,[2] discussed further on, the amphipods live on the sediments. Most species are small (5–20 mm), with a laterally compressed, many-segmented body. At the base of their seven pairs of thoracic legs many have gills that, like the lateral gills on some species, are exposed to currents of water

[2] Previously *Pontoporeia affinis* (see Bousfield, 1989). Also *Hyalella montezuma*, endemic to a spring in Arizona, is a multivoltine pelagic amphipod that migrates similarly to *Monopeoreia* but has modified swimming appendages that allow it to filter-feed pelagically (Blinn and Johnson, 1982; Dehdashii and Blinn, 1991). This species of *Hyalella* has higher production rates than most other amphipods and $P/\bar{B}$ ratios between 3.7 and 5.5.

created by the beating of pleopod appendages on the abdomen. Amphipods have high oxygen requirements and are usually restricted to waters of high dissolved oxygen concentrations (Franke, 1977). Amphipods are generally omnivorous substrate feeders that consume bacteria, algae, fungi, and animal and plant remains (Minckley and Cole, 1963; Marzolf, 1965a; Hargrave, 1970a; Bärlocher and Kendrick, 1975; Kostalos and Seymour, 1976; Moore, 1977). Several amphipods possess digestive enzymes (cellulases, glucanase, and chitinase) that are capable of degrading plant and fungal cell walls (Chamier and Willoughby, 1986). Some amphipods, particularly *Gammarus* spp., are likely much more predacious on living animals and cannibalistic than previously believed (cf. MacNeil *et al.*, 1997).

In a detailed study of the population dynamics of the amphipod *Hyalella azteca* in a eutrophic lake in southeastern Michigan, Cooper (1965) was able to estimate production rates and biomass turnover of the natural populations (Table 22-11). The amphipod populations showed positive intrinsic rates of increase at temperatures above 10°C, with maxima between 20 to 25°C. Reproduction resumed again when water temperatures reached 20°C in the spring. Estimates of mortality rates based on size and age structures of the population indicated that a size-specific mortality factor was operating on the large, reproductively mature amphipods during the summer months. It was established that the highly size-specific feeding behavior of the yellow perch accounted for most of the mortality in the adult amphipod size class. A similar situation was found in the benthic invertebrate populations of shallow experimental ponds (Hall *et al.*, 1970), in which the fish (*Lepomis*) preyed upon larger particles, selectively removing the larger adult stages of *Hyalella* and the terminal aquatic stages of many benthic insects. There is some evidence that heavy predation pressure by fish can lead to genetic selection for smaller-sized adult amphipods (Strong, 1972; Wellborn, 1994). *Gammarus* species are also dominant macroinvertebrate prey of many fish both as a seasonal food source and as a year-round staple, but fish also feed selectively on larger stages and sizes (MacNeil *et al.*, 1999). Cannibalism is common within *Gammarus* spp., and intraguild predation by closely related but competing amphipod species and other invertebrates (e.g., flatworms, stoneflies, and crayfish) is also common. The impact of nonpiscean predators, particularly macroinvertebrates, on *Gammarus* may frequently be stronger than that of fish, amphibians, and water birds.

In spite of the relatively low biomass levels of the *Hyalella* populations, rapid growth rates and short generation times (33 days to maturation at 25°C; 98 days at 15°C) of the animals result in a mean production rate of about 0.13 kg ha^{-1} day^{-1} (0.013 g m^{-2} day^{-1}), which is significant in comparison to other components of the benthic fauna. The observed turnover rate of about 3% day^{-1} is close to the maximum of 4% day^{-1}, estimated from experimental studies, that the amphipod population could maintain over the course of the summer at temperatures above 20°C with any degree of population stability. Similar production rates were found for amphipods of temperate streams (Welton, 1979; Waters and Hokenstrom, 1980). For example, productivity of *Gammarus pseudolimnaeus* in a river in Ontario was 2.94 g DM m^{-2} yr^{-1}, and with a relatively modest mean biomass (0.63 g DM m^{-2}) exhibited a moderately high turnover rate ($P/\bar{B}$ of 4.65) (Marchant and Hynes, 1981).

Extensive studies of *Hyalella azteca* in shallow (z_m = 5 m), riverine Marion Lake, British Columbia, demonstrated that the growth, density, and body size of this deposit feeder depended on the quantity of epipelic algae and sediment microflora (Hargrave, 1970a–c). The highest concentrations of sedimentary chlorophyll and microflora, as well as the lowest

[a] Compiled from data of Cooper (1965).

concentrations of nondigestible lignin-like organic material, occurred in the upper 2 cm of sediment, which was also the limit of the vertical distribution of the *Hyalella* in the sediments. Increased growth of *Hyalella* during June was independent of temperature in Marion Lake but was correlated closely with increased rates of epipelic primary productivity. Egg production began in May as growth rates increased, and the maximum density of *Hyalella* was reached in August.

Bacteria and algae, except for cyanobacteria, were assimilated with an efficiency of about 50%; cellulose and lignin-like compounds were not assimilated at all by *Hyalella* (Hargrave, 1970a). In contrast, the amphipod *Gammarus* could digest and metabolize about 30–40% of the cellulose ingested (Chamier, 1991). Overall, sediment and associated microflora were assimilated with a 6–15% efficiency. In the estimated energy budget for adult *Hyalella* at 15°C in Marion Lake, 49% of calories assimilated were respired, 36% were lost as soluble excretory products, and 15% were accumulated as growth, egg production, and molts (Table 22-12). The fecal pellets produced were colonized rapidly by heterotrophic microorganisms, and the dissolved organic compounds excreted by *Hyalella* significantly increased the rate of recolonization of the fecal material (Hargrave, 1970c). Epipelic algal production was stimulated somewhat by the feeding activities of the amphipod at natural densities, even though <10% of the daily microfloral production was required to supply the energy necessary for observed rates of amphipod growth, respiration, and egg production. The mechanism of stimulation of algal productivity on the sediments is unclear. It may emanate directly from inorganic and organic nutrients from the amphipod excretions, indirectly from increased metabolism of the heterotrophic microorganisms of the sediments, or both. Alternatively, the mechanical disruption of the oxidized microzone of the sediment–water interface may be instrumental in encouraging release of certain reduced, and more soluble, nutrients into the proximity of the epipelic algae. Although these compounds would not migrate far into overlying aerobic water before being oxidized and their solubility reduced, the algae directly at the interface could benefit from such disturbance.

TABLE 22-12 The Estimated Energy Budget of Adult Amphipod *Hyalella azteca* of 700 μg Dry Weight at 15°C Feeding on the Surface Sediment of Marion Lake, British Columbia[a]

Energy	*Calories amphipod*$^{-1}$ *hr*$^{-1}$	*% of total*
Ingestion	0.0525	50.7
Production (growth, molts, and egg production)	0.0012	1.2
Respiration	0.0039	3.8
Egestion	0.0430	41.5
Excretion (soluble organic matter)	0.0029	2.8

[a] From data of Hargrave (1971). The mean caloric value of adult *Hyalella* was 3850 cal g^{-1} ash-free dry weight; therefore, a 700-μg amphipod contains 2.7 calories.

Fungi colonizing autumn-shed tree leaves are the preferred food of many woodland stream-dwelling amphipods (Bärlocher and Kendrick, 1975; Kostalos and Seymour, 1976; Sutcliffe *et al.*, 1981). Less than 20% of the ingested leaf material was assimilated, whereas 75% or more of the fungi of decomposing leaves were assimilated in some cases. Assimilation efficiencies vary greatly with the amounts of microbiota attached to and within detrital leaf materials from different plant species. As a result, growth rates of the amphipods feeding on detritus from leaves, such as oaks that are much more resistant to decay, were slower than those feeding on microflora and detritus of more labile leaves, such as from elm or aquatic plants.

Monoporeia affinis is exceptional among the amphipods in that it migrates extensively into the pelagic zone at night. The behavior and habitat requirements of *Monoporeia* are similar to those of *Mysis*, discussed earlier. *Monoporeia* is restricted to cold, relatively oligotrophic waters and migrates only into the upper hypolimnion and metalimnion, in which temperatures are usually <15°C (Marzolf, 1965b; Wells, 1968). Only a portion of the predominantly benthic population migrates into the water. During daytime, *Monoporeia* is largely on and in the sediments or in the immediately overlying water.

Monoporeia is a burrowing amphipod and a deposit feeder on detritus and algae of surficial sediments (Johnson, 1988). This amphipod is the predominant macrobenthic invertebrate of the upper Laurentian Great Lakes. In Lake Michigan, *Monoporeia* showed no significant correlation with depth, particle size, or organic matter content of the sediments (Marzolf, 1965a). Distribution of *Monoporeia* was, however, positively correlated with the number of bacteria in the sediments, which was correlated directly with larger brood sizes, smaller sizes at maturity and hence more rapid growth rates, and higher production rates (Siegfried, 1985). In experiments with different-sized sediment particles, *Monoporeia* selected sediments with a particle size <0.05 mm. Such sediments contained more bacteria and organic matter than coarser sediments. Extensive recent experiments, however, indicate that juvenile *Monoporeia* acquire only small portions

(<10%) of their carbon and energy requirements from bacteria, and much of the energy is derived from lipids of algal origins that reach the sediments (Goedkoop and Johnson, 1994). Productivity can be significant. For example, *Monoporeia hoyi* of Lake Huron averaged 1.15 g DM m^{-2} yr^{-1}, and with a mean biomass of 0.82 g DM m^{-2} had a modest $P/\bar{B}$ ratio of 1.4 (Johnson, 1988).

Because bacteria and detrital algae of the sediments are the predominant food source of *Monoporeia*, and there is no evidence for planktonic feeding, the adaptive significance of the nocturnal vertical migration of a small portion of the population is unclear. Predation can be high at night, such as by the predatory leech *Erpobdella*, which migrates nocturnally in synchrony with *Monoporeia* and feeds vigorously on the amphipod (Blinn and Davies, 1990). Marzolf (1965b) suggests that the migrations have adaptive value in maintaining genetic continuity across otherwise isolated benthic populations. Migration encourages dispersal and, possibly, copulation with individuals from populations from other areas within the community.

N. Molluscs

The freshwater Mollusca are separable into two distinct groups, the univalve snails (Gastropoda) and the bivalve clams and mussels (Bivalvia or Pelecypoda). Molluscs are soft-bodied and unsegmented with a body organized into a muscular foot, a head region, a visceral mass, and a fleshy mantle that secretes a shell of proteinaceous and crystalline calcium carbonate materials.

1. Gastropoda—Snails

Among the gastropod snails, the univalve shells generally are spirally coiled, while those of the few freshwater limpets are conically shaped. The gastropod mollusc head is distinct, with a pair of contractile tentacles and a ventral mouth with a chitinous, sclerotized jaw and a chitinous internal radula containing numerous transverse teeth. The radula is extended from the mouth and moves back and forth rapidly, scraping and macerating food particles. Respiration in the snails occurs by gills in many aquatic forms (Prosobranchia) and by pulmonary cavities or "lungs" in the pulmonate snails. Some of the most common pulmonate snails, however, are able to stay submersed for a very long time or for their entire life cycle without filling their pulmonary cavities with air. Cutaneous respiration through the body membranes is common to all freshwater snails (Ghiretti, 1966). Even though the lung is retained in pulmonate freshwater snails, it is of secondary function and is used only when the oxygen concentration drops to low values. Then, the snails come to the surface to breathe air while moving or floating. Other pulmonates have water-filled lungs through which gaseous exchange occurs, much the same as it does with a gill. Locomotion in snails is by muscular movements of the ventral surface of the body, the "foot."

The gastropods are separated into two distinct groups (Brown, 1991; Hutchinson, 1993). The subclass Prosobranchia has a gill and a flexible or calcareous operculum that is pulled into the shell aperture to protect the snail. The Pulmonata have a modified portion of the mantle cavity as a lung and lack an operculum. The prosobranch snails are usually dioecious, but there are many variations and a few species are hermaphroditic. The pulmonates are all monoecious. Nearly all gastropods live in standing waters; only one genus (*Acochlidium*) inhabits running water.

Gastropods feed by rasping movements of the radula against a substratum; retractors pull food particles back into the mouth and grind them against the roof of the mouth. Most snails rely on algae, detrital particles, and bacteria of the periphyton on submersed substrata. Claims of food selectivity by snails are frequently made and, although most are poorly substantiated by essential rigorous evaluations of chemical cues and receptors, likely occurs among microhabitats containing different dominant algal sources (cf. Kolodziejczyk, 1984; Lodge, 1985, 1986; Brendelberger, 1997a). Direct effects of grazing on living macrophytes are probably of minor importance, although a few snails consume submersed macrophytes in sufficient quantities to alter growth of the higher plants (Sheldon, 1987; Brönmark, 1989). However, snails can have a significant indirect effect on macrophytes by reducing the detrimental effects of epiphytic microbiota that shade and compete for nutrients from the water. Gastropods possess cellulases that assist in degradation of algae and detrital particles from plant sources (Brendelberger, 1997b). Some prosobranch gastropods can trap food particles from their respiratory current in mucus, which is then ingested.

The efficiency of assimilation (expressed as the percentage of ingested organic carbon that is assimilated) of the stream snail *Potamopyrgus* varied from 3.7 to 9.0%, depending on the type of sediment used as food (Heywood and Edwards, 1962). The average was 4% for adult snails, in which about 7 μg of organic carbon was assimilated per snail per day. Diatoms, a primary food of this snail, are crushed between sand grains, which are ingested with the food, and macerated by the strongly cuticularized stomach walls (Frenzel, 1979). In contrast, the tropical snail *Pila*, feeding on the macrophyte *Ceratophyllum*, had much higher assimilation

rates, possibly >50% (Vivekanandan *et al.*, 1974).[3] Utilization efficiency of the plant food decreased as the supply of food increased. Assimilation efficiencies of diatoms, green algae, and cyanobacteria ingested by several gastropods varied between 30 and 73% and increased slightly with increased temperatures (Streit, 1975a,b; Brendelberger, 1997). Ingested cyanobacteria (*Anabaena*) were not assimilated by *Ancylus*; similarly, the green alga *Chlorella* was not assimilated by the tropical snail *Bulinus* (van Aardt and Wolmarans, 1981).

Pulmonate snails are moderately tolerant of desiccation and low levels of dissolved oxygen through the exchange of oxygen across membranes and anaerobic metabolism (McMahon, 1983). Because of the requirements for appreciable calcium for shell generation, most molluscs are found in waters with a dissolved calcium concentration >5 mg liter^{-1}. Above this concentration, little relationship exists between the chemical parameters and gastropod diversity, and habitat substratum and food availability free from major or frequent disturbance becomes important (Lodge *et al.*, 1987). Interspecific competition in natural communities of freshwater snails has not been demonstrated well and remains unclear; food and niche overlap is relatively narrow in highly heterogeneous and productive habitats (Brown, 1982, 1991; Strong *et al.*, 1984).

Predation on snails can markedly affect snail abundance. Certain fish adapted to crush snails, especially certain sunfish centrarchids, and crayfish are particularly effective in consuming snails that are not able to find cryptic refuge among aquatic vegetation (e.g., Vermeij and Covich, 1978; Brown and DeVries, 1985). Variations in thickness of snail shells, either within a species or between different species, can selectively alter predation vulnerability, as the energetic costs to predators increase as shell thickness increases (Stein *et al.*, 1984). Snails can crawl above the water line for several hours to avoid predation, particularly from crayfish (e.g., Alexander and Covich, 1991) or to deposit eggs on moist soil less vulnerable to invertebrate predation. Very little is known of the effects of parasites on snail dynamics and productivity. Clearly, parasites alter snail growth, and infections can often accelerate resource allocation to reproduction (Brown, 1991).

Many examples of population dynamics of snails exist in the literature, in part because of the relative ease of sampling and following changes in population structures over time. There is unquestionable correlative and experimental evidence to demonstrate that increased food resources commonly lead to enhanced growth, fecundity, and productivity and reduced generation times (e.g., Bruky, 1971; Brown, 1985; Moeller *et al.*, 1998). There is also evidence that restricted food availability can be commonly more important to limitation of somatic and reproductive growth than is predation (Osenberg, 1989; Jokela, 1996). A few examples illustrate the general sequences in the population development and differences in spatial and temporal separation.

The life cycle of freshwater snails in temperate regions, particularly the smaller species, tends to be annual (Harman, 1974). One reproductive period may occur in the spring or fall, or two or more reproductive periods may occur throughout the summer, during which the original cohort is replaced or supplemented. Some species overwinter as juveniles or adults and reach maturity the following spring or summer. Larger species tend to have life cycles that extend over 2, 3, or even 4 years. A few examples of the growth and population characteristics of some freshwater snails and clams illustrate these variations.

In the common pond snail *Physa gyrina* of the midtemperate region, copulation occurred in April (DeWitt, 1954). Egg masses adhere to substrata, and the number of eggs laid, about 100, varies with the size of the snail. After about a week of embryological development at 20–30°C, the young snails hatch and grow very rapidly, attaining most of their adult size of approximately 12 mm in about 8 weeks. Beyond this period, growth is very slow for the remainder of the 12- to 13-month lifespan. Growth in *Physa* is not determinate, but continues throughout the life of the individual.

Analyses of the population-size classes of the pulmonate snail *Lymnaea* that lives along the shore line in littoral regions of fresh waters showed a similar pattern, in which growth of overwintering individuals was linear but slow and then very rapid in the spring and early summer (McCraw, 1961, 1970). Little growth occurred before mid-April or after early July, when most of the production is shunted into reproductive development. Small individuals overwinter, and almost all of the spring and summer population is derived from snails ovipositing in later summer or autumn of the previous year. Although changes in population densities of *Lymnaea stagnalis* did not affect rates of food consumption, egg production under experimental conditions was significantly lower at high population densities (Mooij-Vogelaar *et al.*, 1973). Eisenberg (1966) found in both natural and experimental populations of *Lymnaea elodes* that both the quantity and quality of food limited the population densities. Adult fecundity

[3] The methods employed in measurements of changes in plant matter are questionable, and the reported values of loss most likely are overestimates.

TABLE 22-13 Life History Characteristics of Bivalve Mollusca[a]

Trait	*Unionacea*	*Sphaeriidae*	*Corbicula fluminae*	*Dreissena polymorpha*
Lifespan	<6–>100 yr	<1–5 yr	1–5 yr	4–7 yr
Age at maturity	6–12 yr	>0.2–<1.0 yr	0.25–0.75 yr	1–2 yr
Reproduction mode	Gonochoristic (two sexes)	Hermaphorditic	Hermaphroditic	Gonochoristic
Fecundity (young/average adult/breeding season)	200,000–17 × 10^6	1–135	35,000	30,000–40,000
Growth rate	Rapid prior to maturity	Slow relative to other bivalves	Rapid throughout life	Rapid throughout life
Turnover time	1800–2850 days	Commonly <80 days	73–91 days	50–870 days

[a] Extracted from McMahon (1991).

increased some 25-fold and numbers of young increased 4- to 9-fold when abundant food of high quality was available. Mortality among natural populations of young snails, caused especially by dipteran larvae, was very high (93–98%), but food limitations on fecundity were considered to be the primary mechanism affecting the final population structure.

Comparative life cycle patterns of 13 species of snails were evaluated in the littoral community of a small, shallow eutrophic lake in Connecticut (Jokinen, 1985). The timing and duration of oviposition and juvenile recruitment varied considerably (Fig. 22-3). Four species had a well-defined annual life cycle, three species had almost continual recruitment from spring through autumn, and six species had two or three well-defined reproductive periods per year. Closely related species tended to differ the most in their reproductive periods or duration of oviposition. The division of the reproductive season (April through November) in this lake likely reduced interspecific competition and allowed snails to avail themselves of differences in seasonal variations in food resources.

2. *Bivalvia—Clams and Mussels*

The body of clams or mussels is enclosed in two symmetrical, opposing shell valves and lacks a head, tentacles, eyes, jaws, and a radula. The body is enclosed by membranous tissue, the mantle, which secretes the shell valves. At the posterior end of the clam, the mantle has two openings, the siphons. The lower ciliated siphon draws water into the body cavity. Thus, flow aerates the gills and carries in food particles. Food particles are removed from the water by filtration through the gills and cilia. Water then exits from the upper siphon. The muscular foot can be extended from the valves in front of the clam, implanted in the sediment, and then contracted to draw the animal forward. The food of the clams consists primarily of particulate detritus, microzooplankters, and phytoplankton (see reviews of Fuller, 1974; McMahon, 1991). Clams utilize living phytoplankton; living and active diatoms apparently pass through the alimentary canal unaffected. Some bivalve species supplement filter feeding by consuming organic detritus and associated microbiota of sediments by pedal feeding. Burrowing activities disturb particles that are then directed by cilia toward the mantle cavity, where they are drawn in. As much as half or more of the total organic carbon assimilated may arise from pedal deposit feeding mechanisms (Burky, 1983).

Bivalve molluscs tend to be long-lived and expend appreciable energy in high reproductive rates (Table 22-13). Nonpredatory mortality is known to occur but is poorly understood. Predatory losses can be very high by some large invertebrates (e.g., crayfish) and many vertebrates, particularly by shore birds and ducks, by fish, especially molluscivorous fish such as the carp (*Cyprinus carpio*), channel catfish (*Ictalurus punctatus*), and drum (*Aplodinotus grunniens*), and many semiaquatic mammals (Fuller, 1974). Two exotic species (Asian clam *Corbicula fluminae* and the zebra mussel *Dreissena polymorpha*) introduced recently into North America have caused massive destruction of habitat, reduced biodiversity of other molluscs, and appreciable economic damage. As a result, there has been a spate of recent bivalve literature on the ecology and control of these two species (cf. separate reviews, e.g., McMahon, 1991; Nalepa and Schloesser, 1993).

Filtration rates generally decrease with increasing particle concentration and decreasing temperatures. For example, the filtration rates and ingestion rates of a filter-feeding mussel (*Dreissena*) remained constant when the mussel was fed diatoms (*Nitzschia*) until high food concentrations were reached, above which rates declined (Walz, 1978a). The growth rate increased with rising food concentrations until a plateau was reached at ca. 2 mg C liter^{-1} and achieved a maximum assimilation efficiency of 40% (Walz, 1978b). In both experimental and field studies, high concentrations of inorganic suspended sediment, particularly above 1 mg liter^{-1},

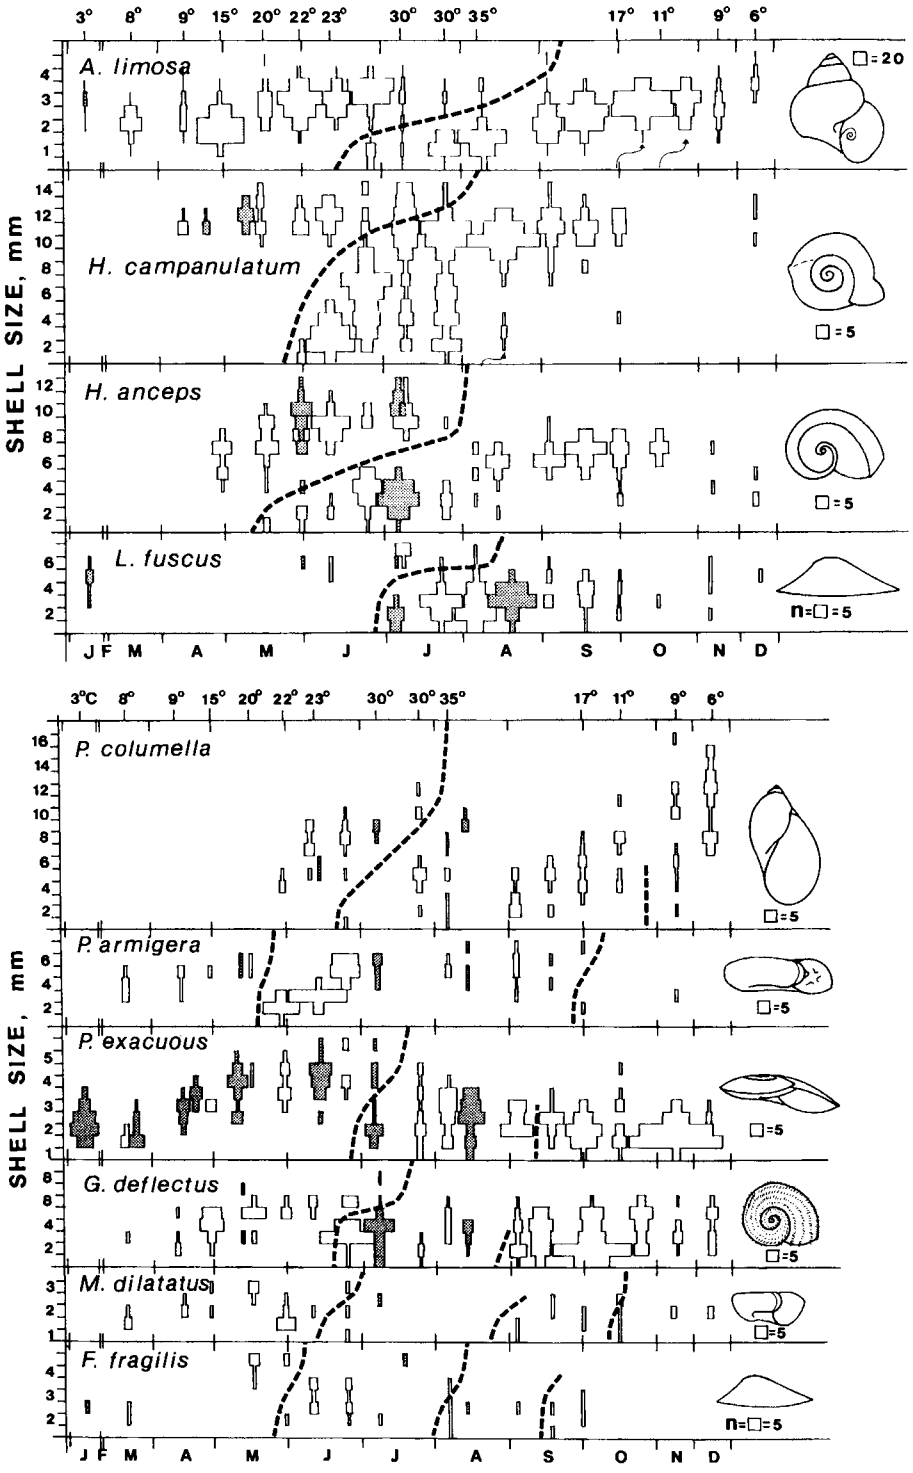

FIGURE 22-3 Life history patterns of snail populations with annual (*upper*) and with more than one (*lower*) generation produced per year in Roseland Lake, Connecticut, 1979–1980. Dashed lines separate generations. Shaded data bars from 1980 were added only when necessary to supplement 1979 data. (From Jokinen, 1985.)

severely reduce filtration rates, ingestion rates, and assimilation efficiencies (e.g., Madon *et al.*, 1998).

Bivalve molluscs can achieve high densities. For example, unionaceans of 10–30 individuals m^{-2} are not unusual. With filtering rates of ca. 300 ml g DM^{-1} h^{-1}, filtering rates in the range of 15–120 liters m^{-2} d^{-1} can remove appreciable amounts of seston and phytoplankton. The lower limit for filtration is about 0.5–1 μm, and as a result many bacteria are not removed and can be stimulated by nutrient cycling from the mortality of phytoplankton (Cotner *et al.*, 1995). Although these filtering rates are prodigious, normal turnover rates and replacement rates of phytoplankton can easily compensate for the losses from bivalve filtering. For example, seston was reduced by less than half of 1% of the total removed by planktivorous feeders in a eutrophic lake as a result of filtration by dense unionacean populations (Kasprzak, 1986). Seasonal energy budgets indicate that much >90% of energy consumption is expended in metabolic costs (Stoeckmann and Garton, 1997). In Lake Erie, with densities between 10,000 and 50,000 mussels m^{-2}, the zebra mussels potentially ingest between 10 and 50% of the summer primary production of phytoplankton.

When bivalve populations reach extreme densities, commonly exceeding 50,000 per m^{-2}, however, as in the case of *Corbicula* and *Dreissena*, many impacts on the river or lake ecosystem occur. For example, densities of unionid clams can decline markedly (90–100%) as a result of competition for food as well as by fouling as the mussels overgrow the larger clams (Ricciardi *et al.*, 1996; Strayer and Smith, 1996; Pace, 1998). Major reductions of phytoplankton densities and chlorophyll concentrations as well as microzooplankton (ciliates, rotifers, and copepod nauplii) can result. Some of the seston reductions from mussel filtration have been remarkable. For example, with the invasion of *Dreissena* into nutrient-enriched river and lake ecosystems, instantaneous phytoplankton biomass decreased by 85% or more in only a few years (e.g., Reeders *et al.*, 1989; Nicholls and Hopkins, 1993; Fahnenstiel *et al.*, 1995; Effler *et al.*, 1996; Caraco *et al.*, 1997). The increased transparency and transmittance of light can shift photosynthetic productivity from phytoplankton dominance in eutrophic environments to benthic algal proliferation (e.g., Lowe and Pillsbury, 1995). Not only is the nutrient turnover and accumulation in the sediment communities greater under such high mussel densities but the enhanced food availability at the sediments can increase other benthic macroinvertebrates as well, in spite of greater competition for habitat space (Stewart and Haynes, 1994). As the organic matter is removed and concentrated into pseudofeces that are directed toward the sediments, large quantities of organic nutrients are removed as well. Marked reductions of biogenic turbidity can result, which in turn reduce the rates of seston decomposition in the water column and rates of consumption of dissolved oxygen. No significant effects on the nutrients of the overlying water column are apparent from the intense benthic feeding and nutrient sequestering.

Freshwater bivalve molluscs are nearly all ovoviviparous and brood embryos through early development stages in the gill. Fully formed juveniles are released from the exhalant siphon in sphaeriids. The sperm of male clams is shed into the water and drawn into the female mantle cavity by the normal water current of the siphon system. Fertilized ova are incubated in portions of the gills, but mortality is very high from bacteria and protozoans. An important exception is the zebra mussel (*Dreissena polymorpha*), which releases both sperm and eggs externally, followed by external fertilization and development of a free-swimming veliger larval stage. The primary stimulus for reproduction appears to be the temperature above a critical level (McMahon, 1991).

In mussels of the Unionacea, the mature larvae hatch after periods of a few months to a year to temporarily free-living forms, called ***glochidia***, which have two chitinous valves bearing ventral hooks in some species. Glochidia development in temperate lakes occurred during the summer and was completed by autumn (Jokela *et al.*, 1991). Glochidia are stored in the gill blades until spring and are then discharged in large numbers, fall to the sediments, and die within a few days if they do not come into contact with a suitable fish host. If they come into contact with a fish, the glochidia attach to surface membranes or to the gills; some species of clams are specific to a particular species of fish. During this parasitic stage, which lasts from about 10–30 days, internal development occurs, although there is little change in size while the glochidia are encysted on the host fish. Juveniles then break encystment and fall to the sediments. Development ensues if substrata and food conditions are within tolerable limits. Large clams live 15 years or longer, while the smaller "fingernail clams" (Sphaeriidae) have a longevity of about a year or slightly longer. Mortality is exceedingly high in the egg, larval–glochidial, and juvenile stages. The adult populations and their distribution can be modified greatly by fish predation, certain birds, and a few mammals such as the muskrat (cf. Fuller, 1974).

Many freshwater bivalve molluscs can tolerate hypoxia or even anaerobic conditions, such as occurs in the hypolimnia of eutrophic lakes. Anaerobic molluscan metabolic pathways degrade glycogen and amino acids, particularly aspartate, to alanine and succinate,

and then to volatile fatty acids (de Zwann, 1983). Some 5–6 moles of ATP are produced per mole of glucose, which is considerably higher than glycolysis at 2 moles ATP per mole of glucose catabolized. Acidic anaerobic end products accumulate under these conditions, however, and these are neutralized by erosion of the calcareous shells. Many species of both sphaerid and unionacean molluscs can tolerate long periods (months or even years) of desiccation in air as water levels change.

Study of the distribution of five species of sphaeriid clams of the common genus *Pisidium* showed that four coexisted among the more heterogeneous substrata of Lunzer Untersee, Austria (Hadl, 1972). The profundal sediments were dominated by a single species. The littoral species were exposed to large seasonal fluctuations in temperature and were gravid in spring and released young in the summer, during which rapid growth occurred. The new generation overwintered to reproduce the following spring. In contrast the deepwater species, which were exposed to relatively constant temperatures throughout the year, exhibited no definite reproductive cycle. Embryos were found throughout the year in mature females. The larger clams (e.g., the *Anodonta*), migrate seasonally on the sediments to different water depths (Burla, 1971). Species of this genus were found to move up to the upper littoral in spring and early summer, where they remained until late in the year. In autumn and early winter, most returned to deeper water. These movements were not correlated with temperature but rather with photoperiod, which may be related more to food availability. Although growth is reduced and development times lengthened at the colder temperatures of deeper waters (e.g., Hanson *et al.*, 1988a; Holopainen and Jónasson, 1989), these effects could be ameliorated by migration seasonally to areas of warmer water and greater food abundance.

3. Mollusc Production Rates

Production rates and turnover values of freshwater molluscs have been studied frequently. Despite low instantaneous biomass, the rapid growth and short life cycles of pulmonate snails yield relatively high production rates and short turnover times (Table 22-14). In contrast, long life cycles result in low production rates in spite of large biomass. Production-to-biomass ratios tend to be low (0.5–2) in molluscs but under exceptionally productive conditions can exceed 5 (Table 22-14). For example, detailed population and growth analyses of the snail *Lymnaea catascopium* in a lake in Québec showed considerable variability in the littoral areas (Pinel-Alloul, 1978). The mean biomass of this

TABLE 22-14 Examples of Production, Mean Biomass, and Ratios of Production:Biomass (*P/B*) for Populations of Gastropod and Bivalve Molluscs

species varied between 3.4 and 7.4 g m^{-2}; production rates ranged between 6.6 and 17.8 g m^{-2} yr^{-1}. Turnover ratios ($P/\bar{B}$), however, were relatively constant at approximately 2 among the different populations and were found to be similar to those of other snail populations (e.g., Browne, 1978; Holopainen, 1979; Frenzel, 1980). Of two annual cohorts of a snail (*Potamopyrgus*) in a southcentral European lake, mean annual biomass was 8.8 g fresh weight m^{-2} (ca. 1.5 g AFDM m^{-2}), which resulted in production to mean biomass ratios of 2.5 and 3.7 for the first and second cohorts, respectively.

In a detailed study of the benthic fauna of a eutrophic, lowland lake in southern Norway, Ökland (1964) studied the mollusc fauna in particular (13 species of gastropod snails and 1 dominant bivalve clam, *Anodonta piscinalis*). The average quantitative data of Table 22-15 are included to point out a typical distribution with depth of the sediments. The greatest quantity of gastropods occurred in the zone of submersed plants at a depth of 1.5 m. The bivalve *Anodonta* was restricted to the littoral, and all mollusks were intolerant of the reduced oxygen concentrations of the deep strata during both summer and winter periods of stratification. The *Anodonta* constituted a trivial proportion of the numerical population density of the total benthic fauna (Table 22-15). Because of their large size and heavy shell, however, their mass can completely bias the quantitative biomass comparisons. Such data, while instructive in a comparative way, are meaningless for productivity estimates unless the rates of turnover of each of the components constituting the categories are known. The much smaller and more numerous nonmolluscan animals have a small instantaneous biomass but in general a higher turnover rate (shorter turnover time) (Table 22-14). The gastropod snails reached maximum numbers and biomass in the fall (October). The sphaeriid clams attained maximum biomass per area in early summer (June) prior to maximum densities in later summer (mid-August).

II. AQUATIC INSECTS

Insects are very abundant and diverse; most are terrestrial. Of those that are aquatic, nearly all are from fresh water. Some orders are entirely aquatic; others inhabit fresh waters only during certain life stages (cf. Hutchinson, 1981, 1993). Most insects are benthic, living on or burrowing into sediments or on macrophytic vegetation and plant detritus. The characteristics of the insects are well known, and no attempt will be made here to summarize the group differences except to point out salient features of the life cycles that are important to feeding and reproduction as related to benthic productivity and distribution.

The chitinous exoskeleton of arthropods necessitates molting for continued growth. The true bugs (Hemiptera), dragonflies (Odonata), stoneflies (Plecoptera), and mayflies (Ephemeroptera) are orders of winged insects that undergo gradual metamorphosis. In these orders, the young are referred to as *nymphs*; their wings develop as external pads, and the organisms increase in size with each molt. The other orders, including the flies (Diptera), caddisflies (Trichoptera), the alderflies and dobsonflies (Megaloptera), beetles (Coleoptera), a few species of moths (Lepidoptera), and spongeflies (Neuroptera) undergo

complete metamorphosis. In this development, the wing pads develop internally in early *larval* instars and then evert to the outside in the preadult instar *pupal* stage. In nearly all of the important aquatic insects, only the immature stages live in the water; the adults and, in some groups, the pupae are terrestrial (cf. Hutchinson, 1981, 1993). Only some of the beetles and hemipterans have adapted to the point where both the adults and immature stages can live in the water.

A. Life History Characteristics

A brief summary of the major life history characteristics follows. In generalizing interrelationships among so diverse a group as the insects, less attention is given to taxonomic characteristics and more attention is given to functional relations of feeding, reproduction, and productivity within aquatic systems.

1. Dragonflies and Damselflies

After fertilization, the eggs of dragonflies and damselflies (Odonata) are deposited into the water, onto substrata in or near the water, or into submersed parts of macrovegetation. Egg development, as in most invertebrates, is temperature dependent; nymphs hatch without diapause after about 2–5 weeks of egg development. Growth in the nymphal stages is quite variable, especially in relation to temperature and food supply. Within a range of about 6 weeks to 3 years, 9 to about 16 instar moltings occur. The mature nymphs often leave the water on some emergent substratum as aerial adults. Of the three primary patterns of life history, spring emergence is common, and univoltine and hemivoltine species usually emerge in summer. The odonate nymphs are almost entirely littoral in habitat, living among macrovegetation and littoral sediments and burrowing into surficial sediments. The nymphs have fairly high respiratory demands and oxygen requirements.

2. Mayflies

The mayflies (Ephemeroptera) are almost totally aquatic (Edmunds *et al.*, 1976; Hutchinson, 1993). The adult longevity is very brief (3–4 days), during which no feeding occurs. After mating in flight, fertilized eggs are laid in the water or on submersed objects; the time to hatching varies from a few days to many weeks. Parthenogenesis is widespread, as well as egg diapause. Growth is relatively rapid, from <1 mm in length at hatching to about 2 cm in length in the nymphal stages of many species. From 9 to over 50 instars of molting occur over an average life cycle of about one year. A few species live as nymphs for 2 years or longer.

All mayflies are restricted to waters of relatively high oxygen content but are widely distributed even in waters with moderate organic loading (Roback, 1974). Respiratory exchange occurs through the cuticle in early instars, but later instars possess respiratory gills and lamellae that induce respiratory currents. Some species can regulate the respiratory movements of gills in response to changing oxygen concentrations (Eriksen, 1963a). Mayfly nymphs are characteristic of shallow streams and littoral areas of lakes and are distributed widely. However, many species are restricted to specific substrata of macrophytes, sediments of waveswept or moving stream areas, or sediments of specific-sized particles (Eriksen, 1963b).

3. Stoneflies

The stoneflies (Plecoptera) are terrestrial as adults, but in the nymphal stages they are strictly aquatic, and most are restricted to flowing waters of relatively high oxygen concentrations. Fertile eggs, laid over or in the water, require 2–3 weeks for hatching in many species and several months among some larger forms. The nymphal instars, from 12 to over 33 moltings, occur in 1–3 years. Nymphs tend to be predominately herbivores and detritivores, and a few become carnivorous in later instars.

4. Hemiptera

The Hemiptera, or true bugs, are essentially terrestrial; a few are semi-aquatic and very few species have adapted to submersed conditions. Most hemipterans overwinter as adults in moist sediments or vegetation (cf. the detailed synthesis of Hutchinson, 1993). Eggs are laid on semi-aquatic substrata or in aquatic macrophytes and develop rapidly in 1–4 weeks. Nymphs also develop rapidly in 1–2 months, commonly with five instar stages, and generally have a 1-yr life cycle. Few hemipterans are truly aquatic, with cutaneous respiration; most are dependent on atmospheric oxygen for respiration. They inhabit substrata either near or above the water, possess adaptations for obtaining air while under water, or carry entrapped pockets of air with them (under hemelytra of the adult or on hydrofuge surfaces of the thorax) on underwater excursions. Several large families of these hemipterans are adapted to stride over the water surface without disrupting the surface tension (see p. 13).

5. Diptera

The most important group of the aquatic insects with complete morphogenesis includes the flies, midges, and mosquitoes (Diptera). The dipterans are commonly dominant components of benthic invertebrate communities in many standing and running waters, and the chironomid larvae are ubiquitous, as will be seen in some of the examples that follow. Much variability is

found in the morphology, reproductive biology, and respiration of dipteran larvae. Adults are essentially never aquatic, but most of their lives are spent as immature forms in fresh waters. The larval stage, with about three or four growth molts, extends from several weeks to at least 2 years in different species, and many overwinter in the larval stage. Most species have one generation per year, some have two per year, and a few of the species studied have a 2-yr life cycle (to 7 years in arctic ponds; Butler, 1982). Most larvae respire cutaneously or by means of "blood gills," which also function in ionic regulation. Fewer larvae rely on air and possess various adaptive structures to obtain air above the water or from the internal lacunae of aquatic angiosperms. Some chironomid larvae possess a type of hemoglobin in their blood that functions efficiently at low oxygen concentrations.

6. Caddisflies and Moths

The caddisflies or Trichoptera generally have a 1-yr cycle (Wiggins, 1977). Adults emerge in the warmer periods of the year, often from overlapping cohorts, from May to October. Eggs are dropped or placed on vegetation or laid under water on submersed substrata and develop in about 1–3 weeks. Many caddisfly larvae build beautifully intricate cases from substrate particles of sand, small stones, leaf fragments, and the like and are highly specific to types of substratum (cf. Cummins, 1964; Cummins and Lauff, 1969; Mackay and Wiggins, 1979; Wallace and Merritt, 1980). Some construct a net that traps microorganisms and detrital particles in flowing water. After 5–7 larval instars, pupation occurs under water within a cocoon. The pupal stage generally lasts only a few weeks, after which the pupa leaves the cocoon, moves to an aerial substratum, and emerges as an adult.

Few species of the moths (Lepidoptera) have aquatic larval stages; most aquatic moth species belong to the family *Pyralididae*. Many characteristics of the life history of the "aquatic caterpillars" are similar to those of the closely related caddisflies.

7. Spongeflies, Alderflies, and Dobsonflies

The spongeflies (Neuroptera) and alderflies and dobsonflies (Megaloptera) are closely related and often are grouped together under the Neuroptera. Both groups are primarily terrestrial for all of their life cycle. Of the few freshwater species, however, some megalopteran larvae are so large that they may represent a significant portion of the biomass of some benthic communities. Eggs generally are laid on aerial substrates overhanging the water. After a rapid development period (1–2 weeks), the larvae drop into the water and feed actively. The aquatic neuropterans (Sisyridae) are restricted to and parasitic on freshwater sponges and can have multiple generations annually. The megalopterans have numerous molting instars and most of their life cycle of 1–3 years is spent in the larval stage. The pupal stage occurs in soil out of water and lasts up to one month. The megalopteran larvae are vicious predators on other insects, and some can reach a size of several centimeters.

8. Aquatic Beetles

Such great diversity exists among the aquatic beetles (Coleoptera) that even broad generalization is difficult. Generally, the beetles adapted for larval and adult existence in water occur among the more phylogenetically primitive coleopteran groups. The life cycles of many (Gyrinidae, Haliplidae, Dytiscidae, and Hydrophilidae) are annual, with 3–8 larval instars. Eggs laid on or in macrophytes or sediments hatch in 1–3 weeks. Larval development is variable (1–8 months), and pupation takes place on some nearby terrestrial or aerial substratum. Overwintering generally occurs in the adult stage. Nearly all adult beetles are dependent on atmospheric oxygen and carry an air supply with them on the ventral side of their bodies or are variously adapted to obtain air from the surface or from aquatic angiosperms. Some larvae have tracheal gills to obtain oxygen directly from the water. Although beetles are generally omnivorous, their feeding habits often change markedly, with some exceptions, between the larval stages (herbivorous) to adults (omnivorous, largely detritus, insect eggs, algae).

B. Environmental Adaptations

Upon their invasion of inland waters, aquatic insects encountered the advantages of smaller fluctuations in temperature on a daily and an annual basis but also the disadvantages of decreased oxygen, greater stresses of osmoregulation, and restrictions to movements by the much more dense water medium. Aquatic insects adapted to life under water by essentially continuing to breathe air and developing special means for continuing respiration under water under greatly reduced oxygen availability (Eriksen *et al.*, 1992). Some insects make frequent excursions to the surface to acquire air directly or carry air stores under water in cavities (plastron) or among pubescent regions. Some immature insects extend tubular structures to the surface to acquire air. A few immature insects can penetrate into the aerenchymatous tissues of higher aquatic plants and remove oxygen.

Adaptations also include cutaneous exchange of dissolved oxygen and carbon dioxide by increased cuticular permeability, but this change requires osmoregulatory mechanisms to retain internal salt

concentrations in a hypertonic hemolymph against the surrounding dilute water of low ionic strength (Ward, 1992). Ions are commonly reabsorbed in the hindgut before urine and feces are eliminated. In saline lake environments, the opposite problem of the need to conserve water arises. Aquatic insects of saline waters commonly osmoregulate by drinking saline water and excreting rectal fluids that are very hypertonic to the hemolymph (Stobbart and Shaw, 1974).

A number of immature stages of aquatic insects, especially among the larvae, develop tracheal gills. Gill surface area is large and increases the gaseous exchanges between hemolymph and the surrounding water. As dissolved oxygen concentrations of the water are reduced, body or appendage movements increase to move water or move within water in order to reduce concentration gradients and enhance exchange.

Some *Chironomus* larvae excrete lactic acid produced in anaerobic metabolism and avoid oxygen debt as a result. At very low concentrations of dissolved oxygen (e.g., 0.5 mg O_2 liter^{-1}), for example, the total energy production of C. *anthracinus* was only 20% of the rate at saturation and more than one-third was used in anaerobic degradation of glycogen (Hamberger *et al.*, 1994). This rate corresponded to a daily loss of ca. 5% of the body reserves. Long-term oxygen deficiency, however, induces a further suppression of energy metabolism. This process can permit these larvae to remain in oxygen-deficient water for several months. Thus, diurnal and especially seasonal changes in lactate and glycogen content of *Chaoborus* are seen in response to migrations diurnally from and into oxygen-deficient waters and as hypolimnetic waters become oxygen-reduced or anoxic seasonally (Franke, 1987a). Hemoglobin does occur in a few chironomids and hemipterans but is used more in buoyancy control than as an oxygen transport pigment during hypoxia.

Clearly, environmental temperature is critical to the ecology and evolution of aquatic insects as in all other organisms and has received exceptionally thorough study (cf. reviews of Ward and Stanford, 1982; Sweeney, 1984; Ward, 1992). Seasonal and diurnal temperature fluctuations that characterize most natural standing and running waters have been summarized in detail (cf. Chap. 6). The seasonal rate of temperature change in streams is usually greater than in lakes, although the annual temperature range is usually less than in lakes. Diurnal changes in temperature in streams are often greater than in the pelagic portions of lakes, although littoral thermal excursions on a diurnal basis can be broad. Thermal stratification is a dominant feature of most lakes of any appreciable depth (e.g., >5–7 m) but is essentially absent in natural streams and rivers.

Among aquatic habitats of temperate and high latitudes, the period of time above the developmental threshold of the organisms under evaluation is the *growing season*. Within this growing season, there may be a higher temperature threshold, the maturation threshold, which must be exceeded for a specified time period to complete larval development. The absolute values and duration of the minimum temperatures to which aquatic insects are exposed are important, but aquatic insects respond in development and maturation to the summation of thermal units ("degree days," see Baskerville and Emin, 1969). Entire orders and other major taxa of aquatic insects evolved in cool habitats, and members of these groups now inhabiting warmer waters are likely later derivatives of cool-adapted ancestral lines.

Nearly all facets of the life history and the distribution of aquatic insects are influenced by temperature. Temperature is a dominant factor influencing the distribution, diversity, and abundance patterns over elevational gradients and downstream along watercourses. Egg development time is inversely proportional (hyperbolic) to temperature, although hatching success is often optimal at temperatures lower than those temperatures that yield most rapid egg development. Fecundity in aquatic insects is directly proportional to adult female size. Diapause dormancy is common as a response, particularly among stream insects, to avoid warm periods, quite in opposition to what is commonly the case among terrestrial insects.

Development time among aquatic insects is variable in response to temperature. Some insects have a distinct temperature threshold for growth and for maturation, whereas others respond to thermal summation. Many species of aquatic insects of both lakes and streams grow and remain active at temperature near 0°C. Fluctuating temperatures, such as is commonly experienced in small streams and littoral areas, often stimulate growth rates appreciably over those rates found under constant temperature conditions. The large thermal differences observed among habitats at different latitudes or altitudes are not reflected as much in differences in growth rates but rather in differences in ***voltinism,*** the number of generations per year. The number of generations generally increases with higher thermal summation on an annual basis. The number of generations per year among aquatic insects is commonly greater in tropical waters of higher temperatures than in temperate regions (Talling and Lemoalle, 1998). Optimal thermal régimes likely exist for individual species, and deviations into warmer (southern in Northern Hemisphere) or cooler (northern) waters adversely affect fitness by decreasing body size and fecundity (Vannote and Sweeney, 1980).

The substrata of streams and the sediments of lake ecosystems have been discussed at some length in other chapters. A large diversity exists of substrata types,

composition (inorganic to organic, ranging from gyttja to large woody tree debris), and especially particle sizes, from silt to boulders. Certainly this range of substrata types results in large differences in stability, particularly in relation to water movements, food organisms associated with the substrata, habitat refuges from predation, and many other factors. However, the velocity and characteristics of water movement in the littoral regions of lakes and in streams are dominant regulatory mechanisms of the development, feeding, growth, and reproductive capacities of aquatic insects.

As we have seen earlier (Chaps. 7 and 18), water movements and currents are steeply attenuated within aquatic vegetation of littoral areas of lakes and within beds of aquatic plants of rivers. However, where current flows are appreciable, there is a tendency for the morphology of aquatic insects associated with substrata to be dorsoventrally flattened, with a smooth dorsum. Although this morphology and behavior may appear to be an adaptation to reduce drag within the boundary layer, a convex surface would generate lift (Statzner and Holm, 1989; Vogel, 1994). Nevertheless, the habitat is clearly in the lower boundary layer of decreased drag. Clinging adaptations (suckers, hooks, spines, glands with adhesives, or "silk") allow exploitation of this habitat. In general, however, insects have developed behavioral patterns to avoid current.

C. Trophic Mechanisms and Food Types

The great diversity of food ingested by the aquatic insects and their various feeding mechanisms can be organized within a functional framework combining feeding mechanisms with the particle size of the dominant food utilized (Table 22-16). Distinctions can be made between herbivory, defined as the ingestion of

TABLE 22-16 A General Categorization of Trophic Mechanisms and Food Types of Aquatic Insects[a]

General category based on feeding mechanism	*General particle size range of food (μm)*	*Subdivision based on feeding mechanisms*	*Subdivision based on dominant food*	*Aquatic insect taxa containing predominant examples*
Shredders	$>10^3$	Chewers and miners of live macrophytes	Herbivores: living vascular plant tissue	Trichoptera (Phryganeidae, Leptoceridae) Lepidoptera Coleoptera (Chrysomelidae) Diptera (Chironomidae, Ephydridae)

living vascular plant tissue or algae; carnivory, the ingestion of living animal tissue; and detritivory, the intake of nonliving particulate organic matter and the microorganisms associated with it (Cummins, 1973; Hutchinson, 1993). The sources of this organic matter originate from (a) sedimenting phytoplankton, (b) benthic aquatic macrophytes, (c) attached microbial communities, and (d) terrestrial arboreal and wetland vegetation and animal matter, such as ants and other insects, that falls, is blown, or is washed into the water. The organic matter in any of these categories can be ingested either in particulate form (by swallowing, biting, or chewing) or in dissolved form (by piercing or sucking). Although the association of aquatic insects with a particular substratum usually is related directly to feeding on that substratum or on the associated microflora, this is not always the case. For example, the insect may use aquatic angiosperms as a source of air or as a site for reproduction or protection from predation. However, the relationship between insects and certain substrates (e.g., angiosperms) is often highly specialized and even species-specific (cf. the compilations of McGaha, 1952, and especially of Gaevskaia, 1966). Other insect groups, especially large ones such as the dipteran Chironomidae, show great diversity in feeding mechanisms and substrata ingested (Table 22-16). Most aquatic insects tend to be nonselective in their food habits, but clearly the abundance, biomass, and diversity of invertebrates is greatest among submersed macrophyte habitats (e.g., Dvořák, 1987).

Chemical communication is likely common among freshwater benthic animals (Dodson *et al.*, 1994). Prey species use chemical signals to modify their morphological development, life history strategies, feeding, and predator avoidance behavior. Such chemical signals can be used in dark or turbid environments, likely at the species level of distinction, by animals that do not have image-forming eyes.

Classification of the functional feeding groups among invertebrates, as has been done in Table 22-16 for aquatic insects, describes the morphological and behavioral capacities of these organisms to consume available food resources (see particularly the reviews of Cummins, 1973; Anderson *et al.*, 1978; Anderson and Sedell, 1979; Wallace and Merritt, 1980; Hutchinson, 1993; Wallace and Webster, 1996). Facultative-feeding invertebrates ingest a wider array of substrates (have a wider niche breadth) and inhabit a greater diversity of stream and lake habitats than more specialized feeders (Cummins and Klug, 1979).

The ingestion of food bears little relation to rates of assimilation. In streams and many shallow lakes and reservoirs, much of the organic matter consumed by benthic invertebrates and other feeders is in the form of dead particulate organic matter from higher plants. This particulate detritus contains a large amount of lignins and celluloses from plant structural tissues in various stages of slow decomposition. The rate of decomposition and abundance of associated decomposing microflora are related to the chemical composition and restricted accessibility to microbial enzymes and the general insolubility of the structural organic compounds.

Assimilation rates may not differ with variations in the caloric content of food material. For example, fortuitous ingestion of inorganic sediment by fine-particle detritivores obviously has low nutritive value, but coatings of organic compounds and attached microflora may be of considerable value. Alternatively, small inorganic particles may aid in digestion by means of mechanical disruption of ingested food cells within the gut. Little is understood about the digestive capabilities or efficiencies of food utilization by aquatic insects (see reviews of Cummins, 1973; Anderson *et al.*, 1978; Cummins and Klug, 1979; Benke and Wallace, 1980; Lamberti and Moore, 1984). Assimilation efficiencies by benthic consumers of plant and detrital particles are nearly always <50%, and most are within the range of 5–30%. Assimilation efficiencies are much lower (ca. 10%) for fine detritus and vascular plant detritus but increases to ca. 30% for algae. Large quantities of viable algae and other microorganisms can be found in gut contents and feces, which suggests incomplete digestion.

Dead plant material entering aquatic ecosystems is rapidly colonized by microbes, and degradation is dominated particularly by aquatic hyphomycetes and other microorganisms (Chaps. 18 and 21). Microbial catalysis of indigestible plant substances into digestible subunits by microbial enzymes and the addition of relatively easily digestible microbial biomass are clearly an important coupling between these recalcitrant organic materials and biotic utilization (Bärlocher, 1985). Different species of invertebrates vary in their abilities to utilize the microbial production and their biomass.

Much of the material ingested by litter and deposit-feeding invertebrates probably is indigestible and must be degraded by the enzymatic activity of symbiotic microflora and fauna of the gut. A number of carbohydrases have been found in the digestive tracts of several species of Trichoptera, the carnivorous amphipod *Gammarus*, and two species of sediment-feeding dipteran *Chironomus* (Bjarnov, 1972). All species degraded mono- and disaccharides, and species differences were found only in polysaccharide degradation. Cellulose was found to be degraded only by the amphipod, and chitinase activity was found only in carnivorous species and in one detritivorous caddisfly. Most aquatic insects have little enzymatic activity toward cellulose, however. Those species possessing digestive cellulase can live in a wide range of habitats because they can utilize a greater array of detritus and algal types than can organisms lacking this physiological adaptation. A number of dipteran and trichopteran larvae have high proteolytic activity for efficient digestion of bacteria and metazoans (e.g., Martin *et al.*, 1981a,b). Despite consumption of detritus laden with microbes, microbial biomass is usually <10% of the total detrital mass (see Table 21-3). In spite of relatively high assimilation efficiencies of microbes (e.g., Martin and Kukor, 1984), acquired organic carbon and nitrogen from these sources are often inadequate (usually <25%) to support the growth and reproduction of the insects. Appreciable sources must come from the particulate organic matter itself (e.g., 73–89% attributable to leaf organic matter in the growth of the dipteran larvae *Tipula*; Lawson *et al.*, 1984).

Macroinvertebrates utilize various feeding modes to compensate for the differing dietary sufficiency of ingested substrates (cf. reviews of Anderson and Cummins, 1979; Anderson and Sedell, 1979; Cummins and Klug, 1979). Shredders and some collectors feed preferentially on particulate organic detritus colonized by microorganisms and utilize the associated microorganisms and partially hydrolyzed substrates. Collectors, scrapers, and facultative shredders may increase consumption of low-quality food (e.g., resistant detrital plant parts) to compensate for the lower nutritional

benefit. In general, gut retention time increases inversely with feeding rate. Feeding and ingestion rates are commonly slower with longer gut retention times as the quality of food declines.

A number of immature freshwater insects that consume relatively resistant plant materials and particulate organic detritus may harbor microbial symbionts in their alimentary tracts (Cummins and Klug, 1979). These animals are analogous to ruminant mammals, which ingest food of high C:N ratios (>17) and absorb through their gut wall materials with lower C:N ratios (<17) produced by intestinal microbiota that degrade polymers and supply essential amino acids.

Aquatic insect predators feed heavily upon other benthic prey. Most studies indicate that apparent prey selectivity is likely more a function of prey vulnerability to capture than of selection by the predator (Peckarsky, 1984b). Assimilation efficiencies of ingested animal prey and bacteria by aquatic insects are generally higher than those for plant and detrital materials, but data are few (Martin and Kukor, 1984). Aquatic insects have evolved a variety of defensive mechanisms and escape tactics by which predation is avoided. Primary defenses, such as morphological and chemical defenses, operate regardless of the presence of a predator (Edmunds, 1974). Primary defenses among aquatic insects include

1. Living in habitat refuges that decrease the chances of the prey encountering predators. Such refuges may be physical (crevices or holes) or temporal (e.g., limiting feeding activity and movements from physical refuges to periods of darkness).
2. Crypsis is any adaptation that causes an animal to be less conspicuous (e.g., visually, or chemically) to the predators. Morphological and behavioral modifications, color similarity to the habitat, and similar methods reduce susceptibility to predation.
3. Some prey contain chemical compounds that are apparently distasteful to predators and induce avoidance.

Secondary defense involves active predator avoidance behavior after the prey has detected the presence of the predator or the initiation of an attack by the predator. Prey can withdraw and escape by fleeing movements upon encountering a predator. Dispersal-related downstream drifting movements of aquatic insects, discussed later, is most active at night when visual predation by fish is reduced. Feigning death or attack postures can deter predators.

Despite the general opportunistic feeding behavior and lack of selectivity of food items, many benthic animals do not eat the same food throughout their development. Size is important at both the upper end of a range where whole particles cannot be ingested ("gape size limitation") and at the lower end of a range where the size of food particle ingested is too small to compensate for the energy expended in acquisition. For example, predatory benthic invertebrates often begin as herbivores or detritivores but shift to carnivores as they mature, and diet can shift with season, locality, and sex (Malmqvist *et al.*, 1991; Giller and Sangpradub, 1993).

Most particulate organic matter that enters lakes and streams from allochthonous and autochthonous sources is not eaten by animals and is either eventually degraded to CO_2 by microflora attached to the particles or stored for various periods of time in the sediments. The feeding and shredding activities of benthic invertebrates, however, can accelerate reduction of particle size and increase surface areas exposed to the microbiota and thereby stimulate microbial degradation rates.

The biomass of aquatic insects is relatively constant when they are supplied with consistent and abundant food supplies of similar caloric and protein content throughout the year (Cummins, 1973; Anderson and Cummins, 1979). The rate of biomass turnover in insects is controlled primarily by temperature and is mediated mainly by the positive relations among temperature, feeding rate, and respiration. The ratios of feeding and respiration to growth are relatively constant. In general, streams exhibit less seasonal fluctuation in temperature than do the littoral regions of lakes. Much of the feeding and growth of aquatic insects living in streams occurs during the fall and winter, even in the temperate zones. Assimilation efficiencies seem to be fairly constant over the broad range of foods consumed by insects. There is a suggestion (Welch, 1968), based on limited and variable data, that this efficiency[4] is somewhat higher in carnivores than in herbivores and detritivores. However, the net or tissue growth efficiencies of carnivores[5] tend to be lower than those of herbivores and detritivores.

III. LITTORAL AND PROFUNDAL BENTHIC COMMUNITIES OF LAKES

Some of the important relationships among the benthic macroinvertebrates can be seen by a comparison of the benthic fauna of the littoral with that of the

[4] Assimilation efficiency is defined here as assimilation/ingestion, or growth plus respiration/ingestion (see Chap. 8).
[5] Defined as growth/assimilation.

profundal. As lakes become more productive and the hypolimnetic water strata undergo periods of oxygen reduction and increases in the metabolic products of microbial decomposition, the number of animals adapted to these conditions decreases precipitously. Those adapted to these conditions are exposed to relatively homogeneous conditions of temperature and substratum throughout the year. Additionally, both competitive pressures for available resources and predation are reduced considerably. Therefore, a commonly observed community structure consists of a rich fauna with high oxygen demands in the littoral zone above the metalimnion. Substratum heterogeneity is much greater in the littoral, and species diversity and competitive interactions are more complex. By contrast, the profundal zone is more homogeneous and becomes more so as lakes become more productive and species diversity decreases correspondingly (cf. Jónasson, 1969, 1978, 1984).

The production of phytoplankton and macrophytes is a major determinant of the subsequent conditions of food supply, oxygen, ionic composition, pH, and numerous other factors that delimit the range and competitive abilities of benthic fauna (cf. general reviews of Macan, 1961; Brinkhurst, 1974; Jónasson, 1978; Ward, 1992; Hutchinson, 1993). The effects are seen not only in the qualitative distribution but also in the quantitative aspects. Two maxima of abundance are typically observed with depth, one in the littoral zone and another in the profundal. Examples of this distribution are very numerous. The data presented in Table 22-17 show these two maxima both in numbers and biomass, as well as the reduction in species diversity in the progression from the littoral to the profundal zones. The same type of distribution is illustrated by the example from Lake Washington (Fig. 22-4). If lakes become extremely enriched, to the point that the population densities of the phytoplankton and epiphytes become so great that they shade out the submersed macrovegetation, then the habitat diversity of the littoral decreases (cf. Fig. 26-1). Correspondingly, the diversity and quantity of littoral macroinvertebrates decrease, and often a maximum in animal biomass can be observed only in the lower profundal zone. With further increases in eutrophication and lengthening of the period of hypolimnetic oxygen reduction and associated chemical changes, the rates of respiratory activity of the adapted benthic animals are reduced. Rates of growth and survival also decline, and some insect larvae increase their life cycles from 1 to 2 years. As hypolimnetic strata of hypereutrophic waters undergo extreme eutrophicational or pollutional loading of organic matter, essentially all of the aquatic insects may be eliminated. Practically the only group of benthic fauna adapted to

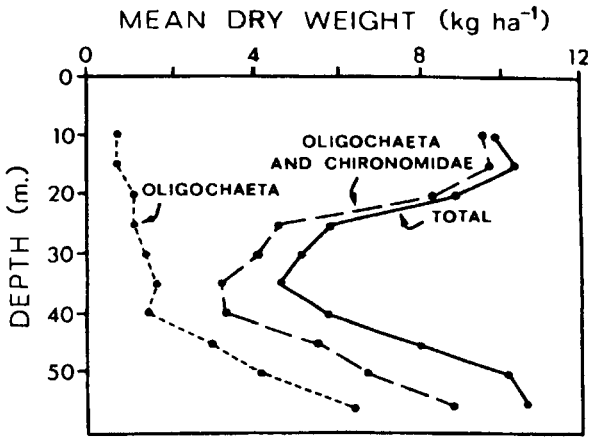

FIGURE 22-4 Vertical distribution of the mean biomass of oligochaetes, of oligochaetes and chironomids, and of the total benthic macroinvertebrates of Lake Washington, Washington. (Redrawn after Thut, 1969.)

conditions of extremely high organic loading is the oligochaete annelids. Variations in the vertical distribution of biomass of benthic invertebrates are discussed in some detail by Deevey (1941), Brinkhurst (1974), and Jónasson and Lindegaard (1979).

The changes in species composition, especially among the dipteran larvae, and the quantity of benthic fauna in the profundal zone of lakes as they become more eutrophic have been subjects of intensive study since shortly after the turn of the century. Prompted by the perceptive work of Thienemann and other German workers, especially Lenz and Lundbeck, an array of typological schemes of lake classifications was developed on the basis of indicator species of dominant benthic fauna. Particular emphasis was given to the distribution of species within the ubiquitous dipteran family of midges (Chironomidae) in relation to the oxygen content of the hypolimnion. Much of the early work on the classification of lakes in relation to the Chironomidae is reviewed in the book by Thienemann (1954; see also the critical discussion by Deevey, 1941; Brinkhurst, 1974). Although these analyses did much to stimulate study of the benthic fauna, such classification systems are of limited value since they do not consider fully the complex interactions of morphometry, the chemical differences among sediments and water, the biotic interactions such as predation, and an array of other factors.

As lakes become more eutrophic, shifts occur in percentage composition of the two dominant groups of benthic animals in the profundal zone of lakes, the Chironomidae and the oligochaetes. The few examples given in Table 22-18, which could be expanded greatly, simply show the general reduction in the number of

TABLE 22-17 Average Numerical Density (no. m^{-2}) and Dry Weight Biomass (g m^{-2})[a] of the Principal Groups of Benthic Invertebrates at Different Depths of Eutrophic Lake Borrevann, Southern Norway[b]

chironomids and other benthic animals and a concomitant increase in oligochaete worms among more productive lakes. The transition can occur during natural development of a particular lake and can be accelerated greatly by the eutrophicational activities of humans, as was shown conspicuously in the case of Lake Erie (Table 22-18) in a period of <30 years (see the general review of this subject by Wiederholm, 1980).

A. Benthic Fauna of Lake Esrom

Certainly one of the foremost analyses of the benthic fauna can be found in the work of Jónasson (1972, 1978, 1984, 1990; Dall *et al.*, 1984). Environmental factors, especially the phytoplanktonic productivity of the moderately large (17.3 km^2) and deep (22 m), eutrophic Lake Esrom, a dimictic lake in Denmark, were studied in relation to the food, growth, life cycles, and population dynamics of three profundal detritivores and two carnivores. Because of the completeness of these studies, it is instructive to discuss them in some detail.

The dipteran detritivore *Chironomus anthracinus* was found to feed at the sediment surface. Its growth was limited to two very short periods, one in spring during the phytoplanktonic maximum when the hypolimnion was oxygen-rich, and the other after autumnal circulation when oxygen was available again but food production was declining. Growth continued during winter as long as the lake was ice free but essentially ceased under ice cover. During the summer, growth stopped when the oxygen concentrations of the hypolimnion were reduced slightly below 1 mg O_2 $liter^{-1}$. Biomass, protein content, and fat content of larvae of this species were positively correlated seasonally with the influx of oxygen and phytoplanktonic detritus to the hypolimnion.

Continuous quantitative data extending over two decades showed that deep (20-m) populations of *C. anthracinus* exhibited a 2-yr life cycle. The 2-yr cycle is maintained by alternate years of high initial population densities in which a large percentage of the population does not emerge as adults in the first year. These larvae prevent a new generation from becoming established because their feeding inflicts severe mortality on new eggs laid on the sediments. As a result, at any given time the population derives from a single generation of eggs. In alternate years, when the density of larvae declines below 2000 m^{-2} after the first year's emergence of adults, a new generation is able to establish itself because now the larvae are not able to feed over the whole of the sediment surface and most eggs survive. During these years of recruitment of a new generation, the larval population is a mixture of two generations (Fig. 22-5).

The larvae of this species in the metalimnetic sediments (11 and 14 m) grew longer because of greater oxygen concentrations, and each individual attained greater biomass. There was more exposure to fish predation in the shallower metalimnetic sediments, however, and population numbers were lower than in the profundal zone. Those at the 11-m depth had a 1-yr life cycle; the transitional zone between 1- and 2-yr life cycles was between 14- and 17-m sediments. In sediments at the latter depth, recruitment of larvae every year was not successful (Fig. 22-5). At 14 m, the

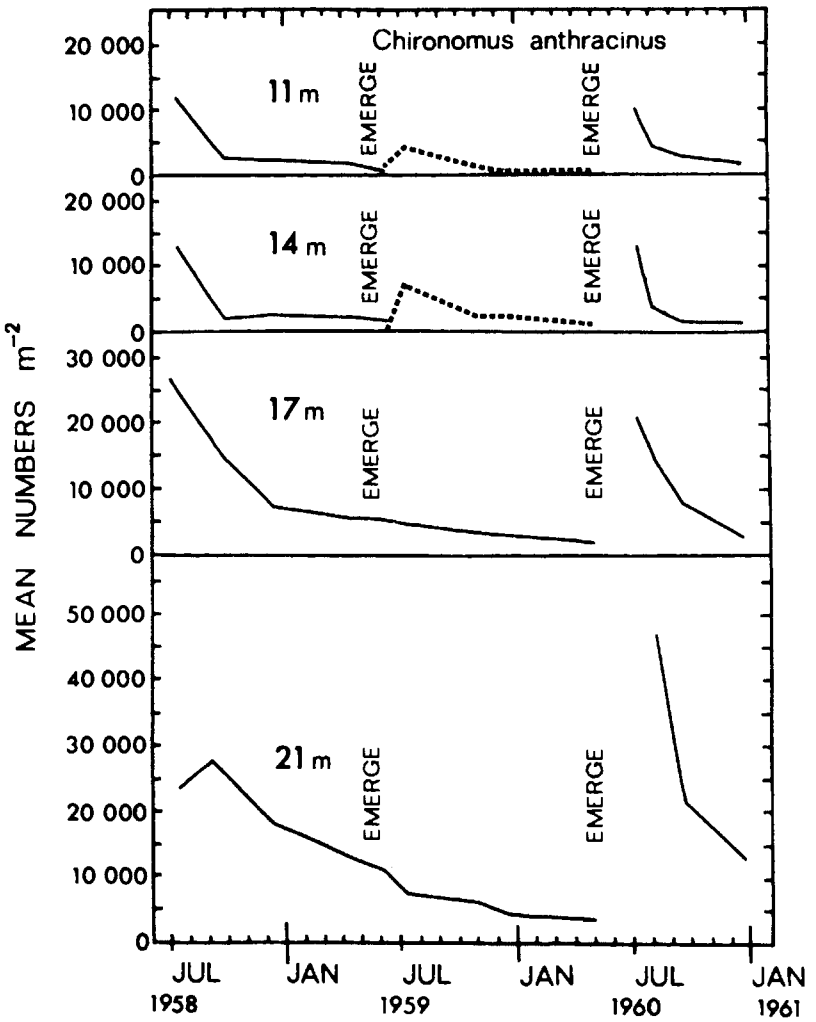

FIGURE 22-5 Seasonal fluctuations in populations of the midge larvae *Chironomus anthracinus* in sediments of different depths of Lake Esrom, Denmark. 1-yr life cycles were found at 11- and 14-m, 2-yr cycles at 17- and 21-m depths. (Modified from Jónasson, 1972.)

larvae succeeded in having a yearly recruitment in some years. Population size increased with depth, probably as a result of reduced fish predation. Larvae of the carnivorous phantom midge *Chaoborus flavicans* and of the midge *Procladius pectinatus* had similar growth patterns and consistently exhibited a 1-yr life cycle. The detritivorous tubificid oligochaete *Ilyodrilus hammoniensis* lived at least 5 years and did not begin to reproduce until after 3 years; the detritivorous small clam *Pisidium* also exhibited a long life cycle.

Detailed analyses of the population dynamics, survivorship, emergence, and respiration permitted an evaluation of the net production of the profundal macroinvertebrates of eutrophic Lake Esrom (Table 22-19). A large portion (89%) of the production was by the three benthic detritivores, mostly by the *Chironomus* species. Jónasson (1984, 1990) was able to extend these data, making a number of reasonable assumptions, to an energy flow budget. In this moderately eutrophic lake, an appreciable portion (perhaps 6%) of the phytoplanktonic primary production reaches the profundal sediments and, while undergoing decomposition, is utilized by profundal invertebrate fauna along with the microflora (Table 22-16).

Despite the relatively high mean annual densities of zoobenthos of Lake Esrom (65,000–200,000 individuals m^{-2}), about half of the animal production arises from the zooplankton and half from the zoobenthos (Table 22-20). In contrast, in the shallow, benthos-rich Lake Mývatn, Iceland, benthos accounts for the primary animal energy flow (ca. 21 g C m^{-2} yr^{-1}), which is some five times greater than that of the zooplankton (ca. 4.3 g C m^{-2} yr^{-1}) (Jónasson, 1979; Lindegaard, 1994). In further contrast, the zooplankton production (ca. 7.5 g C m^{-2} yr^{-1}) of deep, subarctic, oligotrophic Lake Thingvallavatn, Iceland, is four times greater than

that of the zoobenthos (ca. 1.9 g C m^{-2} yr^{-1}) (Jónasson and Lindegaard, 1988; Jónasson, 1992).

Studies of Lake Esrom for nearly a century have demonstrated the negative effects of the gradual eutrophication process on the benthic invertebrates (Jónasson, 1984; Lindegaard *et al.*, 1993). For many decades until the 1980s, Lake Esrom received sewage from nearby communities. Increased algal productivity and increased duration of hypolimnetic oxygen depletion caused marked declines in benthic invertebrates.

[a] From data of Jónasson (1984) and Jónasson *et al.* (1990).
[b] Mean biomass per average lake m^2, expanded over the entire lake area.
[c] Estimated from river inputs only.
[d] Likely underestimates.

The declines of profundal fauna lowered net zoobenthos production to about 30% of the levels in the 1950s. With improved sewage treatment and reduced nutrient loading to Lake Esrom, partial recovery has occurred, with reduced algal production and increased profundal production back to about 80% of the levels in the 1950s.

Food supply is of major importance in the regulation of the population dynamics of detritivore species (cf. also Iyengar *et al.*, 1963), especially in the profundal zone, in which predation shifts from other animals to cannibalism of eggs. Among carnivorous chironomid larvae, the young (first instar) are largely detritivores, but beyond the second instar, they shift to feeding on small chironomid larvae, small crustacea, and some plant food. Although *Procladius* are carnivorous, their diet is highly variable and opportunistic (Kajak and Dusoge, 1970). Mature larvae consume about 10% of their body weight per day and have a relatively high degree of utilization of animal food. Abundant food availability increases rates of growth and development greatly.

The Chironomidae form the dominant macroinvertebrates of all arctic lakes studied (Hobbie, 1973; Butler, 1982). It is noteworthy that those few studied have 2- to 7-yr cycles and are detritivores. The carnivorous *Procladius* is also usually present.

B. Phantom Midges

In addition to the chironomid larvae, oligochaetes, and the small clam *Pisidium*, another major component of the profundal zone of lakes is the phantom midge *Chaoborus*. Extensive studies of *C. flavicans* demonstrate some of the major characteristics of this group (Parma, 1971). This midge dominates the benthic fauna of the profundal zone of Lake Vechten, a small (5 ha), moderately deep (12 m) lake in the Netherlands. Lake Vechten is thermally stratified from April to November and mixes all winter (very brief period of ice cover). The lake is moderately eutrophic, and the hypolimnion becomes anaerobic during stratification.

The lifespan of an adult phantom midge is very brief (<6 days). Eggs (about 500 in number) are laid on the water in rafts and most (97%) hatch in 2–4 days. The larvae can develop to the fourth instar in 6 to 8 weeks. The first and second instars are always limnetic and positively phototactic, and they develop rapidly in a few weeks. The third instar, mostly limnetic but also occurring in the sediments, is of much longer duration; the larvae can overwinter in this stage (Stahl, 1966; Roth, 1968). After a variable period of up to several months, ecdysis to the fourth instar occurs; this instar is limnetic much of the time.

The fourth instar of many species of *Chaoborus* undergoes strong diurnal vertical migrations (see, e.g., Northcote, 1964; Malueg and Hasler, 1966; LaRow, 1968; Goldspink and Scott, 1971). A typical rhythm is movement from the sediments or from their daytime depth to the surface strata at sunset; they stay there until about sunrise, then descend. The initiating cue is light intensity and the orienting cue is gravity (Swift and Forward, 1988). Light intensities are variable at the initiation of and during upward migration, but the rapid movement is correlated with the timing of a relative light change (ca. 1.7×10^{-3} s^{-1}) (Haney *et al.*, 1990). Rates of ascent and descent are about the same at 4–6 m h^{-1}. Migration does not occur as actively at temperatures <5°C. When the larvae are burrowed into the sediments, they push up to the surface of the mud as if to sample the light conditions. If light levels are sufficiently low, they emerge from the sediments and begin the migration (LaRow, 1969). Experiments showed that the migration was influenced in part by the oxygen tension of the water near the sediments (LaRow, 1970). When the oxygen concentrations were high, most of the populations stayed in the sediments; when there was <1 mg O_2 $liter^{-1}$, about one-third of the population migrated into the water above the sediments and about one-third migrated to the surface during the night. Migration varies with season, being highest in midsummer and lowest in winter. There is evidence that *Chaoborus* also migrates horizontally at rapid rates (ca. 20 m h^{-1}) and can move into littoral areas at night (Franke, 1983, 1987b; Voss and Mumm, 1999).

Since the early instars are small and very transparent, predation pressure probably is low. With increasing size, predation pressure in the open water becomes greater and results in a more benthic habit. Oxygen stresses in the hypolimnion impose a demand for oxygen that can be alleviated by moving to the upper strata, but this activity is best accomplished at night when predation pressure from fish is reduced. Fish predation pressure is greater upon the larger third and fourth instar larvae of *Chaoborus* than on the smaller instars. Smaller species, or species in which the larval eye size and visibility to fish is reduced, have less pronounced vertical migration than larger species. Some highly visible species are eliminated in lakes by fish predation and do not occur when fish are present or introduced (Macan, 1977; Northcote *et al.*, 1978; Stenson, 1978a,b; von Ende, 1979; von Ende and Dempsey, 1981).

Pupation takes from 1 to 2 weeks and occurs from May to October in *C. flavicans*. The pupae migrate daily. Pupation and emergence as adults result in a reduction in the total benthic population during summer. Emergence has been correlated with lunar periodicity,

beginning shortly after full moon and ending at the following new moon (e.g., Hare and Carter, 1986; Akeret, 1993). The highest densities of larvae, 1400–1800 m^{-2} in Lake Vechten, occurred in November. Mortality in the winter was high (65%) due to reductions in food supply, and a total mortality of about 97% occurred before the fourth larval stage was reached. The annual net production of the benthic part of the population was estimated to be 0.8–1.25 g m^{-2} yr^{-1} (8–12.5 kg DM ha^{-1}) for *C. flavicans* in this lake.

Production by *Chaoborus* larvae can be very high. The respiration rates of the larvae, when corrected for body size and temperature, were very low by comparison with the rates for most aquatic insects (Cressa and Lewis, 1986). As a result, growth efficiencies are high (40–75%). For example, in the eutrophic Socuy Reservoir, northwestern Venezuela, the largest portion of biomass and production resulted from the older instars (Table 22-21). Instar IV represented some 82% of the biomass and 61% of production. The marked increases in the *P/B* values in the older instars resulted in high average renewal rates (Table 22-21), but these values are similar among many other populations of *Chaoborus* in tropical eutrophic lakes (López and Cressa, 1996).

Chaoborus larvae are omnivorous and shift predominantly to predation on pelagic zooplankton and certain small benthic animals in later instars. All instars ingest large, flagellated phytoplankton, such as dinoflagellates and rotifers, but only instars III and IV fed on crustaceans, such as *Daphnia, Bosmina*, and *Diaphanosoma* (Hare and Carter, 1987; Moore, 1988). In the larger instars, the daily ration of food, amounting to about one crustacean zooplankter per hour, is variable but can amount to approximately 10% of their body weight (Kajak and Ranke-Rybicka, 1970). It was estimated that *Chaoborus* could consume about 12% of the macrozooplanktonic biomass on the average and a greater percentage at certain times of the year, such as late in the period of summer stratification. Predation efficiency on rotifers increased in successive larger instars (I–III) of *Chaoborus* but was lower in comparison with other invertebrate predators (Moore and Gilbert, 1987; Swift, 1992). Ingestion rates of rotifers by older instars of *Chaoborus* (III and IV) were among the highest reported for invertebrate predators on rotifers. Predation upon rotifers, however, was found to be inadequate to significantly affect natural rotifer community dynamics (Havens, 1990). Rotifer reproductive capacity during midsummer in eutrophic lakes was capable of exceeding predatory losses.

Total/mean	35.90	571.38	15.9

[a] From data of López and Cressa (1996).

Predatory larvae of *Chaoborus* release a chemical compound (kairomone) into the water that induces antipredatory morphological changes in daphnid zooplankton (e.g., Hebert and Grewe, 1985; Tollrain and von Elert, 1994). The compounds, characterized as low-molecular-weight hydroxy-carboxylic acids, induce adults to develop a large helmet and pronounced spines along the carapace margin. Conversely, *Chaoborus* movements and activity increase markedly in the presence of chemical compounds released by prey (Berendonk and O'Brien, 1996). Chemical compounds released from planktivorous fish increase sensitivity to low light intensities and accelerated vertical migration rates to refuges in the sediments (Dawidowicz *et al.*, 1990; Tjossem, 1990).

It has been demonstrated further that *C. flavicans* is conspicuously selective in the food it consumes (Swuste *et al.*, 1973). Among zooplankton, copepods were actively selected over the cladoceran *Daphnia*; the pelagic ostracod *Cypria* was attacked but then immediately rejected. When given the choice between benthic oligochaetes and zooplankton, the oligochaetes were taken and predation on *Daphnia* ceased. Similar results have been found in a number of other studies (Swift, 1976; Lewis, 1978b; Smyly, 1980; Vinyard and Menger, 1980; Winner and Greber, 1980; Chimney *et al.*, 1981; Pastorok, 1981; Christoffersen, 1990; Hanazato, 1990; Lüning-Krizan, 1997). Differences in prey size and shape, as well as in swimming, escape, and vertical migration behavior, influence the selection of prey by different instars of *Chaoborus*.

The coexistence of 2 or more species of *Chaoborus* without any apparent great differences in their characteristics or requirements that would reduce competition has been noted often (Stahl, 1966a,b). Previously, it was assumed that the abundance of food precluded serious competition. Roth (1968), however, observed severe competitive interactions among three species of *Chaoborus* in the same lake. Slight differences in morphology of the larvae and their distribution, especially during nocturnal migration, were adequate to permit the two quantitatively minor species to coexist with the dominant species. Similarly, two coexisting species of *Chaoborus*, the dominant profundal fauna of Lake George in tropical Africa and in other lakes, were

found to have interspecific differences in the mean number of eggs per adult female, the nature of egg batches, the morphology of mouth parts, as well as differences in the vertical distribution of the larvae and seasonal occurrence of the adults (McGowan, 1974; Sardella and Carter, 1983).

IV. STREAM BENTHIC COMMUNITIES

The macroinvertebrates (>0.5 mm), particularly the aquatic insects, have received intensive study in running water ecosystems. There is reasonable evidence that many orders and other major taxa of aquatic insects evolved in cool running waters prior to expanding to warmer running waters and lake environments (cf. Ward, 1992). The cool flowing waters, where dissolved oxygen concentrations are high and flow minimizes distances for transport to cell membranes, are logical environments to develop respiratory mechanisms and adaptations for extracting dissolved oxygen from the water. These invertebrates feed largely on algae and other attached microbiota and serve as primary food resources for fish and other vertebrates. Invertebrate turnover rates are intermediate between the microbes and the larger predators (Cummins, 1992). Because of their importance for fish populations and as indicators of water quality (e.g., Holsenhoff, 1987; Waters, 1988; Johnson *et al.*, 1993; Kerans and Karr, 1994), macroinvertebrates have been used widely in stream assessments.

More recent analyses of stream benthic communities have shifted toward analyses of changes in population and community dynamics and production in response to environmental variables. As among all aquatic organisms, environmental parameters influencing growth and reproduction include (a) physiological constraints of parameters such as temperature, dissolved oxygen, and osmoregulation, (b) constraints of food acquisition and food quality, (c) biological interactions of predation and intra- and interspecific competition, and (d) physical constraints of changing habitats within stream ecosystems. This same set of factors, as well as mobility (drift, swimming, crawling, and flight), affects the rates of colonization of new or rewatered channels, rivers recovering from pollution, and unstable rivers with fluctuating discharge (Mackay, 1992). Insects are secondarily adapted to life in water and are dependent on the terrestrial environment for part of their life cycle (e.g., Wallace and Anderson, 1996). As a result, aquatic insects are prevalent in shallow standing waters and streams, decrease in large, deep lakes, and are nearly absent in the open ocean.

Habitats are generally separable into ***riffle*** areas of fast-flowing water characterized by sediment erosion and into *pools* of depositional habitats (pools, backwaters, and side channels). Flow of water is a dominant parameter in running water ecosystems that has led to major morphological and behavioral adaptations of invertebrates in relation to movements, attachment, concealment, feeding, and reproduction (cf. Cummins, 1992; Vogel, 1994). Flow and its velocity fields affect interactively the stream habitat, dispersal of organisms, their acquisition of essential resources, intra- and interspecific competition, and predation efficacy. If benthic invertebrates live on the surface of the substrata, the organisms usually reside within the roughness layer, where the unique arrangement of sediment particles produces strongly sheared and highly three-dimensional flow patterns (Nowell and Jumars, 1984; Bouckaert and Davis, 1998; Hart and Finelli, 1999). Flow velocities within the roughness layer are unpredictable based solely on knowledge of the overlying flow within the logarithmic boundary flow layer. Shear stress is highest in the vertical plane in the wake of boulders, and as a result, turbulence intensity and kinetic energy are greatest in the wake region. Benthic macroinvertebrate fauna is significantly richer and more abundant in the wakes than in the front of boulders. Current velocities decline markedly within sediments, and often benthic invertebrates penetrate well within the hyporheic interstitial spaces among sand and gravel substrata.

It is common to find the maximum density of macroinvertebrates, particularly oligochaetes, chironomids, amphipods, and microcrustaceans (especially cyclopoid copepods and ostracods), at a depth of between 5 and 20 cm within porous sediments (D. D. Williams, 1984; Brunke and Gonser, 1999; Malard *et al.*, 1999). The depth to which hyporheic invertebrates penetrate sediments is likely restricted by the availability of food resources, which generally decrease as the ratio of particulate organic carbon to total fine particles declines. Although bacterial biomass can be appreciable in areas of upwelling in the hyporheic zone (cf. Chap. 21), food resources are generally low within the hyporheic zone, and some of the invertebrates near the surface migrate diurnally, usually at night, to the surface areas for feeding. Most invertebrate movements within the hyporheic zone are over longer periods (days or seasonally). The hyporheic zone can function as a refuge from predation during normal flow conditions, although during severe spates the surficial sediment substrata can be eroded severely with a very high loss (50–90%) of invertebrates (e.g., Palmer *et al.*, 1992). Some benthic microinvertebrates inhabit the hyporheic zone many meters from the stream channel and likely feed on microbes that are

utilizing dissolved organic substrates that are being transported from upland regions through the hyporheic zone to the stream channel.

A generalized model of the shifts in the relative abundances of invertebrate functional groups along a river tributary ecosystem from head waters to mouth was set forth in the brief introduction to the River Continuum Concept in Chapter 8 (pp. 140–142) (cf. Cummins, 1992). The concept was originally developed among small streams of woodland areas where the influence of the terrestrial vegetation was high. Headwater streams of low (1–3) order, supplied largely from groundwater sources, were described as heavily canopied with trees and light limited (Fig. 8-8). Leaf litter from these trees formed a major input of particulate and dissolved organic matter. In middle reaches of streams where tributaries increase stream order (3–5), the water is commonly still clear and shallow, but now the tree canopy does not cover the streams. Consequently, macrophytes and attached algae reach maximum development and enhance food resources for benthic invertebrates (cf. Fig. 15-20 and 15-21). Fluctuations in discharge and temperature are generally larger as the influence of tributary inflows becomes more significant. In the lower reaches of larger rivers with increasing stream order (>6), turbidity increases and water transparency decreases (Fig. 15-20). Primary productivity within the river decreases with increasing reliance on allochthonous sources of organic matter (Figs. 8-9 and 15-21). The River Continuum Concept was later broadened to accommodate regional differences in hydrology, climate, tributaries, location-specific geology and lithology, vegetation, and human-induced factors to encompass broader spatial and temporal scales (Minshall *et al.*, 1983, 1985; Cummins, 1992).

Flooding events are distinct disturbances in small rivers. In large floodplain rivers, however, flooding is less of a disturbance to invertebrates because it provides a periodic habitat expansion in two dimensions (Benke, 1993b). The great majority of invertebrate production in medium-sized to large rivers (>6th order) is by collector organisms (gathering collectors in sand and mud and filtering collectors on snags) that primarily consume amorphous detrital particles and microbes that are flushed from floodplain detritus and soils. Flooding increases snag habitat in the main channel in the vertical direction and inundates large floodplain areas in the horizontal dimension, often 10–100 times greater than the area of the main channel. The flood plain provides invertebrate habitat in benthic zones of heavy organic deposition and on the surfaces of wood, both living and dead, and other wetland vegetation. Therefore, unlike the River Continuum Concept for streams, high invertebrate production and drift levels are dependent on an abundance of snag habitats, the occurrence of natural flooding regimes, and mobilization of organic matter among these habitats (Table 22-22).

It should be noted in the application of the River Continuum Concept (e.g., Figs. 8-8 and 8-9) that the ratio of gross photosynthesis to total ecosystem

TABLE 22-22 Selected Ecosystem and Zoobenthos Community Characteristics for Small-to-Medium-Sized Streams and Floodplain Rivers (e.g., >6th Order)[a]

	Small-to-medium-sized streams	*Floodplain rivers*
Riparian zone	Narrow	Broad floodplain swamps
Channel habitats	Rocky (gravel to bedrock)	Sand, snags
Slackwater habitats	Pools	Backwaters (sloughs)
In-channel system metabolism	Heterotrophic to autotrophic	Heterotrophic
Effects of floods	Catastrophic, brief	Beneficial, prolonged
Floodplain fauna (aquatic)	None on surface	Extensive, year-round
Functional groups (aquatic)		
Channel	Shredders, scrapers	Gathering and filtering collectors
Flood plain		Shredders; gathering collectors
Invertebrate production	Low to moderate ($4–25$ g DM m^{-2} yr^{-1})	Moderate to high (>25 g DM m^{-2} yr^{-1})
Invertebrate drift	Short distances and times; origin from benthic habitats	Long distances and times; origin from snags
Invertebrate food	Microbially colonized riparian litterfall, periphyton	Wetland and swamp-derived DOM, FPOM, microbes

TABLE 22-23 Comparison of Invertebrate Feeding Group Ratios and Stream Ecosystem Parameters for the Kalamazoo River, Southeastern Michigan[a]

	Stream order			
Parameter	*1*	*2*	*3*	*5*
Stream width (m)	1	5	10	45
Trophic status	Heterotrophic	Autotrophic	Heterotrophic	Autotrophic
P/R ratio	0.47	1.13	0.90	1.23
Transport, CPOM / FPOM	0.022	0.016	0.019	0.022
Storage, CPOM / FPOM	0.36	0.11	0.15	0.10
POM, storage/transport	0.10	0.16	0.23	0.16
Mean annual				
Invertebrates $m^{-2} \times 10^3$	19.6	15.0	63.6	41.7
Shredders/total collectors	0.22	0.003	0.002	0.001
Filtering collectors/gathering collectors	0.67	0.42	0.45	1.50
Scrapers/shredders	0.18	12.23	3.99	16.91
Scrapers/(shredders + total collectors)	0.08	0.24	0.11	0.05

[a] All invertebrate data used were means of fall–winter and spring–summer densities m^{-2} of individuals >0.5 mm (extracted from Cummins *et al.*, 1981). *P* = gross annual primary production; *R* = annual community respiration, POM = particulate organic matter (CPOM = coarse POM and FPOM = fine POM).

respiration (*P/R*) indicates whether a stream ecosystem is a net producer or consumer of organic matter but does not indicate the extent to which stream consumers are supported by autochthonous or allochthonous organic matter (Rosenfeld and Mackay, 1987). The transition between dominance by autotrophy and heterotrophy in streams is not properly expressed by $P/R = 1$. Separation of respiration of autochthonous and allochthonous organic matter cannot be measured readily, but estimates of the fraction of net primary production respired in a particular reach of the river improves the assessment of relative *P/R* of the organic sources of the entire heterotrophic community of the ecosystem (Meyer, 1989).

Shifts also occur in the relative abundance of feeding benthic invertebrates as food resources change over the longitudinal profile along the River Continuum Concept. In Figures 8-8 and 8-9 (pp. 140–141), the patterns reflect (a) the importance of particulate organic matter (leaf litter) inputs, commonly maximized in the head waters, which influences the relative density of shredder insects; (b) increases of scraper insect types where light and nutrients favor increased production of attached algae and cyanobacteria, normally in wide, shallow midreaches of rivers; (c) an intensified linkage between the abundance of collector feeding types and fine particulate organic matter, either in the head waters related to litter degradation or in the lower reaches as a result of importation from upstream tributaries and floodplain scouring, and (d) the fairly constant relative abundance (ca. 10%) of predators in all reaches of the river ecosystem.

An example of the shifts in feeding strategies and types by benthic invertebrates, dominated by aquatic insects, is well illustrated in the comparison of invertebrate feeding group ratios along the Kalamazoo River basin in southwestern Michigan (Table 22-23). The ratio of gross primary production (*P*) to community respiration (*R*) can be used as an index (*P/R*) of the relative amounts of autotrophic and heterotrophic metabolism in the water of the stream/river channel. Particulate organic matter (POM) shifts from a dominance of coarse (>1 mm) to fine (<1 mm) size fractions in storage, and organic matter is slowly decomposed in the progression downstream by the actions of heterotrophic microbiota and feeding activities of benthic invertebrates (Table 22-23). In addition, inputs of coarse POM decrease with increasing river size as the relative width of the riparian zone is reduced in proportion to river width and volume. The ratio of shredding to collector feeding types of invertebrates is highest in the headwater regions of high coarse POM, and decrease as the POM shifts to fine size categories (Table 22-23 and Fig. 8-9). Disturbance of the drainage basin, however, such as by clear-cutting of forest or alteration of riparian vegetation, results in less production of fine POM and less retention of organic matter by streams (Dudgeon, 1988; Golladay *et al.*, 1989). These declines in fine POM inputs and in retention by higher velocity, more erosive water flows can result in appreciable reductions in invertebrate production. In contrast, when a river is impounded ("regulated") in a reservoir, the marked reductions in flow and alterations of sub-

strata result in quantitative reductions in total macroinvertebrate community abundance and biomass (e.g., Ward and Voelz, 1988; Gumiero and Salmoiraghi, 1998). Many zoobenthic species are unable to adjust to sublethal modifications of environmental conditions, such as substrata, oxygenation, et cetera, induced by stream regulation.

A. Movement and Drift of Lotic Benthic Invertebrates

Many invertebrates move about localized substrata habitats on a diurnal basis, often hiding in refuges areas during daylight periods and emerging to upper surfaces at night for increased feeding activities with reduced predatory pressures (e.g., Glozier and Culp, 1989). Immature insects also move large distances (several to tens of meters) both upstream and downstream over periods of days to weeks. Dispersal between streams and rivers can also occur in the adult stages by aerial movements.

The drag forces of flowing water, particularly during periods of high flow, can dislodge invertebrates from the substrata with which they are associated and transport them downstream. ***Drift*** is the downstream transport by water currents of organisms normally living in or on substrata. As a result the benthic invertebrates are constantly being redistributed. The extent of this drift dispersal leading to population expansion through movement downstream and colonization of new habitats varies greatly among species. Some species rarely drift at all, whereas others have a marked propensity to drift. For example, some 18% of the invertebrate taxa of the Rhine River of France constituted 98% of the total drifting organisms (Cellot, 1996). Scraper feeding types of insects tend to cling and rarely drift, whereas many gathering-collector insects are swimmers and exhibit directed drift behavior (Wilzbach *et al.*, 1988).

Thus, several types of drift occur. Constant low densities of ***continuous drift*** occur by simple accidental displacement of organisms from the substrata (Waters, 1972; Brittain and Eikeland, 1988). ***Catastrophic drift*** can result in high-density drift movements as a result of major physical (e.g., high flow) or chemical (e.g., pollution) disturbances.

A third drift category is *behavioral drift* that results from distinct diurnal patterns of behavioral activity by which immature insects move at specific times to avoid predators and other stresses. In both temperate and tropical regions, a general pattern of maximum drift occurs during darkness, often with a maximum just after sunset, followed by low drift during daylight in a distinct circadian rhythm (Fig. 22-6, *upper*). Dominant drifting insects include particularly many of the Ephemeroptera, simulid Diptera, and many Trichoptera and Plecoptera. Because of differences in activity associated with life histories, maximum drift occurs in the summer, with reduced drift in spring and autumn periods, and least in winter (Fig. 22-6, *middle*). Drift is least among the most immature instars, and commonly nocturnal drift activity increases among the larger instars (Fig. 22-6, *lower*). Certainly many factors contribute to the diurnal periodicity of drift activity (e.g., light, including moonlight, current velocity, substratum type, turbidity, pollution, food availability, and predation intensity). Clearly, however, the behavioral drift periodicity is not the sole result of passive release of benthos from the substrata and movement by currents downstream. Waters (1972) and Allan (1978, 1995) present compelling evidence that increased insect activity for foraging and increased drifting at night are adaptive responses to reduced risk of visual predation by fish. Invertebrate predation, such as by large stonefly larvae, on drifting invertebrates, however, can be very high during darkness. Increased drift can function as a predatory avoidance mechanism. When predatory fish and large stonefly larvae are absent in streams of certain areas, this behavioral drift periodicity is weakened or absent (e.g., Malmqvist and Sjöström, 1987; Malmqvist, 1988; Lancaster, 1990; Flecker, 1992).

In the main channel of large rivers (>6th order), drift densities of invertebrates are extremely high and are dominated by snag-dwelling aquatic insects and microcrustaceans from swamps and wetlands (Benke, 1993b). Drift distances, drift times, and the percentage of organisms drifting are substantially greater than is the case for invertebrate populations in smaller streams (Table 22-22).

Continual depauperation of benthic invertebrates by accidental or behavioral drift is apparently compensated for, in part, by recolonization of upstream populations by adults migrating in an upstream direction and oviposition in headwater regions. Some upstream movements occur within the streams as well (e.g., Söderström, 1987). Although production in excess of carrying capacity of certain regions of streams would not require compensatory upstream recolonization (Waters, 1961), drift has been demonstrated to be density-dependent. Infrequent dispersal by randomly flying adults coupled with density dependence does allow population persistence (Anholt, 1995). The marked diurnal periodicity of insect drift is certainly coupled to increased susceptibility of dislodgment by current when actively feeding on upper surfaces of substrata during darkness periods of reduced risk of predation.

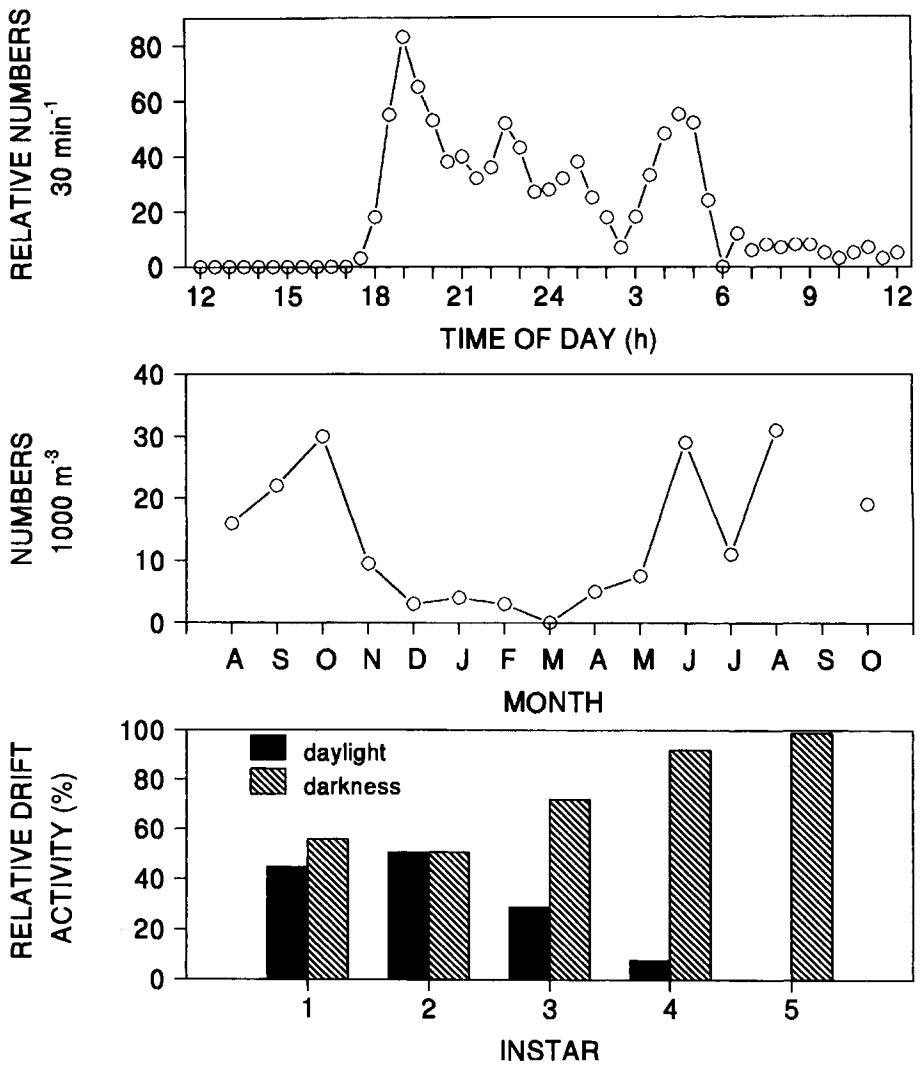

FIGURE 22-6 Drift patterns among certain stream invertebrates. *Upper:* Diurnal variations in comparative 30-min drift catches of the mayfly *Baetis rhodani* in a small stream in July. Ambient light was below 3 μmol quanta m^{-2} s^{-1} at 17.30 h and above this value at 06.00 h. (Drawn from data of Elliott, 1969.) *Middle panel:* Seasonal variations in drift intensity, with maxima in the summer and a minimum in winter, and (*lower panel*) changes in drift intensity with size, where larger instars became increasingly nocturnal in their drift activity, of the larvae of the caddisfly *Rhyacophila nubila* in a small stream. (Drawn from data of Fjellheim, 1980.)

V. RESERVOIR BENTHIC COMMUNITIES

Because soils flooded during the formation of reservoirs are relatively rich in nutrients, phytoplanktonic productivity is high. Although nutrients tend to decline during several years following flooding, usually nutrient loading from the drainage basin is adequate to maintain moderate-to-high primary production. Early high productivity of benthic invertebrates following inundation of the land is often associated with utilization of inundated herbaceous and woody terrestrial vegetation (e.g., Aggus, 1971). When trees and other vegetation are removed before inundation, benthic invertebrate abundance and production can be appreciably reduced (e.g., Applegate and Mullan, 1967).

Fluctuating water levels can alter severely the habitat and survival of benthic invertebrates of reservoirs. Macrovegetation, particularly submersed vegetation, does not survive well under marked fluctuations of water level. As a result, major habitat for benthic invertebrates is almost completely eliminated from many reservoirs. Changes in water level can also expose sediments to freezing conditions, and sandy sediments are more susceptible to freezing in winter than are

organic-rich and stony detrital sediments (Palomärki and Koskenniemi, 1993). Such freezing of the sediments can eliminate over three-quarters of the invertebrate fauna from the exposed sediments.

In contrast, inundation of lowland riverine environments, as is common by the construction of low broad dams by the beaver (*Castor canadensis*) can greatly enhance the development of benthic invertebrates (e.g., Naiman *et al.*, 1984). Sediment accumulation increases markedly from the riverine erosive habitat to greatly enlarged (10- to 20-fold) depositional, organic-rich sediment that is readily colonized by highly productive aquatic macrophytes and periphyton. Increased nutrient loads are leached from the inundated surrounding land, in a manner similar to the well-known increased nutrient loading and productivity that follows periodic drawdown and desiccation of sediments of reservoirs (e.g., Neese, 1946; Baxter, 1977; Duthie and Ostrofsky, 1982). Essentially, the streams are shifted to highly productive wetland ecosystems, in which the productivity of benthic invertebrates increases markedly.

Increased productivity and organic loading to reservoirs can induce hypolimnetic anoxia and related toxic products of fermentative metabolism. The disappearance of many benthic invertebrate taxa and reductions in biomass and production of remaining invertebrates are found commonly in eutrophic reservoirs (Siegfried, 1984; Popp and Hoagland, 1995).

The regulation and suppression of flow in the stream or river below the dam can severely alter the microhabitats utilized by invertebrates downstream from the reservoir. Certain taxa, such as simulid dipterans, can be eliminated by reduced and altered flows, and in general the biomass of invertebrates declines under regulated flows (Gumiero and Salmoiraghi, 1998).

VI. PRODUCTION OF INVERTEBRATE BENTHIC FAUNA

Secondary production of invertebrate benthic fauna can be defined as the living organic matter or heterotrophic biomass produced by the animal populations during (through) an interval of time (Benke, 1984, 1993a). Therefore, secondary production is the flow rate of biomass produced, regardless of its fate (e.g., respiration, loss to predators, or emergence), and its units are biomass or energy per unit area per unit time (cf. Table 8-1, p. 144). As will be emphasized in Chapter 23, organic matter that enters an ecosystem and does not leave it physically (e.g., outflow or emergence of insects) must (a) be destroyed by respiration to CO_2 or CH_4; (b) be stored essentially permanently, such as in the sediments, or (c) be destroyed by physical processes such as photolysis of both particulate and dissolved organic matter with conversion to CO_2. Of course, because organic carbon is inefficiently recycled by consumers, the summed production of consumers exceeds the organic inputs to the ecosystem without violation of the thermodynamic principles (Strayer, 1988b). The secondary production of eukaryotic organisms, specifically the benthic invertebrates in this case, constitutes a small but important portion of the total heterotrophic production.

Measures of aquatic animal production are largely population-oriented, in part because of the methodology used for analyses of changes in complex life cycles. Determination of invertebrate and fish production at the population level usually measures growth and population survivorship of individual species. Single community-level measures for total animal production do not exist, although attempts have been made in that direction (cf. Hynes and Coleman, 1968; Benke, 1993a). Because production is a flow (flux) and biomass is a storage, the ratio of production to biomass ($P/\overline{B}$) is a rate in units of inverse time (Table 8-1). In invertebrates and fish, the time over which a cohort grows and completes development depends on the species and its environmental conditions. This time is quite variable (weeks or years), and cohort production must be known for accurate estimates of production. As discussed earlier among the zooplankton, the relationship of production to mean biomass provides important insights into the production process of different species, feeding types, and modes of reproduction. The extreme heterogeneity in distribution and the complex population dynamics of the benthic invertebrate fauna of lakes and streams have impeded detailed analyses of their productivity. Moreover, mortality from natural causes and by predation is complex and related to changes in the types and intensity of predation, since the macroinvertebrates change their size and distribution during their life cycles. Several aspects of these predation-related changes have already been discussed, especially among the oligochaetes, chironomids, and the phantom midge *Chaoborus*.

When a well-defined cohort structure exists in the population structure, production can be calculated between sampling intervals on the basis of instantaneous growth or size increment summation methods (cf. Benke, 1984, 1993a; Wetzel and Likens, 2000). When cohorts cannot be recognized, corrections are needed for development times that are greater than or less than a year based on changes in size distributions. Many of the existing quantitative data on the benthic fauna are expressed on the basis of biomass per unit area. A comparative set of examples of the average biomass among

South basin (eutrophic)	—	43.2	

[a] Values are only approximately comparable because of the differences in methods and frequency and duration of sampling; all exclude mollusks unless stated to the contrary. Values in parentheses were estimated using the relationship: dry weight equals 20% of wet weight. Although Thut (1969) recommended 12.5%, Winberg *et al.* (1971), Gerking (1962), and others found about 20% (range, 15–25%) more realistic.

many lakes is set out in Table 22-24; the number of examples of this nature could be expanded many times over. Such data, however, are of quite limited value owing to great differences in sampling times and in sampling frequency and duration. As has been pointed out several times in the foregoing discussion, the summer period of low population densities and high predation pressure is often the poorest time for analyses. Many studies are conducted only during the ice-free period. In some streams and especially in sediments from deeper parts of lakes, the maximum period of growth often occurs during the winter months in the temperate zone. More importantly, in most of these studies data are insufficient on size–frequency distribution and other population characteristics to permit an evaluation of turnover rate and production rates. Animals with small biomass but high turnover rates (shorter generation times) can obviously be more productive and contribute as much or more to the system than can animals with high biomass but low turnover rates.

Thus, average data such as are summarized in Table 22-24 are not production estimates and must be viewed with caution. One not-too-surprising trend is observed, namely, that in general, the biomass of benthic fauna increases as the productivity of the ecosystem increases. The biomass of benthic animals of oligotrophic lakes in northern latitudes and alpine regions is quantitatively less than that of lowland lakes in temperate and tropical regions. Within some rather obvious limits, as food supply from autochthonous productivity and the diversity of littoral habitats increases, the productivity of benthic animals increases with greater eutrophication. If the organic loading becomes so great that the conditions of hypolimnion are intolerable to even the most adapted fauna, as occurs in extremely hypereutrophic lakes, productivity of the animals decreases. Generalizations based only on biomass data weaken rapidly beyond this level of discussion.

Changes in the total amount of biomass of benthic fauna with enrichment have been demonstrated conspicuously in the Lake Esrom example discussed earlier and many times in fertilization experiments. For example, high phosphate and nitrogen fertilization of fish culture ponds resulted in a 42% greater yield of benthic invertebrates, and 3.3 times greater yield of zooplankton, than yields of unfertilized ponds (Ball, 1949). In a similar study on ponds in Michigan, fertilization increased biomass of benthic invertebrates by about 75% and increased food organisms utilized by the common bluegill sunfish (*Lepomis*) by about 70%. (Patriarche and Ball, 1949). However, in a more detailed analysis of fertilization relationships in these shallow waters, Hall *et al.* (1970) demonstrated the complex interactions between the shifting development of macrophytic vegetation and increasing densities of phytoplankton, and the effects of these substrata on species composition of benthic animals and on their predation by fish. Although increases in productivity of benthic invertebrates were found in more nutrient-rich waters, in large part the production was compensated for by shifts in species composition owing to changing substrata and increases in mortality as a result of greater fish production and predation.

In the foregoing discussion, examples of estimates of the production rates of benthic macrofauna have been given for individual groups or for specific regions of streams or lakes, such as the profundal zone. Most benthic secondary production studies deal with only one to a few species simultaneously. Studies of the rates of production of the total invertebrate benthic fauna of whole-lake systems, for which sufficient detail is available to calculate turnover rates over the entire year, are much less common. The data in Table 22-25 for lakes and reservoirs and Table 22-26 for streams and rivers can be treated only as estimates, but nonetheless show the general relationships.

1. In plots of the frequency of occurrence of the annual production values among different benthic invertebrate groups (annelids, mollusks, crustaceans, and insects) in many lakes and rivers, the most common production values were between 1 and 10 g DM m^{-2} yr^{-1} (10 and 100 kg DM ha^{-1} yr^{-1}) for all groups (Waters, 1977; Benke, 1984, 1993a). Annual production of a benthic community in the 50 g DM m^{-2} yr^{-1} range is high in both lentic and lotic ecosystems.
   a. Production in running waters is usually at least two times greater than in standing waters. Highest production values were found among the filter feeders that receive food particles largely delivered by current (Fig. 22-7). Lower production values were found among gathering collectors and scrapers.
   b. No obvious relationship is apparent between discharge and between temperature and production, although total production of primary benthic consumers (that consume flow-transported particles) increases directly with discharge in the range of 0.1–2 $m^3 s^{-1}$ (Benke, 1993a).
   c. Benthic secondary production of pollution-tolerant species is usually larger, commonly doubled, in organically enriched environments of both lakes and streams.
   d. Benthic production is generally higher in unshaded than in shaded reaches of streams

TABLE 22-25 Estimates of Annual Production (Dry Weight) of Total Benthic Invertebrates in Lakes and Reservoirs[a]

Clinotanypus sugiyamai	0.052		
Procladius culiciformis	0.006		

[a] Based on the approximate conversion coefficients for invertebrates of Waters (1977): 1 g dry weight = 5 g wet weight = 5 kcal = 0.9 g ash-free dry weight = 0.5 g carbon.

(Hopkins, 1976), related in part to higher autochthonous primary production. Annual benthic macroinvertebrate production commonly increases with stream size, with highest values in 6th- and 7th-order rivers (Grubaugh *et al.*, 1997).

2. The productivity of predatory benthic fauna was consistently found to be much lower than that of the nonpredatory benthic fauna (e.g., Fig. 22-7). For example, productivity estimates of the nonpredatory benthic fauna were found to be 5–35 times lower than those of nonpredatory zooplankton (Winberg, 1970).
3. In general, the productivity of the nonpredatory benthic fauna accounts for <10% of the phytoplanktonic primary productivity and decreases appreciably as the productivity of macrophytes increases and the loading of allochthonous organic matter to the lake increases in proportion to phytoplanktonic productivity.
4. In shallow lakes with relatively low mean depth (2–7 m) or where littoral zone development is extensive, zoobenthos production is commonly higher by 2–5 times than zooplankton production (Strayer and Likens, 1986; Jónasson, 1992; James *et al.*, 1998). In larger, deep lakes zooplankton production commonly equals or exceeds that of the zoobenthos, perhaps related to food limitations in the profundal zone (see Table 22-27).

Annual turnover rates for benthic invertebrates, calculated as the ratio of annual production to mean biomass, vary considerably (see reviews of Waters, 1977; Benke, 1993a). Most values, however, follow the general rule of larger $P/\bar{B}$ ratios with increasing number of generations per year (Table 22-28). Among benthos of lakes, cohort $P/\bar{B}$ ratios show considerable constancy between 3 and 5, irrespective of the length of cohort life, similar to the annual $P/\bar{B}$ ratios for univoltine species. The relationship of the annual $P/\bar{B}$ ratio to voltinism is directly attributable to water temperature among benthic invertebrates, since water temperature is clearly a dominant factor, in addition to food

Hemivoltine (2–3-yr lifespan)	2.2	<1–4
Long-lived mollusks	1.7	<1–5

[a] After discussion of Waters (1977).

Most studies of zoobenthos production report only that attributable to macroinvertebrates (>0.5 mm). Where the meiofauna (all metazoans <0.5 mm) are also analyzed, about half of the zoobenthic assimilation of carbon results from the meiofauna (Strayer and Likens, 1986). As a result, most of the cited values for zoobenthos production are conservative underestimates.

Among stream and river benthos, annual $P/\bar{B}$ values for the fine-filtering and gathering collectors is broad (Fig. 22-7) and is likely related to size variation among this group (e.g., large bivalves versus small dipterans) (Benke, 1993a). Macrofiltering collectors are capable of high production but have high biomass and modest $P/\bar{B}$ ratios. Scrapers are of relatively large size and have modest $P/\bar{B}$ ratios. Over 75% of stream predators have $P/\bar{B} < 10$, with relatively long development times and large body size. The lowest $P/\bar{B}$ ratios are found among the shredders, with $P/\bar{B}$ ratios <10 among 90% of the estimates.

VII. FISH PREDATION AND OTHER MORTALITY OF BENTHIC FAUNA

The subject of fish biology and the fish fauna of lakes and streams is an enormous field to which much attention has been devoted. The diversity in the morphology, physiology, behavior, reproductive capacity, growth, and feeding of freshwater fishes is a field of study that has been treated in detail in many recent works. This separation of the treatment of fish biology, ecology, and population dynamics with limnology is perhaps justifiable from the standpoint of giving most appropriate attention to these organisms of major economic importance and because the subject matter is so extensive. The schism is unfortunate in many other ways, however, particularly because fish behavior and feeding can alter the trophic structure and productivity of lakes and rivers appreciably.

As already discussed in the coupling of fish with zooplankton, fish are an integral component of freshwater ecosystems. Although the amount of energy and carbon flux to the fish trophic level is exceedingly small in most aquatic systems, fish are an operational component within the ecosystem. The impact of fish on the operation of the ecosystem in terms of carbon flux and nutrient regeneration at times can be quite significant, as has been discussed repeatedly in nearly every foregoing chapter. For example, the shift of fish species feeding on larger-sized food organisms to planktivorous species can have marked effects on zooplanktonic composition and productivity. This change can in turn influence the species composition of phytoplankton and facets of productivity at the primary level.

Another conspicuous example occurs during eutrophication of lake ecosystems, in which fish species change dramatically from salmonid and coregonid species of quite stringent low thermal and high oxygen requirements to warmwater species that are increasingly tolerant of eutrophic conditions. The warmwater fish are restricted to the epilimnion during summer stratification. Certain fish, such as the carp, have omnivorous feeding habits and can be very effective in modifying the littoral substrata to the point where many submersed macrophytes are eliminated (cf. Chaps. 18 and 20). Such feeding activities often can so disturb the sediments that turbidity is increased and transparency and phytoplanktonic productivity decline.

In general, evidence suggests that the proportion of zoobenthic production utilized by invertebrate predators is likely at least as great, if not greater, than that of vertebrate predators in many streams and lakes (Strayer and Likens, 1986; Wallace and Webster, 1996). For example, in Mirror Lake, New Hampshire, predation by invertebrates accounted for 80% of the fate of zoobenthic production, versus 15% by predation by fish and the remainder as insect emergence. In Lake Pääjärvi, Finland, some 50% of zoobenthic production was removed by invertebrate predation, 40% by fish predation, and the remainder in insect emergence (Sarvala *et al.*, 1981).

Nonetheless, a large number of studies have indicated the major effects of fish predation on the population dynamics and productivity of benthic macroinvertebrates, as has been discussed already in this and previous chapters. Many other examples exist (e.g., Post and Cucin, 1984). In Third Sister Lake, Michigan, the littoral benthic fauna increased to a maximum concentration in early winter (Ball and Hayne, 1952). The invertebrate populations declined steadily after the formation of ice cover until spring loss of ice, when an abrupt reduction occurred as adult insects emerged. During summer stratification, the populations and their biomass progressively increased from this annual spring low to the autumn and winter maxima. Experimental removal of all of the fish from the lake not only resulted in a large increase in the biomass and numbers of benthic fauna but made the low populations characteristic of early summer much less pronounced than under conditions of normal fish predation. Experimental manipulation of fish populations in half-hectare ponds showed that the presence of fish predation resulted in a very significant increase in the rate of production of benthic invertebrate fauna and a reduction in their biomass (Hayne and Ball, 1956). In the absence of fish, the apparent production rate of benthic fauna decreased and stabilized at a higher level of benthic faunal biomass relative to ponds in which fish predation occurred.

Although there are great differences in the qualitative composition of invertebrate fauna and seasonal succession of fauna among littoral stands of emergent vegetation, little difference is found between the quantity of macrofauna and the production of higher emergent vegetation in productive lakes or ponds (e.g., Dvořák, 1970). The presence or absence of submersed vegetation, however, results in large differences. These plants can in turn be influenced markedly by fish and waterfowl. A number of studies have experimentally excluded the feeding and disturbance activities of fish and waterfowl from the littoral vegetation (see, e.g., Korínková, 1967; Kajak, 1970). The biomass and production rates of benthic macrofauna were severely reduced (usually by >50%) when the populations were exposed to fish (carp) and birds (especially ducks). The reductions resulted from increased predation pressure and from losses of submersed vegetation (the latter provided both refugia and food). Although mortality of benthic invertebrates can be very high from fish predation (at least half), availability of adequate food supply

TABLE 22-29 Estimated Rates of Production of Profundal Macroinvertebrates of Lake Beloie, Russia, over an Annual Period, 1935–1936, and the Fate of the Fauna within the Lake[a]

	kg (dry weight) lake^{-1}	*Percentage*

is usually the dominant factor controlling the population dynamics and productivity of benthic invertebrates (see Lellák, 1965; Hall *et al.*, 1970).

Studies of the profundal macroinvertebrate fauna—for example, in the early detailed analyses by Borutskii (1939)—showed that predation mortality, chiefly by fish, was relatively low (Table 22-29). Only a small percentage of the profundal macroinvertebrates lived to the adult stage. His studies indicated that the turnover rate was about two times the mean biomass, which is in general agreement with other studies (production rates equal about two to five times the mean annual biomass). There is evidence that the turnover values are considerably higher in the littoral zone (4–8 times the mean annual biomass) (see, e.g., Anderson and Hooper, 1956).

In a detailed study by Gerking (1962), the production rates of zooplankton and macroinvertebrate fauna were determined both directly and by measuring utilization by the dominant predator, the bluegill sunfish (*Lepomis macrochirus*). Population dynamics and mortality analyses showed that the dense fish population grew slowly in this eutrophic Indiana lake because individuals became overcrowded and undernourished. The diet of the fish was varied, but the dominant prey were midges (45%) and *Daphnia* (26%) among all size classes of fish (Table 22-30). Each year the diet shifted from a high proportion of *Daphnia* in July to a high proportion of midge larvae in August as the cladoceran populations decreased drastically during the summer. The estimated fraction of midge production that was consumed by fishes during the summer was 0.50 (Table 22-30), which indicates a high cropping efficiency of the benthic fauna, much higher than "losses" through emergence as adults.

It is often assumed that density-dependent competition for food resources becomes inconsequential when predation suppresses consumers (e.g., Hairston *et al.*, 1960; Carpenter and Kitchell, 1993; many others). Clearly, however, resource limitations and predation operate simultaneously on populations, and metabolic limitation is essential for thermodynamic and ecosystem stability (e.g., Wetzel, 1995; Osenberg and Mittelbach, 1996). In many situations, small insectivorous fish can influence benthic insect populations markedly at certain times of the year, but careful analyses indicate that seasonal limitations of detritus and associated microbes can influence insect growth and production more than predation (e.g., Batzer, 1998). Complex interactions of life history sequences, food availability and omnivory, food quality changes, prey refugia, and a number of other factors in addition to predation all influence growth and production of benthic invertebrates.

The production rate of the bluegill fish was estimated by multiplying the instantaneous rate of growth by the average summer biomass and adding the recruitment to this value (Table 22-30). The minimum summer production of benthic fauna was computed as the amount necessary to replace the losses by predation. Midges and other dipteran larvae accounted for more than one-half of the production of food that was derived from the bottom fauna. Therefore, it was estimated that minimum food production was 4 to 5 times the production of bluegills during the summer, and probably near 10 times bluegill production on an annual basis. As is common among fish of the temperate zone, both reproduction and growth of the bluegill sunfish are limited to the spring, summer, and early autumn. Spawning occurs for about a month in the spring, depending on the temperature. Growth occurs for about 5 summer months, during which time nearly all of the annual production occurs, about 625 kg ha^{-1} in this example (Table 22-30). Growth and feeding decreased abruptly in the autumn and remained low for the remainder of the year. In contrast, the production of benthic fauna continued for much of the year and increased greatly in the fall, under reduced predation pressure, until about the time ice cover formed. On an annual basis, the benthic faunal production is much larger (approximately 5–10 times) than that utilized by fish.

A similar situation in found in running water ecosystems. In studies of a stream in New Zealand, Allen (1951) found turnover rates by $P/\bar{B}$ ratios of benthic invertebrates to be much higher that reported previously.[6] Allen estimated that fish required many times more benthic prey biomass than was available at any instant in time, a discrepancy later termed the

[6] Subsequently corrected by Gerking (1962) and reduced by a factor of 2–3, but the values still demonstrated the large discrepancy.

[a] Modified from Gerking (1962). Mahon (1976) reevaluated the fish production data of Gerking's study and found that production values of the younger bluegills were underestimated (corrected to approximately 625 kg ha^{-1} yr^{-1} total annual production). Most of these younger-aged fish would prey more heavily on zooplankton than upon benthic organisms.

Allen paradox (Hynes, 1970). Much of the discrepancy is related to the multiple generations per year of the prey species, where high prey turnover sometimes required by predators is easily obtainable, with an annual $P/\bar{B}$ of 30–40, by Chironomidae and other fast-growing invertebrates in warm environments (Benke, 1979, 1993; Waters, 1979). Such high annual $P/\bar{B}$ values are commonly found in both streams and small lakes among the benthos.

When discussing production of invertebrates within the stream and river channels, it is important to note that appreciable numbers and biomass of terrestrial arthropods enter streams, particularly during the summer (Mason and MacDonald, 1982; Cloe and Garman, 1996). Terrestrial arthropods represent an important energetic subsidy to stream fish during the period of low aquatic macroinvertebrate availability. Values of terrestrial arthropod inputs between 50 and 200 mg DM m^{-2} day^{-1} during late spring and summer periods are common. High mortality, particularly in the early stages of aquatic insects, is often attributed to predation, starvation, or mechanical (accidental) death (e.g., from molar abrasion of sediments in flowing waters). It is apparent that fish and other invertebrates can

consume a major portion of benthic prey production in habitats, such as productive streams, where refuges are limited. However, there are many other sources of mortality of benthic invertebrates. Significant mortality occurs even when all of these causal mechanisms are eliminated. Protozoan, fungal, and anaerobic bacterial pathogens are common among invertebrates and likely result in a constant attrition of the diverse benthic communities (e.g., Cummins and Wilzbach, 1988).

Although much of the food demand by fish is apparently derived from surficial macroinvertebrates, which had high (6.9) $P/\overline{B}$ ratios, other prey sources with lower $P/\overline{B}$ ratios (hyporheic and terrestrial macroinvertebrates) were also important (Huryn, 1996). Where predation by fish is reduced or absent, invertebrate production is controlled to a greater extent by resource availability, and $P/\overline{B}$ ratios are lower (Huryn, 1998).

VIII. FISH PRODUCTION RATES

Although an enormous literature exists on the yield of fish per given area of freshwater habitat, relatively few analyses exist of their growth and mortality over annual periods. Consequently, only a few reasonable estimates of production rates can be made. Growth is highly variable among different species of fish. In general, the instantaneous growth is correlated inversely with fish size. At greater sizes, most of the food energy is utilized for maintenance; in young fish, a larger proportion of the energy intake is diverted into growth. Hence, the ratio of production to biomass usually decreases with age and greater size. Reproductive effort by sexually mature members of a fish population can represent a high proportion of the annual fish production.

Summary estimates of net production rates of various fish groups set forth in Table 22-31 demonstrate the general ranges encountered. Production rates are considerably higher in tropical waters than they are in temperate fresh waters, where growth is restricted to about half of the year. In fertile standing waters, the production rates of herbivorous fish in the tropics can reach several hundred g m^{-2} yr^{-1} (Chapman, 1967, 1978). In standing waters of temperate regions, in which a single species often predominates, the range of rates is from 1 to about 20 g m^{-2} yr^{-1}. Production rates in streams are usually higher than in standing waters (Table 22-31) and average about 50 g m^{-2} yr^{-1} in temperate areas.

Annual $P/\overline{B}$ ratios for fishes are generally lower than is the case among most invertebrates as a result of their longer lifespans (several years). Relatively high $P/\overline{B}$ ratios are found in the sculpins, for example, which have shorter lifespans (Table 22-31), because the younger, faster-growing stages contribute disproportionately to the population productivity. Annual $P/\overline{B}$ ratios of a population in an expanding or colonizing stage, such as in a new reservoir or in a stream recovering from flood damage, will be high, because growth is high relative to mortality (Waters, 1977). A population that is overcrowded and stunted, as is commonly the case with sunfish populations in temperate lakes, have lower annual $P/\overline{B}$ ratios, slower growth, and longer lifespans. A very approximate estimate of annual production can be obtained if the annual mean biomass of zooplankton is multiplied by 15–20, of benthic animals by 6–8, and of fish by 0.5–1.0 (1.2 for stream salmonids).

TABLE 22-31 Estimates of Rates of Production of Fish from Various Fresh Waters[a]

Fish group/communities	*Annual production* ($kg\ ha^{-1}\ yr^{-1}$)[b]	*$P/\overline{B}$ ratios*
Salmonidae (trout, salmon)		
From standing waters	0.21–66	0.62–2.0

[a] After data from numerous sources, particularly Chapman (1967, 1978), Winberg *et al.* (1970), Waters (1977), and Morgan *et al.* (1980). Values are expressed as wet weight; approximate conversion values for fishes: 1 g wet weight = 0.2 g dry weight, or approximately 1 kcal.

[b] $kg\ ha^{-1}\ yr^{-1} = 0.1\ g\ m^{-2}\ yr^{-1}$.

IX. INVERTEBRATES AND FISH AMONG AQUATIC ECOSYSTEMS

The diversity of invertebrates associated with benthic substrata and their productivity is enormous among river, reservoir, lake, and wetland/littoral ecosystems. Because of the unusually extensive study and understanding of benthic invertebrates, particularly insects, of streams, some comparative distinctions are possible between small-to-medium-sized streams (1st–5th order) and larger floodplain rivers (6th or greater order). An overarching emergent property is

TABLE 22-32 Comparative Characteristics of Zoobenthos and Fish Communities among River, Reservoir, and Natural Lake Ecosystems[a]

	Rivers			
	Small-to-medium-sized streams	*Floodplain rivers*	*Reservoirs*	*Natural lakes*
Benthic invertebrate habitat	Narrow riparian zone; rocky (gravel to bedrock) and flooding brief but catastrophic	Broad floodplain swamps; sand, snags, and backwater sloughs; flooding prolonged and beneficial	Large, astatic littoral sediments, with large, irregular water-level fluctuations; sediment loading high and gradation high	Shoreline development low, water levels stable; sediment loading low; gradation slow
Zoobenthos community structure and feeding	Diverse with shredders and scrapers dominant in channel; absent on surface of flood plains. Food often dominated by microbially colonized litterfall and periphyton	Very diverse, with gathering and filtering collectors in channel and shredders and gathering collectors in flood plains. Food dominated by wetland and floodplain DOM, FPOM, and microbes	Low diversity with minimal and irregular littoral zone; largely gatherers	Moderate in profundal to very high diversity in littoral and marginal wetlands; decreasing diversity in profundal of eutrophic lakes; diverse feeding especially in littoral areas
Zoobenthos production	Low to moderate (4–25 g DM m^{-2} yr^{-1})	Moderate to high (>25 g DM m^{-2} yr^{-1})	Low generally and dominance of rapid growth (r) selection; high production common during initial flooding of terrestrial vegetation	Moderate in mesotrophic lakes, decreasing with major reductions as hypolimnetic oxygen depletion occurs; increasing markedly with greater littoral and wetland development
Fish communities	Warm and cold water species; numerous adaptations to turbulent environment	Largely warm water species; numerous adaptations to a turbid environment	Predominantly warm water species composition; differences often related to initial stocking; spawning success variable and low with low water levels; egg mortality increases with siltation; larval success reduced with less refugia	Warm and cold water species composition; spawning success good; egg mortality lower, larval success good
Fish production	Moderate to high, average ca. 50 g DM m^{-2} yr^{-1}	Moderate to high	Initially (5–20 years) high, then decreasing	Productivity moderate

[a] Assembled from the syntheses of Ryder and Psendorfer (1980), Wetzel (1990b), and many sources cited in those papers and the present chapter.

clearly that zoobenthos community structure is more diverse, more robust in responsiveness to disturbances (resilient), and more productive when the river or lake ecosystem includes an extensive littoral and associated wetland region (Table 22-32). That generalization can apply as well to fish communities.

The summary synthesis of the benthic invertebrates in this chapter indicates the remarkable variation in adaptive characteristics that emerge among the many organisms utilizing these habitats on surfaces (inert, organic, living, dead, decomposing detritus, et cetera). Strategies to acquire as much of the available organic resources as possible for growth and reproduction are played against minimizing expenditures of energy used in competitive interactions with other species, all done within environmental constraints on the individual physiological capacities of each species.

X. SUMMARY

1. The distribution, abundance, and productivity of benthic organisms are determined by several ecological processes: (a) the historical events that have

allowed or prevented a species from reaching a habitat; (b) the physiological limitations of the species at all stages of the life cycle; (c) the availability of energy resources; and (d) the ability of the species to tolerate competition, predation, parasitism, and natural mortality.

2. The benthic animals of inland waters are extremely diverse. Representatives of nearly every animal phylum occur in or are associated with the sediments of lakes and streams. This diversity and extreme heterogeneity in distribution, modes of feeding, reproduction, and morphological and behavioral characteristics make generalizations difficult for the entire benthic animal community. Nonetheless, complex general patterns of coexistence, interrelationships, and community productivity emerge. Invertebrate and vertebrate (primarily fish) predation upon benthic animals is an important regulator of spatial and temporal population structure and dynamics.
3. Most freshwater protozoa and other protists are attached to benthic substrata. Few protozoans tolerate low dissolved-oxygen concentrations; most inhabit surficial sediments and migrate to shallower water when dissolved oxygen of deeper strata declines in stratified productive lakes.
   a. Protistan species are segregated by differences in food utilization, reproduction, and timing of population development. Heterotrophic flagellates dominate in many benthic communities and can exceed 2×10^9 cells m^{-2}.
   b. Many protozoan and other protistan populations exhibit summer maxima; their population densities are positively correlated with summer increases in temperature and with the abundance of microbial food items of the surficial sediments. Consumption of total available benthic microbial production is low (usually $<5\%$), however.
   c. Little is known of natural protozoan productivity in fresh waters. Although instantaneous protistan community biomass is low, rates of turnover (number of generations) are high. Benthic protistan productivity, analogously to protozooplanktonic communities, is likely much higher than is generally recognized and often dominates benthic productivity.
4. Freshwater sponges are rarely abundant in freshwater ecosystems.
   a. Sponges require large amounts of silica for the development of spicules that are bound by collagens to form an inorganic skeleton, which can function as a deterrent to predators.
   b. The contribution of sponges to total benthic productivity is usually minor.
5. The hydroid coelenterates are not common in fresh waters and rarely is their productivity a significant portion of the whole.
   a. Development is rapid in spring, and population maxima occur in early and late summer.
   b. Occasionally, dense populations of *Hydra* can impart significant predation pressures upon populations of small zooplankton and mortality to larval fish.
6. The turbellarian flatworms are the only important free-living members of the Platyhelminthes in fresh waters. Most are restricted to quiescent shallow areas of lakes and low-velocity streams where water movement is reduced.
   a. Flatworms prey upon other small invertebrates, and species segregate by the dominant type of prey consumed and by differences in reproductive capacities. Distribution and abundance are determined primarily by interspecific competition for food.
   b. Abundances in excess of 50,000 m^{-2} are common and are greater in littoral and wetland areas than among profundal sediments.
   c. Flatworm productivity is correlated directly with the general fertility and productivity of fresh waters.
7. Free-living nematodes, or roundworms, are widely distributed in fresh waters and can constitute a significant component of the benthic fauna. Nematode feeding habits are diverse: some species are strict herbivores, others are strict carnivores on other small animals, and still others are detritivores on dead particulate organic matter. A large proportion of production is expended in reproduction, inasmuch as mortality is high in the egg and juvenile stages.
   a. In the temperate zone, population dynamics of many nematode species exhibit three generations per year, with maximum production during winter and spring periods with reduced fish predation and increased food abundance.
   b. Highest densities (to $>750{,}000$ m^{-2}) are among deep, fine, organic-rich sediments. The greatest productivity of nematodes is commonly found among littoral substrata of productive lakes, in wetlands, and in floodplain areas of streams.
8. Horsehair worms (Nematomorpha) are free living as adults and parasitic on invertebrates as larvae. Little is known about the feeding habits, population dynamics, or productivity of these modest (to 1 m in length) animals, although they likely have

little impact on the material and energy fluxes within most habitats.

9. Colonial bryozoans are rarely quantitatively important in inland waters but occasionally form massive colonies in shallow waters and wetlands for brief periods.
   a. A number of invertebrates live commensally within bryozoan colonies.
   b. Bryozoans and these coinhabitants are heavily preyed upon by fish.
10. Two major groups of aquatic annelids, or segmented worms, form significant components of the benthic fauna.
   a. Oligochaete worms are diverse and occur in a spectrum of fresh waters, from unproductive to extremely eutrophic lakes and rivers.
      i. A large number of species of oligochaetes coexist in sediments of lakes, but species abundance patterns differ at different water depths, since the particle size and organic content of the sediment change with depth. Resource partitioning occurs by differences in worm morphology and selective feeding on microbiota.
      ii. As lakes become organically polluted and dissolved oxygen concentrations become reduced or are eliminated, an abundance of tubificid oligochaetes is commonly found concomitant with a precipitous reduction and exclusion of most other benthic animals. As long as some oxygen is periodically available, and toxic products of anaerobic sedimentary metabolism do not accumulate, the rich food supply and freedom from competing benthic animals and predators permit rapid growth.
      iii. Oligochaetes lack discrete age classes and production is approximately continuous. Maturation requires 1–4 years, with much variation in relation to optimality of growth conditions.
      iv. Oligochaete densities can be very large (>50,000 per m^2). Productivity can vary greatly from year to year because of changes in mortality associated with population dynamics of major long-lived predators (e.g., chironomid midge larvae).
   b. Leeches are primarily ectoparasites that intermittently consume vertebrate blood. A few species are predators on other invertebrates and consume their prey entirely.
      i. Leech abundance is highly variable but generally increases in more productive fresh waters.
      ii. Mortality is extremely high (ca. 95%), particularly among eggs and the young, from predation and food availability.
      iii. Production rates of leeches are greatest in the first year of the typical 2-yr life cycle. Rates of growth and production are most rapid during spring and early summer and are manifoldly higher in shallow areas.
11. The tardigrades, or water bears, are small, arthropod-like organisms of the littoral areas of lakes and streams. Tardigrades are of much evolutionary interest but little is known of their population dynamics and comparative productivity.
12. Water mites (Hydrachnida) are extremely speciose and are often found in abundance (>5000 m^{-2}) in littoral areas of lakes and stream backwater areas and the hyporheic zone of stream sediments.
   a. Larval water mites often parasitize up to 50% of aquatic insects, and adults are voracious predators of eggs, larvae, and smaller invertebrates.
   b. Little is known of the productivity of water mites.
13. The bivalved microcrustacean ostracods are widespread in fresh waters. Because of their small size (<1 mm), occurrence in surficial sediments, and difficult taxonomy, little is known of ostracod ecology, population dynamics, or productivity,
   a. Ostracods occur in the surficial sediments (0–5 cm), where they feed by filtration on bacteria, algae, detritus, and other microorganisms.
   b. Reproduction is parthenogenetic for much of the ostracod life cycle. Egg development is variable and is strongly temperature-dependent. One to three generations occur per year.
   c. Little is known about the effects of invertebrate or fish predation on ostracod population dynamics.
   d. Ostracod densities increase in more productive lakes (to >50,000 m^{-2}). Little is known of their productivity rates or of their roles in benthic metabolism; both are probably more significant than is presently realized.
14. Representatives of four groups of malocostracean crustaceans can form major components of the benthic fauna of some inland waters.
   a. The mysids, or opossum shrimps, feed by filtration on small zooplankton, phytoplankton, and particulate detritus.
      i. All mysids exhibit rapid diurnal migrations from the sediments into the metalimnion or lower hypolimnion (waters of <15°C) at night.

ii. Mysids are size-selective predators; their introduction into a lake can lead to marked alterations in the composition and productivity of the zooplankton community.
iii. When lake productivity is high, the mysid life cycle is 1–2 years in duration; when productivity or temperatures are low, mysids may require up to 4 years to complete their life cycle.

b. The isopods, or sowbugs, occasionally become a significant part of the benthic animal community of lakes and streams, commonly in turbulent littoral and stream habitats.
i. Isopod populations commonly have two distinct cohorts (spring and autumn).
ii. Productivity is greatest in the spring from the overwintering cohort.

c. The decapod crustacean, or freshwater crayfish and shrimps, is primarily herbivorous on algae and larger aquatic plants.
i. Crayfish ingest large amounts of herbaceous and detrital materials while searching for and ingesting animal protein.
ii. Longevity varies up to 16 years, although sexual maturity often occurs between the first and fourth years. Mortality from predation by fish is low where refuges are abundant but can be high in stream environments.
iii. Despite the long life cycle of crayfish (to 3–4 years), populations often reach high densities (e.g., 15 m^{-2}). Annual production is moderate, however, because of low growth rates.

d. The amphipods, or scuds, are generally omnivorous substrate feeders on bacteria, algae, fungi, and particulate organic detritus; they are restricted to well-oxygenated waters.
i. Size-selective fish predation commonly severely reduces the larger-sized adult amphipods.
ii. The amphipod *Monoporeia* burrows into the sediments and is a surficial deposit feeder during the daylight period. At night, *Monoporeia* migrates into the upper hypolimnion and metalimnion (<15°C), similarly to the mysids. In contrast to the mysids, however *Monoporeia* does not feed on plankton. The adaptive value of its nocturnal migration is unclear.

15. The freshwater mollusks consist of univalve snails (Gastropoda) and bivalve clams and mussels (Pelecypoda).
a. The snails are grazers by rasping movements on attached microorganisms and detrital particles; efficiency of assimilation is highly variable, but mostly in the range of 5–50%. Clams and mussels are filter feeders on particulate detritus and microzooplankton of or near the sediments.
b. Mortality is very high among young snails and bivalve molluscs, particularly by insect, crayfish, and fish predation, but food limitations on fecundity are often a primary mechanism affecting growth and population structure.
c. In spite of the large biomass of mollusks, the life cycle is long (1–4 years in snails; 1–15 years in clams) and productivity is moderate to relatively low. Bivalve molluscs expend much energy in respiration and high reproductive rates. Egg and juvenile mortality is commonly very high in both groups.
d. When bivalve populations reach extreme densities (>50,000 m^{-2}), such as in the case of *Dreissena* and *Corbicula* when introduced exotically into new habitats, filtering activities can ingest between 10 and 50% of summer phytoplanktonic production, creating marked reductions in turbidity and increased water transparency, as well as indirect effects of food competition among other organisms.

16. Aquatic insects are extremely diverse. Some orders of insects are entirely aquatic; others inhabit fresh waters only during certain life stages.
a. Most insects are benthic, living on or burrowing into sediments or on macrophytic vegetation and plant detritus.
b. In nearly all aquatic insects only the immature stages, particularly the nymph and larval stages, live in the water; in nearly all groups the adults, and in some groups the pupae, are terrestrial.
c. Aquatic insects adapt to low dissolved oxygen contentin water by acquiring air from the surface or taking air below water, increasing cuticular permeability to gases, developing tracheal gills, or, in some chironomid dipterans, developing the capacity for anaerobic metabolism.
d. Temperature is a dominant factor influencing the distribution, diversity, and abundance of aquatic insects along elevational gradients and along river courses. The number of generations (voltinism) generally increases with high annual thermal summation.
e. The velocity and characteristics of water movements in the littoral regions of lakes and in streams are dominant regulatory mechanisms of the development, feeding, growth, and reproductive capacities of aquatic insects.
f. Feeding mechanisms and types of food ingested by insects are extremely varied.

i. Organic matter is ingested either in particulate form (by swallowing, biting, or chewing) or in dissolved form (by piercing or sucking) (see Table 22-16).
ii. The association of aquatic insects with particular substrata is usually directly related to feeding on that substratum or on its associated attached microflora.
iii. Most aquatic insects tend to be nonselective in their food habits; a few species feed specifically on a given species of food substrate. Facultative-feeding invertebrates ingest a wider array of food substrates and inhabit a greater diversity of stream and lake habitats than do more specialized feeders.
iv. Assimilation efficiencies by benthic consumers of plant and detrital particles are <50% and most are within 5–30%; efficiencies of ingested animal prey and bacteria are generally higher than of plant and detrital materials. Microbial biomass is usually <10% of total detrital mass.
v. Some immature detritivorous insects harbor microbial symbionts in their alimentary tracts that degrade relatively resistant plant detritus. Species possessing these symbionts or digestive cellulase can utilize a wider range of habitats because they can use a greater array of detritus and algal types than can organisms that lack these adaptations.

g. The biomass of aquatic insects is relatively constant if food supplies of similar nutritional content are available. Insect biomass turnover is controlled primarily by water temperature and is governed by the positive relation between temperature, food availability, feeding rate, and respiration. Abundant food availability increases rates of growth and development. The growth efficiency of carnivores tends to be less than that of herbivores or detritivores.

17. The benthic community structure in lakes usually consists of a rich fauna with high oxygen demands in the littoral zone above the metalimnion. Heterogeneity of substrata is great in the littoral; benthic animal species diversity is greater in the littoral than in the more homogeneous profundal zone. As lakes become more productive, the number of benthic animals adapted to hypolimnetic conditions of reduced oxygen and increased decompositional endproducts declines.
    a. Two maxima in abundance and biomass of benthic animals are often observed—one in the littoral zone, the other in the lower profundal zone.
    b. As lakes become more fertile, submersed macrovegetation can be eliminated as a result of light attenuation. Maximum abundance and biomass of benthic animals may then shift to the profundal zone.
    c. With further eutrophication and intensive organic matter decomposition in the profundal zone, much of the benthic fauna of the profundal zone can be eliminated.
    d. As lakes become more tutrophic, a shift occurs in the percentage composition of two dominant benthic groups, with a decrease in the dipteran chironomid larvae and an increase in the more tolerant oligochaete worms (e.g., tubificids).
    e. The dipteran phantom midge *Chaoborus* is another major component of the profundal benthic fauna of lakes. *Chaoborus* larvae migrate into the open water at night and prey heavily on zooplankton. Feeding on limnetic zooplankton by *Chaoborus* is highly selective.
18. Benthic invertebrates of streams feed largely on algae and other attached microbiota and serve as primary food resources for fish and other vertebrates.
    a. Environmental parameters influencing growth and reproduction include:
        i. Physiological constraints of temperature, dissolved oxygen, and salinity-osmoregulation,
        ii. Constraints of food acquisition and food quality,
        iii. Intra- and interspecific competition and predation, and
        iv. Changing habitats in the substrata and associated food by physical variations in hydrology.
    b. The depth to which invertebrates penetrate sediments is influenced by the availability of attached food resources and decreases as particulate organic carbon among the particles declines.
    c. The relative abundances of invertebrate functional groups shift along a river tributary ecosystem from head waters to the mouth as the food resources change over the length of the river (see Figs. 8-8 and 8-9). Particulate organic matter and shredder insects are commonly maximized in head waters; scraper insect types that utilize increased production of attached algae and cyanobacteria are dominant in the shallow midreaches of rivers.
    d. Benthic organisms can be transported downstream in drift by water currents. Some species rarely drift, whereas others have a marked

propensity. Behavioral drift results from distinct diurnal patterns where maximum drift occurs during darkness when predation is reduced.

19. Composite densities of benthic invertebrates are often lowest during summer, especially among insect-dominated communities, both in streams and in the profundal zone of lakes. In general, biomass and productivity of benthic fauna increase as the overall fertility and productivity of lakes and streams increase.
    a. Mortality of benthic invertebrates from fish predation commonly increases with rising ecosystem productivity, in part offsetting enhanced benthic productivity.
    b. The most common production values among different benthic invertebrate communities (annelids, mollusks, crustaceans, and insects) are between 1 and 10 g DM m^{-2} yr^{-1} (10 and 100 kg DM ha^{-1} yr^{-1}). The annual production of a benthic community in the range of 50 g DM m^{-2} yr^{-1} is high in both lake and stream ecosystems.
    c. Production in running waters is usually at least two times greater than in standing waters.
    d. The productivity of nonpredatory benthic animals (herbivores and detritivores) is at least 5–10 times greater than that of predaceous (carnivorous) benthic animals.
    e. In shallow lakes with relatively low mean depths (2–7 m), zoobenthos production is commonly higher by 2–5 times than is zooplankton production. In larger, deep lakes, zooplankton production commonly equals or exceeds that of the zoobenthos.
    f. Most of the values given for zoobenthos production are conservative underestimates because about half of the total zoobenthos production occurs from the meiofauna (all metazoans <0.5 mm), which are rarely quantified.
    g. Ratios of annual production (P) to mean biomass ($\overline{B}$) for benthic invertebrates vary considerably, but in general $P/\overline{B}$ ratios increase with increasing number of generations per year (voltinism) (see Table 22-28). The relation of this annual $P/\overline{B}$ ratio to voltinism is, in part, related to water temperature, since temperature affects the number of generations in many of the dominant benthic organisms.
    h. Mortality of zoobenthic production by invertebrate predators is usually as great, if not greater, than that of vertebrate predators in many lakes and streams.
20. Although growth among different fish species is highly variable, growth rate and size are generally inversely correlated. In young fish, more energy is diverted into growth, and in larger fish, more food energy is utilized for maintenance.
    a. High production-to-biomass ratios of certain groups of benthic invertebrates are common in both streams and small lakes. The high prey turnover allows relatively high predator growth.
    b. Production rates of fish are considerably higher in tropical fresh waters than in temperate waters, where growth is restricted to about half of the year. In temperate regions, production rates are usually higher in streams than they are in standing waters.
    c. Annual production-to-mean-biomass ratios are higher among fish with shorter life cycles than they are among fish species that have slower growth and longer lifespans. Similarly, in cases where young stages contribute disproportionately to population productivity, annual $P/\overline{B}$ ratios are greater. In general, annual $P/\overline{B}$ ratios are highest among planktivorous fishes, lower for benthic feeders, and least for carnivores.

IX. Summary

I. OVERVIEW OF ORGANIC TRANSFERS AND USES

The trophic structure of aquatic ecosystems has been dominated by evaluations of the rates of energy fixation by primary producers of pelagic communities and of transfer efficiencies of this algal–cyanobacterial energy by feeding to higher trophic levels. Original promulgations of energy flow in communities emphasized restrictions to trophic complexity by limitations of energy transfers among trophic levels (Lindeman, 1942; Hutchinson, 1959; Wetzel, 1995). These relationships of pelagic trophic structure and energy fluxes, however, consider solely particulate organic carbon—the ingestion and utilization of particulate organic matter (POM).

Flows of energy within the trophic structures specifically addressed predation (ingestion of particles of organic matter). As we have discussed in detail in Chapters 16 and 22, decades of ensuing studies of feeding relationships have greatly increased our understanding. In particular, studies addressed variations in size of ingested POM, morphological aspects of ingestion (e.g., filtration and gape), and avoidance of

ingestion (e.g., transparency/visibility, interference by cellular or body projections). Many additional excellent studies addressed behavioral capabilities of organisms for movements within the pelagic zone in relation to refuges or escape from predators, nutritional differences in particulate food, and other factors. Despite recognition that many organisms ingest variable amounts of particulate detritus (dead organic matter) and that particulate detritus usually dominates over living POM of the plankton (e.g., Saunders, 1972), quantitative measures of consumption, assimilation, and residual egestion of detrital POM and its associated microbes remain practically unknown.

From the inception of evolving ecological constructs, early trophic dynamics, particularly among lakes, emphasized integration and interdependence among biotic components internally, but these dynamics were entirely predation based (see Chap. 16). As the metabolism of community components was analyzed with increasing accuracy, however, flux pathways and rates of transfer of organic carbon demonstrated a number of complexities and inconsistencies that could not be explained within the conventional food-web paradigms. Early carbon budgets demonstrated the importance of allochthonous dissolved organic carbon (DOC) from terrestrial, wetland, and littoral production. For example, the total annual budget of carbon fluxes of several lakes demonstrated that most of the DOC was relatively recalcitrant DOC derived from structural tissues of terrestrial and higher aquatic plants, even though higher aquatic plants colonized only small portions of the benthic area (discussed in greater detail later). Importantly, most of the heterotrophic respiration of organic matter occurred in the sediments, with a massive net evasion of CO_2 to the atmosphere.

Predation by ingestion of living particulate organic matter is not the prevailing cause of mortality of organisms. In addition, and also of great ecosystem significance, assimilation efficiencies of ingested food are modest at best under natural conditions (usually $<<50\%$), and much of the ingested organic matter is released or egested as both soluble and particulate detrital organic matter. Furthermore, commonly $>90\%$ of the total organic matter produced within the ecosystems or imported to the ecosystems are metabolized but are never consumed by particulate-ingesting metazoans. Recognition of this reality has been agonizingly slow, or, alternatively, it is acknowledged but completely ignored as the predation emphasis continues. Effective management of aquatic ecosystems is difficult and certainly imprecise if most of the metabolism, energetic fluxes, and control mechanisms of that microbial metabolism are poorly understood and separated from higher trophic levels.

The evaluation of organic carbon budgets of rivers, particularly among low- and medium-order streams, demonstrated that running waters are heterotrophic and allochthonously mediated ecosystems. These evaluations have assisted in erosion of the autochthonous dogma of lakes. Nonetheless, despite organic carbon budgets that indicate up to 99% of organic matter fluxes within aquatic ecosystems are detrital-based, the predation-based paradigms continue to prevail as the primary constructs of ecosystem operations, whereas in reality they are the minority. Essentially, all inland water ecosystems are microbially based heterotrophic ecosystems in which heterotrophic utilization of organic matter within lakes and streams exceeds—usually greatly exceeds—autochthonous autotrophic production.

A general consensus has emerged concerning the functions of dissolved (DOM) and particulate (POM) organic matter in aquatic ecosystems (Wetzel, 2000a). Two important changes in thought have arisen. Sealing a lake or river off from its drainage basin would drastically alter metabolism and biogeochemical cycling within it. Although lakes and rivers are frequently referred to as ecosystems, important influences of the drainage basin, particularly imported detrital organic matter, intimately link lakes and rivers with their surrounding terrestrial and wetland environments. A lake and associated inlet rivers themselves are only individual components of a larger landscape unit, the lake ecosystem, which must include the entire drainage basin of the lake per se. Clearly, inland water systems are being treated as integrated ecosystems with the increasing and full appreciation that the metabolism of lakes and rivers is dependent to a major extent on metabolism in the adjacent drainage basin.

Second, commonality of function is found amidst the plethora of individual habitat and biotic diversity (Wetzel, 1995, 2000a,b). This important merger is especially evident in the recognition that processes are functionally similar in freshwater and marine ecosystems. Differences between these ecosystems are apparent because of differences in the sources of organic matter, which affect the rates of utilization, not the process of utilization. The rates of utilization differ because of the dominance of more recalcitrant organic substrates in inland water ecosystems, as discussed here.

II. DEAD ORGANIC MATTER: THE CENTRAL ROLE OF DETRITUS

A. Carbon Content and General C:N Ratios

Nearly all of the organic carbon of natural waters consists of dissolved organic carbon (DOC) and dead particulate organic carbon (POC). DOC has been

separated from POC by many techniques (e.g., sedimentation, centrifugation, and filtration). However, DOC is defined arbitrarily in most studies by the practical necessity of fractionation of POC from DOC by filtration at the 0.5-μm size level; hence, DOC concentrations frequently include a significant colloidal fraction in addition to truly dissolved organic carbon (e.g., Lock *et al.*, 1977; Gustafsson and Gschwend, 1997). Living POC of the biota constitutes a very small fraction of the total POC. The metabolism of the biota, however, creates a series of reversible fluxes between the dissolved and particulate phases of detrital carbon.

Detrital DOC and POC have long been known to exceed by many times the amount of organic carbon present as living material in the form of bacteria, plankton, flora, and fauna (Birge and Juday, 1926, 1934; Saunders, 1969; Wetzel *et al.*, 1972). An example from a lake in southeastern Michigan demonstrates the general relationships found among many lakes and rivers (see Fig. 17–9). The amount of carbon in higher organisms is even smaller than the smallest amount indicated in Figure 17–9, and is trivial ($\ll$1%) in comparison to the whole amount of carbon in the lake. In some lakes that receive large amounts of allochthonous dissolved organic matter, such as large, deep Loch Ness of Scotland with soft water of low alkalinity, total carbon is dominated by DOC and constitutes some 70% of the total (Jones *et al.*, 1997). These relationships are instantaneous measures of chemical mass, however, and, as indicated earlier, bear little relationship to the metabolic fluxes of carbon.

In spite of the relatively crude techniques for separation of particulate from dissolved organic matter and the approximate chemical analyses available to earlier workers on the subject, the massive data of Birge and Juday (1926, 1934) on a large number of Wisconsin lakes provide an initial orientation to general relationships. Seston consisting of living and mostly dead particulate organic matter was separated by centrifugation from colloidal organic matter and true DOC. The organic matter was analyzed for proteinaceous nitrogen and other nitrogen-containing compounds, lipids present in ether extracts, and the residual carbohydrate. The range of total organic carbon content of natural open waters is generally in the range of 1–30 mg C liter^{-1}. Higher values usually are encountered in very productive habitats, such as shallow waters of wetlands, and under organically polluted conditions. The average values from over 500 Wisconsin lakes were: dissolved organic matter 15.2 mg liter^{-1}, and particulate organic matter 1.4 mg liter^{-1}, a ratio of 11:1 (cf. Meybeck, 1982; Wetzel, 1984; world DOC average of rivers is 5.8 mg C liter^{-1} and of all surface waters 6.5 mg C liter^{-1}). Variations among different habitats, however, are very large (Table 23-1). The average composition of the dissolved organic matter (detailed in Table 12-8 of the earlier discussion on dissolved organic nitrogen) was crude protein 15.6%, lipid material 0.7%, and carbohydrate 83.7%.

Stokes's law states that spherical particles of a given density sediment through water at a rate directly proportional to the square of their radii. Both POC and DOC move with water, but nondecomposed POC ultimately will be deposited at the bottom of static water. If associated with inorganic particulate matter, DOC will also sediment, for example, when it is adsorbed to clay, organic, or $CaCO_3$ particles. These factors result in a displacement of some terrestrial production to the littoral zone of lakes with surface runoff and ground water. Littoral and pelagic production can also be largely displaced as detritus to the benthic sediments of lakes.

TABLE 23-1 Median Organic Carbon Content *of the Water* of Natural Aquatic Ecosystems[a]

Habitat	*Total organic carbon (mg liter^{-1})*	*Dissolved organic carbon (mg liter^{-1})*	*Particulate organic carbon (POC)*	*DOC:POC ratio*
Open ocean	0.5	0.45	0.05	9:1
Ground water	0.7	0.65	0.05	13:1
Precipitation	1.1	1.0	0.1	10:1
Oligotrophic lakes	2.2	2.0	0.2	10:1
Rivers	7.0	5.0	2.0	3:1
Eutrophic lakes	12.0	10.3	1.7	6:1
Wetlands–marshes	17.0	15.3	1.7	9:1
Bog water	33.0	30.3	2.7	11:1
World average, surface waters	—	6.5	0.6	10:1

[a] Extracted from Thurman (1985), Wetzel (1984), Hessen and Tranvik (1998), and Keskitalo and Eloranta (1999).

In terms of energetics of the ecosystem, the medium of exchange is detritus; functionally, POC and DOC are equivalent. These two detrital fractions are merely arbitrary divisions within a smooth continuum of large particles to small molecules (Rich and Wetzel, 1978). Although the specific nature of the detritus modifies the way in which it is utilized and its effects upon the environment, detritus inevitably carries energy from its point of origin to its place of transformation.

B. Composition of Organic Matter

Before discussing our limited knowledge of the utilization and degradation of detrital DOM and POM in river and lake ecosystems, a brief consideration of the heterogeneous composition of such materials must be presented. Detailed early reviews, including Vallentyne (1957) on the distribution and composition of organic matter in lakes, Breger *et al.* (1963) on organic geochemistry of all major components, and Konanova (1966) on soil organic matter, are especially recommended. Numerous compendia have appeared on organic matter in natural waters (e.g., the lengthy summations of pelagic and littoral organic compounds of Datsko, 1959; Duursma, 1961; Hood, 1970; Khailov, 1971; and particularly Thurman, 1985. Freshwater symposia include, for example, Maistrenko, 1965; Shtegman, 1969; Trifonova *et al.*, 1969; and Faust and Hunter, 1971. Humic substances in water are reviewed comprehensively by Swain, 1963; Haworth, 1971; Schnitzer and Khan, 1972; Gjessing, 1976; Stevenson, 1982; Aiken *et al.*, 1985; Hayes *et al.*, 1989; Suffett and MacCarthy, 1989; Purdue and Gjessing, 1990; Drozd *et al.*, 1997; Keskitalo and Eloranta, 1999; and especially Hessen and Tranvik, 1998.

The organic matter of soils and waters can be viewed as a mixture of plant, microbial, and animal products in various stages of decomposition; it consists of compounds synthesized biologically and chemically from degradation products and of microorganisms and their remains in various stages of decomposition. This complex system may be simplified by separation into two categories: nonhumic and humic substances (Aiken *et al.*, 1985; Thurman, 1985).

a. ***Nonhumic substances*** are a class of compounds that includes carbohydrates, proteins, peptides, amino acids, fats, waxes, resins, pigments, and other low-molecular-weight organic substances (see discussion in Chap. 17). These substances generally are labile, that is, relatively easily utilized and degraded by hydrolytic enzymes produced by microorganisms, and often exhibit rapid flux rates. Because of relatively rapid rates of utilization and turnover, the instantaneous concentrations of nonhumic substances in water are usually low.

b. ***Humic substances*** form most (70–80%) of the organic matter of soils and waters. Humic substances are naturally occurring, biogenic heterogeneous organic substances that are generally dark-colored (yellow to black), recalcitrant to biological degradation, and high in molecular weight (from hundreds to many thousands of daltons). Humic substances are formed largely as a result of microbial activity on plant material, but further polymerization can occur abiotically (cf. Larson and Hufnal, 1980; Haslam, 1998). The resulting compounds are relatively resistant to further microbial degradation and tend to have low turnover rates in aquatic systems.

1. Humic Substances

Humic substances are traditionally separated into three categories, each of which is defined in terms of acid-base–solubility characteristics of the materials when extracted into an alkaline solution: (1) ***Humic acids*** precipitate in water upon acidification (pH 2), but are soluble at greater pH; (2) ***fulvic acids*** are soluble at any pH value; and (3) ***humin*** is insoluble in water and in dilute solutions at any pH value. These three fractions have certain structural similarities but differ from one another in molecular weight and functional group content. Fulvic acids are of lower molecular weight than humic acid or humin fractions and have a higher proportion of oxygen-containing functional groups. This fractionation scheme is arbitrary; the individual fractions are all heterogeneous mixtures of various substances (sugars, carbohydrates, phenols, proteins, et cetera), whose specific compositions vary with the source material and its state of degradation.

High-molecular-weight humic materials exhibit a colloidal structure that is important in the physical behavior of humic solutions. The colloidal particles (approximately 0.02 μm in size) exhibit Brownian movement and can be fractionated by ultrafiltration, dialysis, gel permeation chromatography, ultracentrifugation, or electrophoresis. The molecular weight of humic substances influences their proton and metal binding characteristics, partitioning behavior, and adsorption properties (Gustafsson and Gschwend, 1997; Cabaniss *et al.*, 2000). Average molecular-weight (MW) distributions of aquatic fulvic acids vary from 2.7 to 3.7 kD and include low-MW fractions of 1110 D and a high-MW fraction of ca. 4890 D. Less than 10% of dissolved humic substances were found to be >5 kD. The low-MW fractions are more hydrophilic, exhibit faster diffusion and increased mobility, and are commonly more bioavailable. In contrast, the high-MW components have increased uptake of hydrophobic

organic compounds, greater aromatic components, decreased mobility and diffusion, and are usually appreciably less susceptible to biological utilization. Molecular-size fractionation helps little in evaluation of bioavailability of different compounds, particularly above the size of effective cellular membrane permeability of ca. 500 D to transport of organic molecules. Bonding structure, particularly of the carboxyl group (C = O) and of aromatic components, and availability of sites for enzyme hydrolysis are of greater importance.

A basic characteristic of the humic colloids, as well as of truly dissolved humic and fulvic acid fractions, is their association with organic and inorganic materials via adsorption or peptization. The importance of the association of humic materials with Fe, P, Ca, and other ions has already been indicated in previous chapters. The pH and ionic strength of the solution governs both the extent of condensation and colloidal size, as well as the availability of adsorption sites.

Colloidal humic materials provide a very large surface area that is suitable for the adsorption of both inorganic and organic materials (e.g., Poirrier *et al.*, 1972; Stevenson, 1972; Seitz, 1982). Consequently, humic materials can fundamentally alter the availability of required or toxic metals and organic substances to aquatic biota. The binding of herbicides or pesticides (e.g., DDT) to humic materials, for example, can significantly change transport, fate, and bioaccumulation characteristics of these toxicants. Humic constituents can also link normally thermodynamically discrete redox couples by functioning as broad redox potential "flavoproteins" (Zimmerman, 1981). This feature can facilitate the oxidation or reduction of a number of biologically important substances (e.g., Miles and Brezonik, 1981; Francko and Heath, 1982; Gustafsson and Gschwend, 1997).

Humic material of the series humic acid–hymatomelanic acid (an alcohol-soluble component of humic acid)–fulvic acid–humin consists of polymeric micelles whose basic structure is aromatic rings that are variously bridged into condensed form by —O—, —NH—, —CH_2—, or —S— linkages (Swain, 1963; Schnitzer and Khan, 1972). Attached hydroxy and carboxyl groups provide acidity, hydrophilic properties, base-exchange capacity, and tanninlike character (e.g. they react with proteins). Fulvic acid is the least polymerized of the fractions, while humin is the most condensed humic component. Fulvic acid is highly oxidized, stable, and water soluble (Schnitzer, 1971). About 60% of the weight of the fulvic acid fraction is composed of functional groups such as carboxyls, hydroxyls, and carbonyls attached to a predominantly aromatic nucleus ring structure. Fulvic acid is a naturally occurring metal complexing agent that can bring di- and trivalent metal ions into stable solution from practically insoluble hydroxides and oxides. Carboxylic acid groups are of major importance in natural organic matter because they dominate the acidity and contribute to the solubility of the compounds.

Recently, structural information of humic substances has been increasingly examined with ^{13}C nuclear magnetic resonance (NMR) spectroscopy, which yields structural information of mixtures of organic compounds. Major bands in the spectra indicate functional groups (Table 23-2) and allow examination of variations in relative intensities of different groups in relation to differences in sources and biogeochemical transformations. For example, one could examine increases in aromatic carbon content (110–160 ppm) as dissolved organic matter from plant sources moves downgradient through a stream and wetland to a lake.

Analyses of chemical constituents of humic and fulvic acids can be further examined by pyrolytic thermal degradation of bonds and analysis of the fragmented chemical products by gas chromatography and mass spectrometry. These properties and proportions of various functional constituents, such as carboxyl, phenol, and methoxyl components, allows reconstruction of potential source materials. That is, the chemical composition of the fragments allows reconstruction of

TABLE 23-2 Spectral Regions for Different Functional Group Carbon Atoms in ^{13}C-NMR Spectra of Plant and Microorganism Tissue and Natural Organic Substances[a]

Designation	*Spectral regions (ppm)*	*Functional group carbons*
AL-I	0–62	Aliphatic carbons
AL-II	62–90	Alcoholic carbons in carbohydrates and other aliphatic alcohols and ethers
AL-III	90–110	Anomeric carbons in carbohydrates and some aromatic and olefinic carbons
AR	110–160	Aromatic and olefinic carbons
C-I	160–190	Carboxylate and amide carbons
C-II	190–230	Carbonyl carbons in aldehydes and ketones

source materials and interpretation of potential sources of the organic compounds.

Humic substances contain a variable amount of nitrogen (1–6%), which is largely hydrolyzable to amino compounds. Most of the combined amino acid nitrogen occurs in amino acid–peptide linkages. The remainder is in the form of amino sugars, ammonia, and amine linkages.

2. Formation of Humic Compounds

Cellulose and lignin in plant structural materials account for the largest portion of organic material and humic compound formation. In spite of the diversity of vegetation types, a general similarity of the constituent functional groups is found during decomposition of detrital organic materials (McKnight and Aiken, 1998). The formation of humic substances occurs during the degradation of plant material; both microbiological and abiotic processes contribute to its production. Carbohydrates serve as the main microbial source of energy and carbon in the intercellular synthesis of protein and hemicellulose.

Lignin contains abundant aromatic rings and no nitrogen. Degradation of lignin in plant structural material is carried out by a limited number of microorganisms, primarily fungi under aerobic conditions. Polyphenolic lignin of higher plant tissues is modified during this degradation, and humiclike substances of high molecular weight result (Zeikus, 1981; McKnight and Aiken, 1998). By means of extracellular enzymes and abiotic processes, decomposition products are further partially degraded and oxidized, which results in soluble macromolecules enriched with carboxylic and other oxidized functional groups. Further degradation of these compounds results in the generation of humic and fulvic acids and various products of decomposition (e.g., fats, amino compounds, CO_2, CO, H_2, CH_4, N_2, NH_3, and H_2S). Additional polymerization of the decomposition products can occur on the surfaces of clay particles (Wang *et al.*, 1978; Larson and Hufnal, 1980; Steinberg and Münster, 1985). Autolysis of the microorganisms themselves represents a major source of humiclike substances.

It is clear that the fungi play a major role in the degradation of plant material and the synthesis of humic substances. Fungi, as well as cellulolytic actinomycetes and myxobacteria, enzymatically oxidize lignin-derived polyphenols, which condense with proteinaceous degradation products to form humic acids. Humic substances of terrestrial plant and soil systems form largely from cellulose and lignin. Mainly fungi degrade celluloses, hemicelluloses, and lignin of needles and other products of conifers. This coniferous litter is easily leached, especially of organic acids (Nykvist, 1963). Litter of deciduous vegetation, however, is decomposed more readily by fungi and bacteria to lignoprotein complexes. When allochthonous inputs of particulate organic matter from higher plants are large, as in the case of many river systems and many lakes with extensive littoral vegetation, fungi clearly dominate the degradation of lignified and cellulolytic tissue for subsequent bacterial decomposition. In the open water of lakes, in which autotrophic production by algae results in plant constituents composed mainly of hemicelluloses, proteins, and carbohydrates, cellulolytic activity is reduced. As would be anticipated, fungal populations are well developed in sediment accumulations, in littoral regions of higher plant densities, and in streams receiving large amounts of terrestrial plant debris. Sparrow (1968) and Suberkropp (1992) provide excellent reviews of the distribution and general ecology of the freshwater fungi.

The phenols, quinones, phenolic carboxylic acids, and related compounds, common constituents of humic substances, can be inhibitory to bacterial fermentation and to fungi. These inhibitory compounds, and associated acidity and resultant low redox potentials, frequently lead to accumulations of humic substances undergoing very slow rates of degradation. The antiseptic qualities of humic substances from plant remains result in accumulations in topographical depressions—for example, in the peat of bogs and lake sediments—over long periods of time without significant degradation. The superb preservation of human bodies placed into peat bogs in Europe over 2000 years ago (Glob, 1969) attests to the effectiveness of these combined properties and conditions.

C. Flocculation of Dissolved Organic Matter—Shift to Particles

Dissolved organic compounds, particularly in the colloidal size range of ca. 1 nm to 1 μm, can aggregate by a number of different processes. Flocculation, a generic term covering all aggregation processes, refers to the formation of a particle larger than 1 μm on which gravity dominates over colloidal interactions (Gregory, 1989; Buffle and Leppard, 1995). Hydrophilic colloids are thermodynamically stable and can be induced to aggregate and precipitate only by changing solvency conditions, such as by temperature changes. Hydrophobic colloids consist of substances of low solubility that exist in a finely divided state in water and remain kinetically stable by interparticle repulsion. This repulsion is usually electrical and most aqueous colloids are charged.

Flocculation occurs when particles collide and can adhere. An attractive energy from van der Waals forces is balanced by repulsion from negative electrical

charges borne by most natural colloids. In many cases, hydrophobic particles will have a hydrophilic surface in the sense that it can be wetted by water. Hydrogen-bonded water molecules, for instance, hydrate insoluble oxides. Increased inorganic ionic salinity can give a lower colloidal stability for hydrophobic charge-stabilized colloids by reduction of both the effective surface potential and the extent of the diffuse layer surrounding the compounds. Aluminum and iron salts, commonly used in water treatment facilities, remove dissolved organic matter, especially high-molecular-weight humic substances, in which a colloidal metal-humate complex flocculates to a precipitate. Multivalent cations (Fe^{3+}) are more effective in flocculating ability than mono- and divalent cations (Na^{+} and Ca^{2+}) (Liu and Shei, 1991). An increase in temperature will also increase coagulation. The smallest colloids (<100 nm) coagulate into aggregates in the size range of 0.1–10 μm. Particles larger than 10 μm rapidly settle by sedimentation.

Many different types of aggregations are found, varying with source materials and conditions of flocculation. Colloidal constituents include biological debris, particularly from algae and cyanobacteria (Strycek *et al.*, 1992), iron oxyhydroxides, calcium carbonates, clays, amorphous silica, polysaccharides and other fibrillar material, gel-like organic material, and soil-derived fulvic and humic compounds (Buffle and Leppard, 1995). The proportion of organic matter increases with decreasing sizes of the colloidal material. Loose aggregates (flocs) can be formed by binding of several colloids and bridge together with other living or dead cells or particles. The structure, size, density, and formation rates of these flocs depend on the macromolecules, their relative length compared to colloid size, and relative concentrations of each.

A number of physical processes increase colloidal and particle collisions and probability of adhesion (particle stickiness) (O'Melia and Tiller, 1993; Kepkay, 1994): (a) Brownian motion, (b) shear from laminar or turbulent flows, (c) differential settling of large particles that collide with smaller particles, (d) diffusive capture of smaller particles within the boundary layer of larger particles, (e) aggregation of colloids (surface coagulation) at the gas–water interface by rising bubbles, (f) scavenging of small colloids by filtration as water passes through rapidly sinking porous macroaggregates ("lake snow"), and (g) bacterial motility in which swimming bacteria (to 30 μm s^{-1}; Lauffenberger, 1983) collide with colloids by interception rather than by diffusion. Aggregation into macroparticles can then occur with the formation of organic precipitates (lake snow).

The amorphous particles of organic coagulated precipitates contain appreciably less recalcitrant organic matter than do morphologically distinguishable particles (range of 10–100 μm) that are clearly plant fragments (Bowen, 1979, 1984). The colloidal organic matter, some of which is certainly in microaggregated particles, is clearly susceptible to appreciable degradation by bacteria (see Middelboe and Søndergaard, 1995). The amorphous particles are also more digestible when treated with simple digestive enzymes than are morphous particles and support better growth of detritivous animals. The role of these amorphous aggregations in the energetics of higher trophic levels remains unclear but is likely considerably underestimated. In some cases, higher animals, such as black fly larvae, appear to be able to induce aggregation of amorphous particulate organic material by passing water containing DOM in sufficient quantities to support growth (Ciborowski *et al.*, 1997).

III. ALLOCHTHONOUS ORGANIC MATTER

The sources and composition of organic matter are diverse and poorly understood. Production of dissolved and particulate organic carbon is a result of autotrophic synthesis and partial heterotrophic metabolism. Instantaneous measurements of the chemical mass of DOC and POC, however, are highly biased toward recalcitrant[1] compounds, that is, compounds that are relatively stable chemically, of low solubility, and slowly degraded microbially. These recalcitrant components of detrital organic carbon persist in inland waters for longer periods of time than do more labile organic compounds. The readily utilizable labile components cycle rapidly at low equilibrium concentrations but can represent major carbon pathways and energy fluxes. Moreover, in streams and most lakes, much of the detrital organic carbon, mostly dissolved, originates from terrestrial, wetland, and littoral-zone plant sources.

Most lakes are small, with a high proportion of their surface area being littoral zone. The flood plain and streamway adjacent to river channels also constitute large areas of littoral and wetland areas of high productivity of aquatic plants and terrestrial vegetation that are tolerant of wet soils. Allochthonous and littoral sources of dissolved and particulate detrital carbon form major inputs to both the lacustrine and river ecosystems, and these sources of organic compounds

[1] The word *recalcitrance* connotes contumacious reduction in capabilities for microbial degradation, usually related to the chemical structure of the organic matter (Alexander, 1965b) and is used in preference to *refractory*. Although interpretations vary, the term *refractory* often implies chemical resistance and nondegradability, which is not true in these natural ecosystems.

and energy markedly influence metabolism of organisms in the open-water in-lake, and in-stream communities. In streams, dissolved organic carbon is decomposed by both the benthic microflora and the planktonic bacteria (Cummins *et al.*, 1972; Wetzel and Manny, 1972b; Dahm, 1981). In the relatively static waters of lakes, gravity acts as an important selective agent by which sedimentation displaces a major portion of carbon and its metabolism to the sediments (Vallentyne, 1962; Wetzel *et al.*, 1972). To adequately assess the importance of the complex carbon cycle that is central to both the structure and function of lakes and streams, one must know of the productivity of all components of the ecosystem and have an understanding of the origins and metabolism of detrital organic carbon from all sources.

The importance of these and related studies to the present discussion is their relationship to the amount of allochthonous organic carbon entering most lakes from terrestrial, wetland, and littoral areas and to the qualitative changes in composition of this organic matter en route, usually in streams and ground water and then often littoral zones, to the pelagic zone. For example, humic and fulvic acids constituted over 60% of the riverine dissolved organic carbon (DOC) in the Amazon River, where fulvic-to-humic-acid ratios in the mainstem river averaged 4.7 (Ertel *et al.*, 1986). All of the dissolved humic and fulvic acids had clearly recognizable lignin components at levels (8 and 3% of the carbon, respectively) suggesting a predominantly allochthonous source from higher plant tissues. Fulvic acid substances had consistently lower lignin levels, lower lignin phenol methoxylation, higher acid:aldehyde ratios, and higher C:N ratios than coexisting humic acids—all indicative of greater aerobic degradation rates of the fulvic acid fractions. At least 40% of the total fluxes of carbon were associated with dissolved humic substances in the Amazon River. This situation is likely common among most stream and river ecosystems.

As the total organic matter of lake water increases, the percentage in the dissolved fraction increases disproportionately to that of the particulate fraction. The nitrogen content of the organic matter decreases progressively with increasing DOC concentration and similarly declines as the proportion of allochthonous to autochthonous organic matter increases. As a result, the organic C:N ratios increase—a reflection of an increased input of organic compounds low in nitrogen as well as decreased decomposition rates of the more recalcitrant organic compounds.

Dissolved organic matter of allochthonous origin contains a very low percentage of nitrogen (C:N about 50:1), while that produced autochthonously within the lake by algae and some macrophytes has a much higher initial nitrogen content (C:N about 12:1). Much of the DOC originating allochthonously from terrestrial and marsh plants is totally dominated by fulvic and humic acids that originate from the structural tissues of higher plants. Numerous studies have shown a nearly linear relationship between color units (Chap. 5) and dissolved organic matter or carbon. That color is associated with the chromophoric molecules of largely humic and fulvic acids of the colloidal or high-molecular-weight fractions of truly dissolved organic carbon (cf. Black and Christman, 1963; Stewart and Wetzel, 198la).

Chromophoric dissolved organic matter (CDOM) is an optical definition for that portion of DOM that is able to absorb solar radiation. The molecular components, ***chromophores***, absorb UV radiation, and conjugation of chromophores results in absorption of solar radiation >290 nm. The concentration of CDOM, as indicated by the color of water, often correlates with the concentration of DOC (Juday and Birge, 1933; Birge and Juday, 1934), which indicates that CDOM is a major constituent of total DOC. Humic substances constitute a major portion of CDOM.

As CDOM absorbs UV and visible radiation, the molecules are electronically excited, which may lead to photochemical reactions that can modify the bonding structure of the macromolecules. Some of the energy is released as heat and some as emission of photons in fluorescence. Quantum yields for fluorescence are ca. 1% and have been found to vary little (<2.5-fold) in natural waters (Green and Blough, 1994). In some indirect photochemical reactions, the primary absorbing CDOM transfers energy to another molecule, such as oxygen, before returning to its ground state. The CDOM-initiated photochemical reactions in surface waters can mineralize organic compounds with the generation of CO_2, CO, NH_4, and PO_4. Photochemical reactions can covert DOC to dissolved inorganic carbon rapidly (Miller and Zepp, 1995) with simultaneous loss in absorption of UV and visible light by CDOM and in the quantum yields for photochemical reactions (Lean, 1998; Andrews *et al.*, 2000). In clear lakes with low DOC concentrations, DOC is not as strong a predictor of the attenuation coefficients for UV radiation. The photochemical reactions can also modify DOM by partial photodegradation with a reduction of molecular weight and an increase in bioavailability of the organic compounds.

The colloidal fraction of measured "dissolved" organic matter was often considered small (Krough and Lange, 1932), but because many humic substances can be large macromolecules and occur in aggregations, the colloids can constitute a significant fraction in waters

TABLE 23-3 Annual Average Particulate, Colloidal, and Dissolved Organic Fractions of Lake Furesø, Denmark[a]

Organic fraction[b]	*Total dry weight*[c] (*mg liter*$^{-1}$)	*Organic weight*[c] (*mg liter*$^{-1}$)	*Crude protein* (%)	*Lipid material* (%)	*Carbohydrate* (%)
Particulate	2.1	1.56	53.2	9.9	36.9
Colloidal	3.6	0.67	41.5	11.7	46.8
Dissolved	Approx. 70	8.8	37.5	—	62.5

with moderate-to-high concentrations of dissolved organic matter (see p. 734). Nitrogen content decreases and carbon content increases in the progression from particulate to colloidal to truly dissolved organic matter fractions (Table 23-3). The colloidal fraction is high in lakes rich in DOC, such as bog waters, and in hard waters in which organic compounds are adsorbed onto carbonate particles (cf. Ohle, 1934b; White, 1974; White and Wetzel, 1975).

Both allochthonous and autochthonous sources of detrital particulate organic matter (POM) and dissolved organic matter (DOM), therefore, constitute variable inputs to aquatic ecosystems. As is emphasized repeatedly in this synthesis, POM tends to remain near sites of production. Lateral transport of POM is small, relative to DOM transport, in terrestrial soils, and in land–water interface zones such as flood plains, wetlands, and littoral areas. As we have seen earlier (Chap. 21), even in streams, large POM is often retained (snags and debris dams) and transport is mainly via DOM and fine POM. Transport of DOM is the primary movement of allochthonous organic carbon and energy to all aquatic ecosystems (Wetzel, 1993, 1995).

Authochthonous sources within the lake or river supplement the allochthonous inputs and include

1. Littoral photosynthetic sources of POM and of DOM by active secretion, decomposition, and lysis of the macrophytes and attached algae and cyanobacteria
2. Primary producers of the open-water zone, primarily the algal and cyanobacterial phytoplankton. Under some circumstances, sulfur photosynthetic and chemosynthetic bacteria are also significant sources of organic carbon.

Rapid transformations between POC and DOC by heterotrophic microflora progressively degrade organic matter to CO_2 and heat. The amount of organic carbon utilized and transformed by animals is a quantitatively small portion (<10%) of that of the whole ecosystem. Most of the heterotrophic metabolism, which is almost entirely microbial, occurs both in the open water and in the sediments. Because so much detrital organic matter from pelagic and littoral sources is displaced to the sediments, much heterotrophic decomposition occurs in benthic sediments. The benthic region is the dominant site of organic carbon transformation to CO_2 in most lake ecosystems, especially as depth and volume decrease, in most reservoir ecosystems, and in all river ecosystems.

A. Allochthonous Organic Matter from Terrestrial Sources and within Streams

Terrestrial plants form much of the allochthonous organic matter of aquatic ecosystems. The organic carbon of residues of plant structural tissues is transformed variously by microbial utilization and degradation both at the sites of growth and while the organic matter is being transported by runoff ground water and vadose-surface water. Most (>95%) of the organic matter produced in the terrestrial portions of the drainage basin remains at the sites of production and is largely decomposed (Fisher and Likens, 1977; Dosskey and Bertsch, 1994). Little is stored permanently. Export of nondecomposed organic matter is largely as dissolved organic compounds in runoff and ground water. There is large variability in dissolved organic carbon (DOC) concentrations in terrestrial soils along this flow path (Cronan and Aiken, 1985; McDowell and Likens, 1988; Mulholland *et al.*, 1990; Nelson *et al.*, 1993; Hope *et al.*, 1994; Webster *et al.*, 1995; Kalbitz *et al.*, 2000; Magill and Aber, 2000).

When anthropogenic inputs of organic matter are low to rivers, concentrations of inorganic nitrogen are usually low and dissolved organic nitrogen (DON) is the primary form of nitrogen (Hedin *et al.*, 1995; Stepanauskas *et al.*, 1999, 2000). Much of that DON (to 70%) is bioavailable. Spring flooding from snowmelt is frequently a major hydrological event, and in some boreal rivers >50% of the annual water discharge may occur in a few weeks. During spring floods,

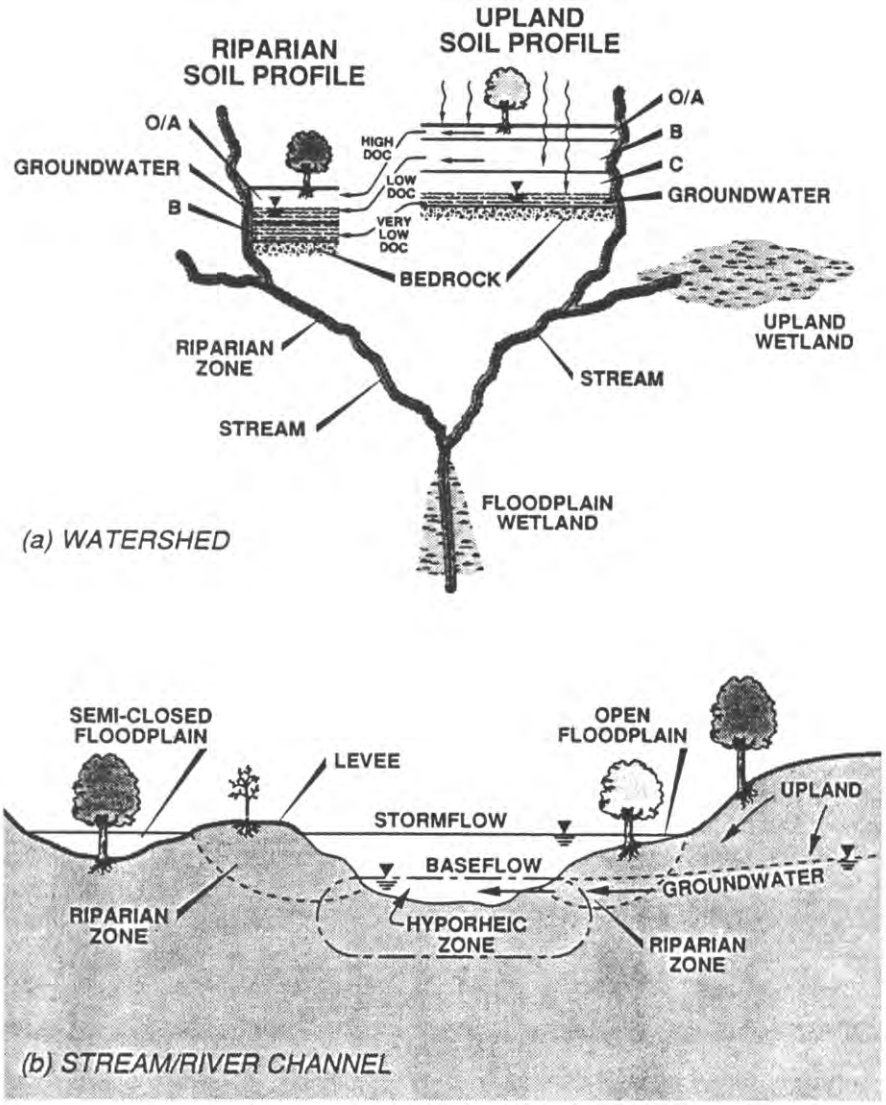

FIGURE 23-1 Potential dissolved organic carbon sources and hydrologic linkages with the stream/river at (a) the drainage basin (watershed) and (b) floodplain/channel spatial scales. (Extracted from Mulholland *et al.*, 1990.)

DON fluxes may exceed the baseflow fluxes by several orders of magnitude. During the flooding period, DON bioavailability increases markedly and has been correlated directly with increased concentrations of amino acids and related compounds.

Highest DOC concentrations occur in surface soil horizons (O and A) as a result of inputs from throughfall of the vegetation canopy and decomposition of surface POM (Fig. 23-1a), and tend to be much greater in forest soils among coniferous vegetation than among hardwood trees. Many humic substances of plant origins form microaggregates with clay-sized particles, which tend to reduce alteration by microbes (Clapp and Hayes, 1999). Removal of terrestrial vegetation, such as by clear cutting of forests of a drainage basin or removal of riparian vegetation for agriculture, reduces the inputs of organic matter to the soils and reduces the release of DOC in runoff to streams (Meyer and Tate, 1983; Delong and Brusven, 1994; Guyot and Wasson, 1994).

Seasonally, the concentration of DOC in soil leachates is inversely correlated with temperature. Additionally, warm temperate and tropical communities are more productive than those of temperate regions, but oxidation of organic matter of forest origin is rapid and reduces DOC concentrations in leachates. Hence, the mean DOC concentrations of streams among the tiaga is much greater (ca. 10 mg liter^{-1}) than from other upland habits (see Table 23-1), exceeded only by the DOC of swamps and wetlands (Thurman, 1985).

Concentrations of DOC decline steeply in lower soil horizons (B and C), primarily because of adsorption and coprecipitation in mineral soils with iron and aluminum sesquioxides (McDowell and Wood, 1984; David and Vance, 1991; Kaiser and Zech, 1998). Rates of microbial respiration in the upper soil horizons, especially B, indicate constant renewal of adsorption sites occurs as adsorbed DOC is utilized. Where soils, such as tropical podsols, do not have an iron-rich clay horizon, large quantities of DOC, particularly hydrophobic DOC, can be released. It is also probable that organic acids of root exudates from terrestrial vegetation can alter stereochemical hydrophobic arrangements within micellelike conformations of humic substances (Piccolo *et al.*, 1996; Nardi *et al.*, 2000). Organic compounds adsorbed to the soil can then be mobilized and released.

As DOC moves laterally within soils in gravity flows along decreasing elevation levels and reaches the floodplain and riparian soils, further changes occur (Fig. 23-1b). The DOC moving through soil particles is subject to continual microbial degradation and becomes progressively more recalcitrant. For example, over half of the DOC leached from soils was found to be readily biodegradable by soil microbes (Baker *et al.*, 2000). Indeed, the concentrations of DOC are reduced appreciably by microbial degradation. Despite this utilization in soil and groundwater flows, concentrations of dissolved organic carbon and nitrogen are often significantly higher in ground water than in surface water (Ford and Naiman, 1989).

During baseflow conditions of low-flow inflows, microbial activity of flood plain and subsurface ground water can be limited by DOC availability. DOC concentrations of subsurface flows tend to be positively correlated with discharge within the river channels and decrease with greater distances from the head of entry places, such as the head of gravel bars (Vervier and Naiman, 1992). DOC from these soil and groundwater sources is augmented by formation of DOC in small streams by both abiotic processes, such as leaching from particulate materials, and biotic, soluble processes and leaches rapidly (<24 h) from detrital particulate terrestrial vegetation.

During low-flow periods, DOC concentrations in the soils increase. Subsequent rapid declines in DOC concentrations are roughly proportional to increased water percolation through the soils such as is released from rapid snowmelt and from precipitation events (see p. 747) (Lewis and Saunders, 1989; Ciaio and McDiffett, 1990; Clair *et al.*, 1994; Hornberger *et al.*, 1994; Jones, et al., 1996). Maximum DOC concentrations appear in receiving streams and rivers soon thereafter and rapidly decline as the rivers return to base flows. As the area of flood plains increases in lowland river ecosystems, stream DOC concentrations often increase during high flows as DOC-rich water originating in wetlands is transported to the channel (e.g., Dalva and Moore, 1991).

The DOM input from terrestrial organic matter to streams results from direct leaching from living vegetation or from soluble compounds carried in runoff from dead plant material in various stages of decomposition (Fig. 23-2). POM, again mostly of plant origin, can fall directly into stream water from overhanging tree canopies, be transported by runoff water, particularly from flood plains, or be windblown into the stream. Foliage from trees and ground vegetation can provide very significant inputs of organic matter to streams, both as POM and as leached DOM from the dead POM. The variability in the ratios of DOC:POC in streams and rivers is very large (range between 0.09 to 70; Moeller *et al.*, 1979).

Total transport of organic carbon in the world's rivers from land masses to the ocean in both dissolved and particulate forms is ca. $0.37–0.41 \times 10^{15}$ g C yr^{-1} (Schlesinger and Melack, 1981; Meybeck, 1993c). Although this organic carbon transport is a small flux in the global carbon cycle, fluxes from land can be significant, though highly variable. Transport losses range from <1 g C m^{-2} yr^{-1} in grassland ecosystems to 10 g C m^{-2} yr^{-1} from some cultivated forests. Wetlands tend to release appreciably greater amounts of organic carbon (to ca. 20 g C m^{-2} yr^{-1}) (Table 23-4).

1. Transformations

The large (coarse) as well as fine particulate matter of terrestrial vegetation entering streams is leached of a significant portion of its organic content as dissolved compounds (Fig. 23-2). The amount and degradability varies with the plant species. For example, slower uptake by stream bacteria of DOC in an old-growth forest could be a result of a more limited supply of labile DOC as well as a greater concentration of inhibitory compounds such as polyphenolic and terpene compounds in the stream water (Dahm, 1984). Much of this DOM leachate, however, is metabolized very rapidly. As a result, bacterial populations in the water, attached on sediments, and in the hyporheic zone within the sediments increase markedly in response to the DOM loading. For example, in large experimental streams, leaf leachate was demonstrated to have a bacteriologically labile dissolved organic carbon (DOC) fraction that was decomposed rapidly ($T_{1/2}$ = 2 days) and a recalcitrant DOC fraction ($T_{1/2}$ = 80 days) (Wetzel and Manny, 1972b). Most of the recalcitrant dissolved organic nitrogen compounds persisted in a relatively unmodified state for at least 24 days. As the DOC mixtures from natural sources are degraded,

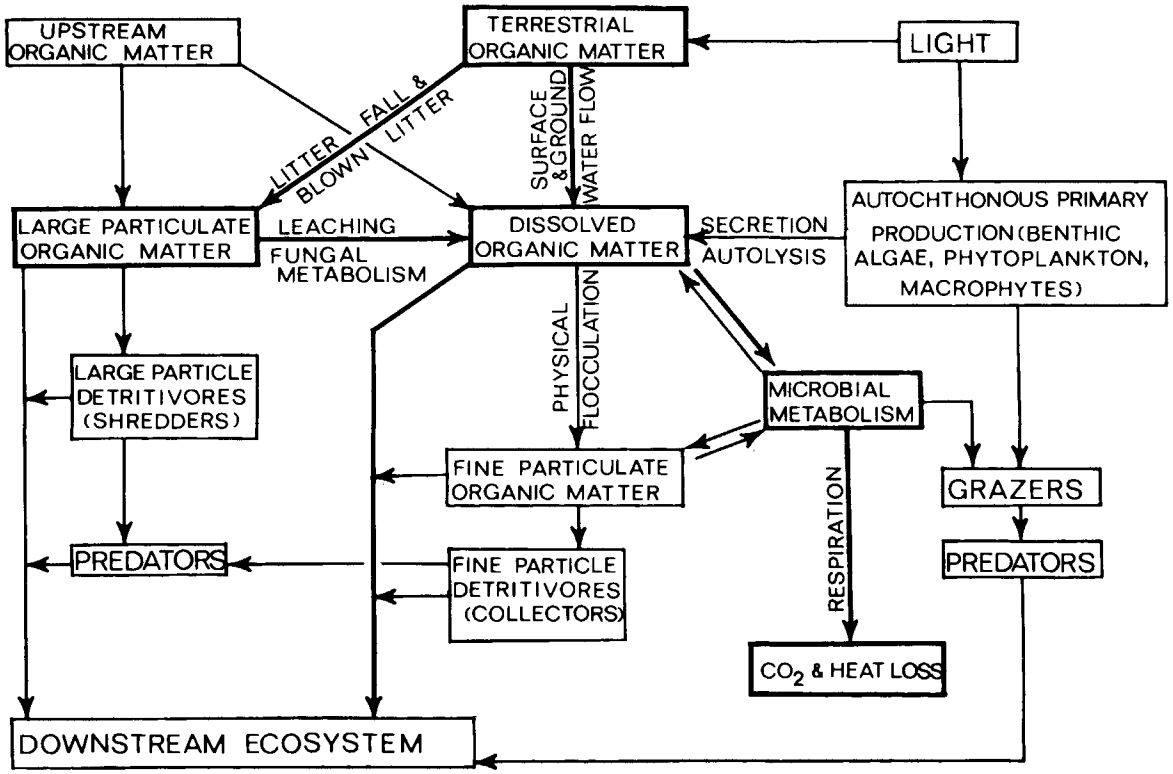

FIGURE 23-2 Simplified compartment model of the structure of an idealized stream ecosystem. Heavier lines indicate dominant transport and metabolic pathways of organic matter. (Composite of modified figures after Fisher and Likens, 1973; Cummins *et al.*, 1973.)

TABLE 23-4 Annual Riverine DOC Flux from Different Soils and Vegetation Habitat[a]

Biome	*Soil C:N*	*Observed DOC flux* ($g\ C\ m^{-2}\ yr^{-1}$)[b]
Cool grasslands	13.5	0.386
Tropical savannah	13.6	1.090
Taiga	13.8	0.700
Siberian steppe	14.7	1.290
Warm deciduous forests	15.3	1.410
Warm mixed woodlands	16.7	1.714
Cool deciduous forests	17.1	1.927
Warm conifer forests	21.0	3.684
Cool conifer forests	21.0	4.226
Northern mixed forests	23.2	5.260
Heath/moorlands	24.6	5.650
Tropical forests	25.0	6.336
Boreal/peat mix	25.7	6.349
Peatlands	30.1	8.567
Swamp forests	32.4	9.913

largely by benthic microbes, aliphatic compounds such as organic acids are being released as degradation products along with CO_2 and CH_4 (Schindler and Krabbenhoft, 1998). These gaseous products either oxidize or evade to the atmosphere.

A quantity of the dissolved leachate precipitates to particulate form (Lush and Hynes, 1973); the rate of precipitation and the size of the resulting particles depend upon leaf species and water chemistry. As will be discussed later, a portion of the DOC can be photolysed upon exposure to sunlight to simple organic substrates readily utilizable by bacteria or to CO_2.

Aggregations of large POM, such as leaf packs trapped among stream sediments, rocks, and large woody debris undergo colonization by fungi in complex successional patterns within the detrital microhabitats (cf. detailed discussion in Chap. 21). As the resistant plant material is degraded, solubilized products of decomposition are utilized by bacteria living in highly stratified populations in the steep redox gradients of the compacted plant material (Fig. 23-2). The detrital material and its associated microflora serve as a major nutritive source for numerous aquatic invertebrates, especially the immature insect fauna (Kaushik and Hynes,

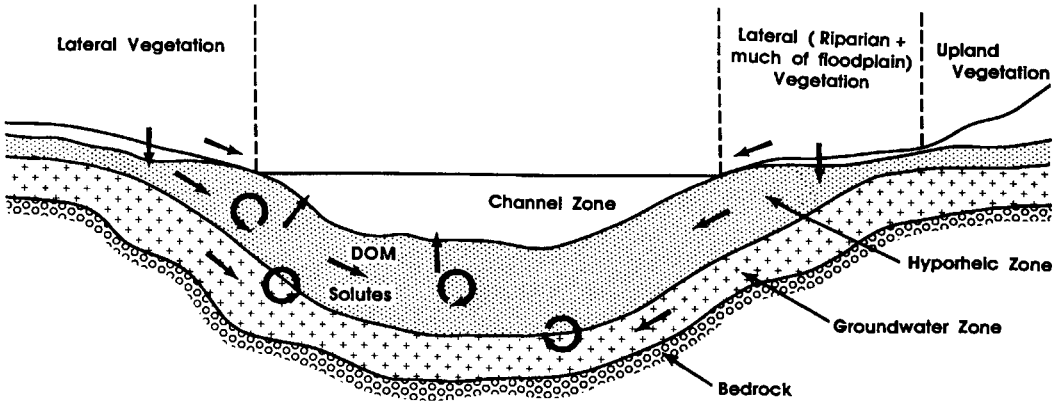

FIGURE 23-3 Conceptualization of lateral and vertical boundaries of running water ecosystems. The stream ecosystem boundary is defined as the hyporheic/groundwater interface and thereby includes a substantial volume beneath and lateral to the main channel. Vegetation rooted in the hyporheic zone is therefore part of the stream ecosystem primary production. Arrows indicate flow pathways of dissolved organic matter and inorganic solutes derived from plants and plant detritus within the stream ecosystem and flood plain. (From Wetzel and Ward, 1992; extensively modified from Triska *et al.*, 1989.)

1971; Cummins, 1973; Cummins *et al.*, 1973; Iversen, 1973; Anderson and Sedell, 1979) (see Chap. 22). There is no question that the shredding, collecting, and grazing activities of aquatic insects play a role in quickening the reduction of the size of POM and increasing the surface area for subsequent microbial degradation. It is also clear that a major portion of the animal nutrition is obtained from the microflora attached to the resistant detrital POM. Only a few animals are adapted with symbiotic gut microflora to utilize the particulate plant material directly (see Chap. 22).

Most of the lateral streamside and floodplain vegetation, however, will fall to the ground or hydrosoils beside the main channel and be incorporated into subsurface soil regions, including lateral hyporheic zones. Both organic matter stored and/or produced within the main channel, as well as that which feeds into the hyporheic zone from lateral regions, can fuel microbially active subsurface regions, where both aerobic and anaerobic processes further transform the detrital organic material (Fig. 23-3). Some of the dissolved organic and solute material eventually reemerges in the main channel, where it can serve as nutrient sources to within-channel microbial communities (e.g., Crocker and Meyer, 1987; Dahm *et al.*, 1987; Triska *et al.*, 1989; Coleman and Dahm, 1990; DeAngelis *et al.*, 1990; Leff and Meyer, 1991; Kaplan and Newbold, 1993).

There are few detailed analyses of the metabolism of organic carbon in streams. However, there is sufficient evidence to indicate that

1. Allochthonous inputs of terrestrial organic matter, in the form of detrital DOM and POM, commonly form the dominant source of material and energy for stream and river ecosystems (Tables 23-5 and 23-6). Much of that DOC is released from soils into ground water and from anaerobic processes in adjoining wetlands (e.g., Dahm *et al.*, 1987; Eckhardt and Moore, 1990; Dillon and Molot, 1997b).

2. From 10 to 25 times more organic matter occurs as DOM than occurs in particulate form on an annual basis (e.g., Table 23-5).

3. Groundwater inputs of DOM are the major source to upland streams, and most of the water reaching the streams passes through soil strata and is exposed to microbial degradation (e.g., Wallis *et al.*, 1981; Rutherford and Hynes, 1987).

4. The rates of decomposition of DOM are rapid (days) in comparison to those for much of the POM (leaves in weeks and woody material in years).

5. Bacteria rapidly metabolize the labile components of DOC and DON, but more recalcitrant components are decomposed at slower rates and are exported downstream (Wetzel and Manny, 1972; McDowell and Fisher, 1976; Leff and Meyer, 1991; Perdue, 1998; Findlay and Sinsabaugh, 1999; Stepanauskas *et al.*, 1999, 2000). Proteinaceous moieties in DOM are preferentially degraded. DOM with higher percentages of aromatic carbon and carboxyl (COOH) content are less bioavailable.

6. Despite variations related to the source materials of the DOC, bacterial utilization and growth efficiencies can be high (Kaplan and Bott, 1983; Findlay *et al.*, 1986; Edwards and Meyer, 1987).

7. Much of the bacterial respiration of DOM occurs in the hyporheic zone of the sediments or along the surface of the sediments. Community respiration of

hyporheic sediments can be very high with as much as 60% degradation (McDowell, 1985; Hedin, 1990; Fiebig and Lock, 1991; Findlay and Sobczak, 1996; Pusch, 1996).

8. Up to half of the DOC of stream water can be metabolized by microbes attached to sediment particles from interstitial water flowing through the hyporheic zones of porous sediments of streams (e.g., Crocker and Meyer, 1987; Findlay *et al.*, 1993).

9. Rates of physical and microbial degradation of DOM, particularly humic substances, can be greatly accelerated by exposure to sunlight (see later discussion). In the absence of light, abiotic removal of DOC is slight (e.g., Kuserk *et al.*, 1984).

10. Large POM is decomposed slowly and has a longer retention time within a particular reach of the stream (Chap. 21).

Total organic carbon turnover length is the average downstream distance traveled by a carbon atom in a fixed or reduced (organic) form, calculated as the ratio of the downstream transport of organic carbon (per unit stream width) to benthic respiration (per unit area). Therefore, turnover length measures the rate at which organic material is lost from streams relative to the rate at which it is used (Webster *et al.*, 1995). Turnover length increases downstream and therefore with increasing stream order and average discharge. The bioavailability of riverine dissolved organic matter (DOM) appears to be greater under low discharge conditions and decreases with distance downstream. The chemical composition of the DOM tends to become more recalcitrant with greater time in the river (Leff and Meyer, 1991; Sun *et al.*, 1997). Downstream decreases in bioavailability were attributable primarily to selective degradation of aliphatic carbon in the riverine DOM.

[a] From Hill and Webster (1983). AFDW = ash-free dry weight.

Estimations of the rates and importance of autochthonous primary production in streams by the attached benthic algae, lotic phytoplankton, and larger aquatic plants are very difficult (reviewed by Wetzel, 1975b; Minshall, 1978; Bott, 1982; Wetzel and Ward, 1992) (cf. Chaps. 15, 18, and 19). Overwhelming evidence indicates that terrestrial photosynthesis and importation of this organic matter to stream ecosystems are the primary carbon and energy sources of these systems; that is, that streams are largely heterotrophic. Such is indeed the case in heavily canopied woodland and forested streams in which autochthonous primary production is very low or negligible.

In noncanopied streams and in rivers as they increase in size and decrease in velocity of flow, the significance of primary productivity of lotic phytoplanktonic and attached algae and macrophytes increases (Fig. 23-4). Animal consumers within the floodplain habitats of large rivers depend heavily on algal organic matter from both phytoplankton and periphyton for

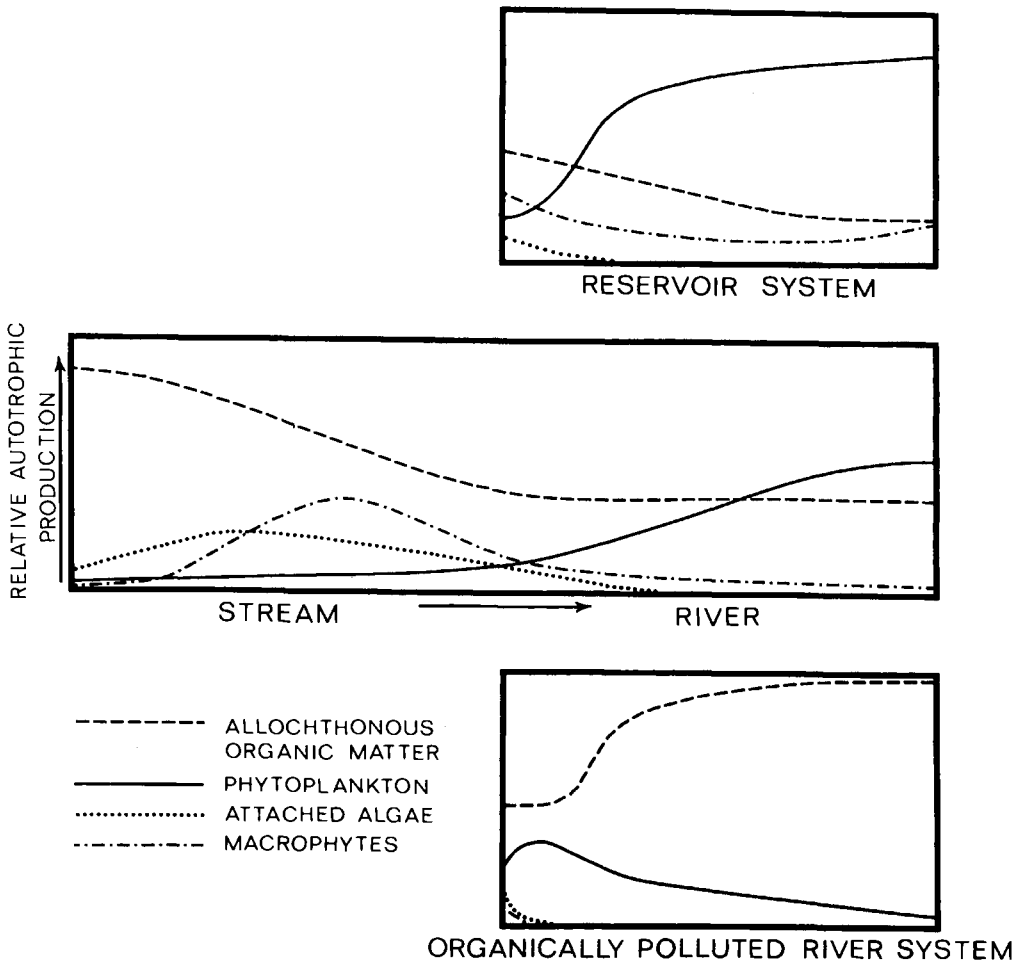

FIGURE 23-4 Generalized scheme of the relative contributions of allochthonous organic matter and autotrophic production by attached algae, phytoplankton, and aquatic macrophytes in the transition of a stream to a river system, if it is impounded where velocity of flow is reduced or practically eliminated or if it is organically polluted. (From Wetzel, R. G.: Primary production. *In* Whitton, B. (ed.): *River Ecology*. Oxford, Blackwell Sci. Publs., 1975.)

growth (Hamilton and Lewis, 1992; Hamilton *et al.*, 1992). However, the heterotrophic metabolism of these river ecosystems is totally dominated by microbial metabolism. Running waters can clearly vary in their proportion of heterotrophic and autotrophic metabolism. The relative significance of these types of metabolism is dynamic and varies considerably at local levels within a river system and seasonally with shifts in many physicochemical parameters and shifts in loading with allochthonous (natural or artificially by pollution) organic matter. On an annual basis, however, all streams and rivers are net heterotrophic ecosystems (Wetzel, 1995, 2000a).

In many rivers, particularly those of low elevational gradients, flooding events are important for redistribution of both particulate and dissolved organic matter. Inundation of the flood plains of rivers can increase the loading of organic matter from the decaying vegetation of the flood plain. Flooding behavior is very variable in relation to climate, precipitation periodicity and intensity, and extent of water-level regulation by reservoir damming. Examination of the extent and duration of floodplain inundation and flooding periodicity of an unregulated sixth-order river in the southeastern United States over a six-decade period indicated that >50% of the flood plain was inundated 15% of the time (54 day yr^{-1}). During 50% inundation, system width exceeded channel width by 19 times (Benke *et al.*, 2000). Over 50 to 100% of the flood plain was inundated for several months during the winter–spring period of high precipitation. Floods of 50% inundation of the flood plain had a duration of at least 30 days.

The flood pulse for this forested floodplain river was less predictable, and floods tended to be of shorter

duration than those of large tropical rivers. Flooding in this river was correlated primarily with seasonal differences in temperature and plant evapotranspiration. Thus, increases in temperature with decreases in precipitation will lead to large decreases in export of dissolved organic substances (Clair and Ehrman, 1996). Evapotranspiration is linked to precipitation in determining the river discharge because even large increases in precipitation can lead to decreasing discharge when accompanied by higher temperatures. In contrast, in tropical rivers, where annual patterns of flooding are driven by large seasonal variations in precipitation, flood plains can be inundated for four or more months (Junk, 1997a,b; Lewis *et al.*, 2000).

The primary productivity within reservoirs is extremely variable because of individual characteristics of morphometry, seasonal changes in water-retention times, and human manipulations of water level and retention. In general, nutrient loading and trophic state are higher at the river end of reservoirs than at the deeper, dammed end. Although phytoplanktonic productivity per unit volume may be higher at the river end than at the dammed end, increased inorganic turbidity and light reduction at the river end can cause a reduction of the depth of the trophogenic zone and a decrease in total productivity (e.g., Fig. 23-4). The primary productivity per unit area in some reservoirs can be approximately the same over the length of the reservoir. In these cases, the higher trophic state and volumetric productivity at the inflow end of the reservoirs shift to lower epilimnetic trophic states, lower volumetric productivity, but increased depth of the trophogenic zone at the dammed end.

2. General Metabolism of Organic Matter in Streams

Therefore, in summary, much of the dissolved organic matter in streams originates from lignin and cellulose and related structural precursor compounds of higher plants. These substances are abundantly produced in the true lake and river ecosystems—that is, the ecosystem includes the drainage basin and organic matter produced photosynthetically within it. The productivity of terrestrial vegetation and aquatic plants associated with the land–water interface region is manifoldly (usually several orders of magnitude) greater than that of algae. Organic substances from higher plant tissues are abundant, chemically complex, and relatively recalcitrant to rapid biological degradation (Thurman, 1985; Haslam, 1998). During oxidative and anaerobic degradation, these compounds are modified by microbial activities in detrital masses, including standing dead tissues that can remain in an oxidative aerial environment for months or years. Much of the dissolved organic compounds released from partial decomposition of the plant tissues and from associated microbial degradation products are leached and partially degraded en route toward recipient lakes and streams. That microbial modification continues during partial decomposition in terrestrial soils and hydrosoils of wetlands. Once within land–water interface regions, water containing dissolved organic compounds moves, often diffusely, through dense aggregations of living emergent and submersed aquatic plants and massive amounts of particulate, largely plant derived, detritus (extensively reviewed in Wetzel, 1990a). The enormous surface areas of these habitats support large aggregations of rapidly growing microbial communities. During transport through these microbial metabolic sieves associated with wetland and littoral areas, appreciable further selective degradation of more labile dissolved organic constituents occurs before final movement into the receiving lake body or river channel per se.

Although difficult to generalize, a common pattern is that DOM entering rivers is quite different among different sources. For example, in the Amazon ecosystem, heavy storm precipitation events transport relatively labile DOM, whereas DOM from wetlands and ground water tends to be hydrophobic and recalcitrant from selective biological utilization of the more labile components (McClain and Richey, 1996). DOM from litterfall leachates tends to be relatively labile.

As will be emphasized further on, the trophic dynamic structure of aquatic ecosystems depends operationally on a dynamic detrital structure (Wetzel *et al.*, 1972; Wetzel and Rich, 1973; Rich and Wetzel, 1978; Wetzel, 1995). From the standpoint of carbon fluxes, most energy and organic carbon of the systems is dead, of autotrophic origin, and undergoing microbial degradation, the rates of which are variable and serially decrease with increasing recalcitrance of the organic matter. In lakes, reservoirs, and rivers, detrital organic matter is the main supportive metabolic base of carbon and energy. Since most lakes of the world are small to very small, much of the autochthonous production of detrital matter originates from benthic littoral and wetland vegetation, which augments the loadings of dissolved organic matter from terrestrial origins. Similarly, detrital heterotrophic metabolism dominates in streams, where usually the major sources are allochthonously derived terrestrial plant material. Common to both lake and stream ecosystems is the dominance of detrital metabolism, which gives the ecosystems a fundamental metabolic stability. The trophic structure above the producer–decomposer level, with all of its complexities of population fluctuations, metabolism, and behavior, has a relatively small impact on the total carbon flux of the system. The detrital system provides stability to streams; the slower,

relatively consistent degradation of dissolved and particulate detritus by microorganisms underlies the more sporadic autochthonous metabolism that responds rapidly to, and depends to a greater extent on, environmental fluctuations. Autochthonous primary production is often small and variable, but in combination with allochthonous, autotrophically produced detritus, drives the lotic system. The functional operation of lentic and lotic systems converges at this point of similarity in detrital metabolism.

B. Allochthonous Organic Matter Received by Lakes via Streams and Rivers

1. *Dissolved Organic Matter*

The DOM of surface runoff is composed of relatively recalcitrant organic compounds resistant to rapid microbial degradation. The amounts of DOC and POC reaching a lake and the chemical composition of these organic compounds change seasonally with the volume of flow in relation to duration of retention in the stream, the growth and decay cycles of the terrestrial and wetland vegetation through which runoff flows, and other factors, especially climatic variations.

An example is seen from quantitative analyses of dynamics of influxes of allochthonous detrital soluble and particulate organic carbon to a small temperate lake over an annual period in relation to their fate within and losses from the lake (Wetzel and Otsuki, 1974; Wetzel, 1989). Detrital organic carbon influxes were determined in water from a primary inlet stream, both before and after its flow had traversed a wetland adjacent to the lake, and from a second inlet stream, both at its headwaters and after the stream water passed through the wetland. Similarly, measurements were made of organic content of ground water where it entered the lake and at the outlet. Concentrations of organic carbon in inflows and outflows were converted to values of total carbon loading and outflow using a detailed annual water budget (Fig. 23-5). The DOC and the dissolved organic nitrogen (DON) increased significantly (×2) during the active growing season as the inlet water of the streams passed through the

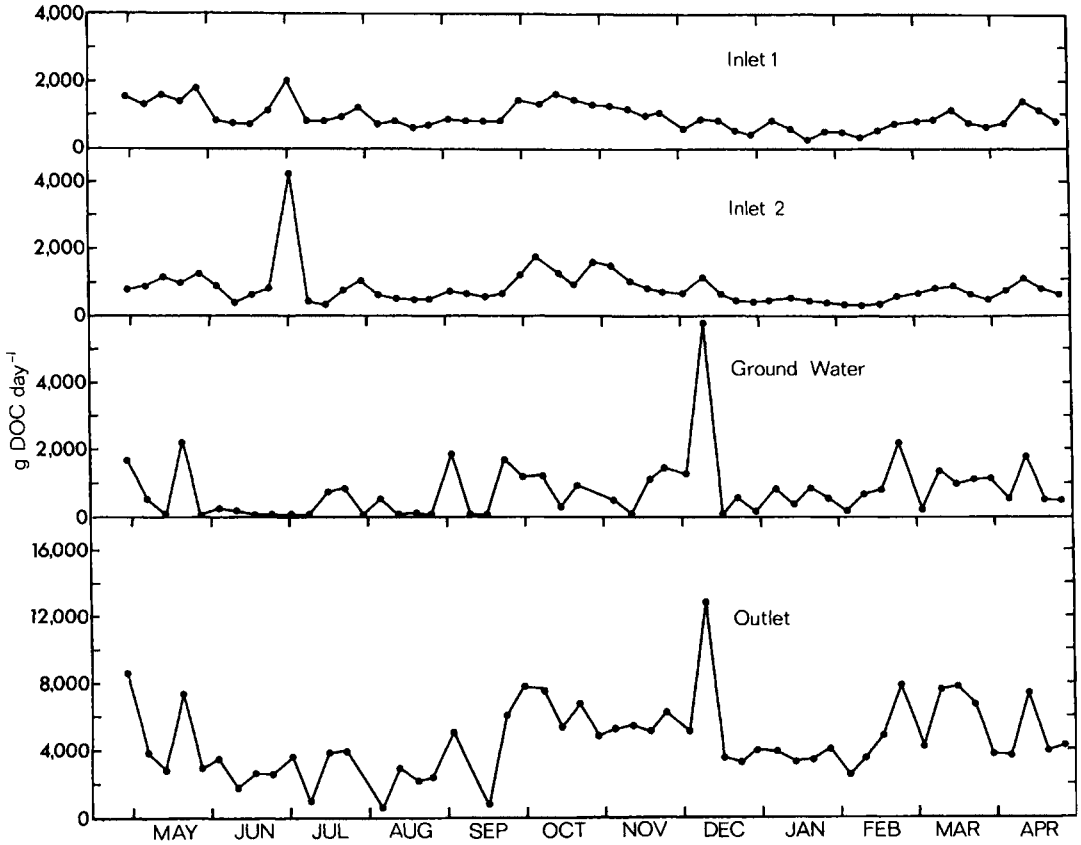

FIGURE 23-5 Dissolved organic carbon entering Lawrence Lake, Michigan, via ground water and the two stream inlets and leaving via the lake outlet. (From Wetzel, R. G., and Otsuki, A.: Allochthonous organic carbon of a marl lake. *Arch. Hydrobiol.* 73:31–56, 1974.)

marshes prior to entering the lake (Wetzel, 1989). The dissolved organic C:N ratios (DOC-C:DON-N) varied between 15 and 150, with an annual average of ca. 30 over the year of study. In addition, the DOC:DON ratios decreased during the active growing season (April–October) as one progressed from the upper wetlands toward the wetlands of the littoral of the lake (Wetzel, 1989). Similar results were found in larger streams as they passed through extensive marsh systems (Manny and Wetzel, 1973; Grieve, 1994).

The DOC:DON ratios decreased during the active growing season of the wetland from values twofold higher during the colder and winter periods of the year (Wetzel, 1989). Clearly, the wetland plants and attendant microflora of the sediments and detrital particulate organic matter served as a distinct source for dissolved organic nitrogen during much of the year but particularly during the active growing season of the wetland ecosystem. Much of the DON-N was associated with the humic compounds. For the smaller amounts of more labile DON-N associated with proteinaceous and amino compounds, degradation rates were rapid. For example, mineralization of protein-N by the wetland sediment microflora had turnover rates of 13–69 h between May and October (Cunningham and Wetzel, 1989). Utilization of amino-N was 9–57 times more rapid than that of protein-N, with turnover times of 1.6–3.7 h in the wetland sediments over the growing season.

The lowest inputs of DOC occurred during the summer, when there was little precipitation, temperatures and bacterial metabolism were higher, and vegetation was growing rapidly (Wetzel, 1989). During the autumn and early winter, DOC increased markedly. The DOC content of the ground water was very low, but because of the large volume of this inflow, it constituted one-third of the annual influx of allochthonous DOC (Table 23-7). A net loss of 15 g DOC m^{-2} $year^{-1}$ from the outflow of this lake was observed, which represented a major pathway of organic carbon removal from the lake. Spectrophotometric analyses (absorption of ultraviolet light and fluorescence) of water flowing into and out of the lake indicated that a high percentage of the DOC was composed of humic compounds and yellow organic acids.

Inlet 2	7.94
Ground water and seepage	6.01
Total	20.95
Outflow DOC	35.82

[a] From Wetzel, R. G., and Otsuki, A.: Allochthonous organic carbon of a marl lake. *Arch. Hydrobiol.* 73:31–56, 1974.

Analogous situations exist in large rivers, particularly those with extensive flood plains. For example, in Australian floodplain rivers, in-stream primary productivity is trivial in comparison to that of riparian floodplain sources of organic matter (Robertson *et al.*, 1999). Riverine forests have primary production of ca. 600 g C m^{-2} yr^{-1}, whereas those of floodplain aquatic macrophytes and periphyton exceed 2500 g C m^{-2} yr^{-1} and 620 g C m^{-2} yr^{-1}, respectively. Large pools of particulate organic carbon as detritus exist as litter (>500 g C m^{-2}) and coarse woody debris (ca. 6000 g C m^{-2}). Bacterial decomposition of particulate and dissolved organic matter of the sediments is very high, with respiration and methanogenesis generating and releasing ca. 1 g C m^{-2} day^{-1}. Very large quantities of DOC are released plant from litter and exported to the river channels. Similar production, utilization, and transport of organic matter is found in other large rivers (e.g., Hedges *et al.*, 1994; Lewis *et al.*, 2000). For example, in the Amazon River, highly degraded leaf material is solubilized during degradation and then partitioned between soil minerals and water during transport to the river, which results in suspended fine particulate organic materials of soil detritus origin that are nitrogen-enriched coexisting with dissolved organic substances that are nitrogen-poor.

2. Particulate Organic Matter

Concentrations of POC in the influxes, in water within the lake, and in the outflow water were consistently about 10% that of the DOC. Inputs of POC were minimal during the summer months, when marsh vegetation was growing rapidly, but increased markedly during periods of high autumnal rainfall and spring runoff (Fig. 23-6). Groundwater POC was very low, but on an annual basis constituted over one-fourth of the allochthonous POC input (Table 23-8). Allochthonous POC was small in relation to the quantities of littoral and pelagic organic carbon synthesized within the lake and represented <5% of the gross inputs of POC to the lake.

The quantity of windblown POM to Lawrence Lake was negligible. Leaf litterfall and material blown into a lake can become significant in small lakes or ponds in heavily forested areas, but generally this input is small (Table 23-9) in comparison to other sources of organic loading from external sources. Domestic and industrial POM pollution of lakes by organic wastes is

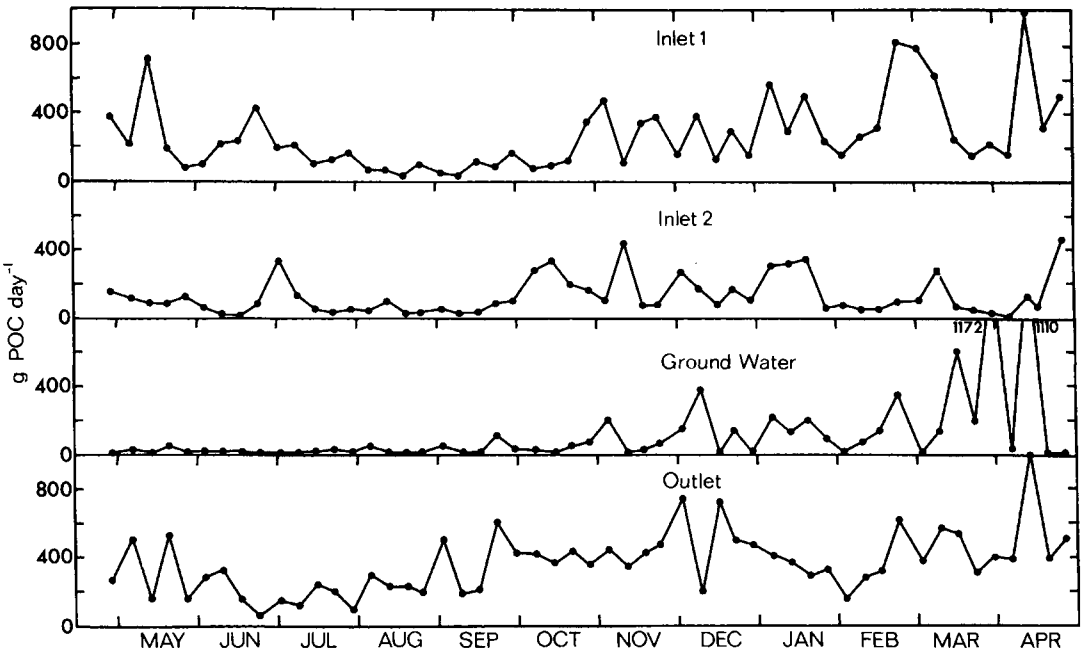

FIGURE 23-6 Particulate organic carbon of allochthonous inputs entering and leaving via the lake outflow, Lawrence Lake, Michigan. Note that the POC values are an order of magnitude lower than those of DOC in Figure 23-5. (From Wetzel, R. G., and Otsuki, A.: Allochthonous organic carbon of a marl lake. *Arch Hydrobiol.* 73:31–56, 1974.)

an exceedingly individualistic parameter that lends itself poorly to generalization. Pollution of this nature is normally transported to lakes and reservoirs via stream and river inflows rather than via groundwater sources. The types of organic pollution, partial degradation en route, and effects on stream properties are treated excellently by Hynes (1960, 1970). As pointed out by Pieczyńska (1972; cf. also Rai and Hill, 1981), the degradation of organic matter by microflora in lakes that receive a high proportion of allochthonous organic matter is generally more variable and requires a greater diversity of metabolic pathways than microbial degradation in lakes that receive POM predominantly from autotrophic sources. It should be stressed, however, that many lakes derive much of their organic carbon and many nutrients from terrestrial and wetland sources of the surrounding drainage basin. The magnitude of allochthonous inputs is difficult to measure and, more importantly, the metabolic role of allochthonous materials within the lake is difficult to separate from that of autochthonous inputs. Despite much recent progress in understanding, this area is in great need of further investigation.

TABLE 23-8 Annual Particulate Organic Carbon Entering Allochthonously and Leaving Lawrence Lake, Michigan, 1971–1972[a]

POC	$g\ C\ m^{-2}\ yr^{-1}$
Influxes of POC	
Inlet 1	1.99
Inlet 2	0.962

Outflow POC	2.75

[a] From Wetzel, R. G., and Otsuki, A.: Allochthonous organic carbon of a marl lake. *Arch. Hydrobiol.* 73:31–56 1974.

Leaf fall into streams, particularly among forest-canopied small streams (first to fourth order), is, of course, a major input of organic matter, as has been discussed repeatedly earlier (cf. Chaps. 8, 18, 21, and 22). Mean DOC concentrations in water of small streams is directly related to the mass of leaf litter (Mulholland, 1997; Meyer *et al.*, 1998). In-stream generation of DOC from leaf litter trapped and stored among stream sediments contributes about 20% of the daily DOC exported from many forested headwater streams. In the temperate zone, this source of DOC is very seasonal—greatest during autumn and winter and least during spring and summer. The remainder of DOC emanates largely from the floodplain vegetation and its degradation and from terrestrial sources.

TABLE 23-9 Estimates of Airborne Transport of Particulate Organic Matter, Largely Leaf Litter, to Lakes[a]

Location	*Lake area (ha)*	*% as leaves*	*Total airborne litter to lake*	*Source*
Mikolajskie, Poland	469	100	8 kg leaves ha^{-1} yr^{-1}	Szczepański (1965)
Wingra, WI	130	>80	23 kg litter ha^{-1} $autumn^{-1}$	Gasith and Hasler (1976)
Glenwild, NJ	44	66	176 kg litter ha^{-1} $autumn^{-1}$	M. Sebetich (pers. comm).
Mirror, NH	15	62	113 kg litter ha^{-1} yr^{-1}	Gosz *et al.* (1972); Jordan and Likens (1975)
Frongoch, Wales	7.2	95	14 kg litter ha^{-1} yr^{-1}	Hanlon (1981)
Lawrence, MI	4.9	<1	<2 kg litter ha^{-1} yr^{-1} of 89 kg POM[a] ha^{-1} yr^{-1} of allochthonous POM entering lake	Wetzel and Otsuki (1974)

[a] POM = particulate organic matter (>0.5 μm).

The implications of the preceding discussion are that a large portion of the particulate and dissolved detrital organic matter that enters lakes from allochthonous sources has undergone microbial stripping of more labile compounds. The bulk of organic detrital carbon is in the form of humic and other substances that are relatively resistant to further microbial degradation. It is then necessary to superimpose upon this variable allochthonous input of detrital organic matter the organic matter that is produced in the body of water itself by phytoplankton of the open water and that produced in the littoral zone.

3. Total Energy Transfer Rates

In previous discussions, we have systematically scrutinized the autochthonous synthesis of organic matter in both the open water (Chap. 15) and the littoral regions (Chaps. 18 and 19). The utilization of portions of this organic matter by planktonic and benthic animals was considered in Chapters 16 and 22. The complexities of microbial degradation of the dissolved and particulate organic matter in the open water and the sediments were treated in Chapters 17 and 21, respectively. These analyses provide the parts that can be fitted into an integrated whole that quantitatively combines the pathways of flow among producer, consumer, and decomposer components.

Historically, integration of the ecosystem components has been attempted in many different ways. Early attempts coupled the plant and animal components qualitatively as complex food webs, in which the feeding or trophic relationships among organisms were interconnected. Although these analyses provide descriptors of the biotic components, the food-production and food-consumption processes are very dynamic and constantly change with differing environmental conditions and during the life histories of the organisms. So many organisms are involved that it is exceedingly difficult to quantify, in the words of Hutchinson, the roles of even the major actors of the ecological play.

Alternatively, the energy content of organisms and communities has been examined. Present technology is incapable of measuring directly the rates of energy transfer among individual organisms and communities.[2] If the energy content of all organisms and their energy expenditures for all behavioral, maintenance, and reproductive costs were known, however, it would be possible to estimate the energy transfer among biotic components. The dearth of bioenergetic knowledge for many of the organisms occurring in fresh waters means that only very approximate estimates are possible at this time.

Quantitative carbon fluxes among communities of freshwater ecosystems have been used with some success. The underlying premise of this approach is that the synthesis of organic matter begins with the fixation (primarily photosynthetic) of CO_2. Much of this organic carbon is variously cycled within the ecosystem before being respired (primarily via decomposition) and returned as CO_2. Despite the limitations of this approach, discussed later, much functional information on the operation of freshwater ecosystems has emerged from quantitative analyses of rates of carbon cycling and what parameters regulate these rates.

We initiated discussion throughout previous chapters with the quantitative aspects of productivity and the dispersion of gross productivity in metabolic respiration, growth, and reproduction to obtain estimates of net productivity. These values were expressed in terms

[2] In the future, it should be possible theoretically to quantify directly energy fluxes from a source of molecular mass in one organism to other organisms that are physiologically similar. In addition, it should be possible to evaluate energy dissipation routes and transfer rates into reproduction, growth, and losses by direct measures of molecular energy fluxes.

of carbon wherever possible for comparative purposes under differing physical, chemical, and biotic (e.g., predation) environmental conditions. The biotic components were coupled qualitatively earlier, as, for example, in Figure 17–1. It is now instructive to examine the mass and flux of organic carbon among the components in as quantitative a manner as possible in representative lakes, reservoirs, and rivers. None of these ecosystem analyses is complete, but the analyses do provide insight into the relative importance of the different communities and processes. Additionally, they emphasize areas in need of intensive further investigation in order to quantitatively evaluate control mechanisms of those energy fluxes.

IV. DISTRIBUTION OF ORGANIC CARBON

A. Dissolved of Organic Carbon (DOC)

A conspicuous feature of the depth–time distribution of total dissolved organic carbon in a lake (e.g., Fig. 23-7) is the absence of strong vertical stratification or seasonal fluctuations, despite the parallel thermal and density stratification and seasonal pulses of metabolic activity. It is apparent that the DOC pool consists primarily of carbon compounds relatively recalcitrant to rapid bacterial decomposition. Inputs of these dissolved organic substrates are approximately equal to their slow rates of microbial degradation. Highest concentrations occur during summer stratification in the epilimnion and consistently fluctuate to a greater extent in the upper strata, especially near the surface, than do concentrations in the hypolimnion. It is evident from earlier discussion (see Chaps. 15, 18, and 19) that extracellular release of DOC by living and senescing phytoplanktonic algae and littoral algae and macrophytes is associated with a portion of the higher epilimnetic concentrations of DOC. Decomposition of largely labile secreted organic compounds often is very rapid (e.g., <48 h), and their dynamics would not be delineated by the sampling frequency (weekly) employed for this generalized picture of the DOC pool. In addition, an appreciable input of allochthonous DOC commonly enters the upper strata during the period of summer stratification. In addition to the data presented here, the relative constancy of the DOC pool spatially and temporally was also found in many other waters (e.g., Fukushima *et al.*, 1996).

The constancy of the DOC pool is reflected further in annual average values per square meter of water column and for the whole lake calculated as the depthwise integration of the DOC concentrations and volume of water of each meter of water stratum (Table 23-10). Much of the seasonal change is observed in the surface waters, subject to greatest insolation (Hessen *et al.*, 1997). DOC concentrations at lower depths are relatively constant. Horizontal variations of DOC within this lake were very small (<10% deviation from the mean of the central depression). In some lakes, however, and especially in reservoirs, point-source inputs of DOC, such as river influxes high in DOC, would cause greater horizontal variations within the basin and irregular temporal fluctuations.

Therefore, the major sources to the DOC pool are (1) photosynthetic inputs of the littoral and pelagic flora

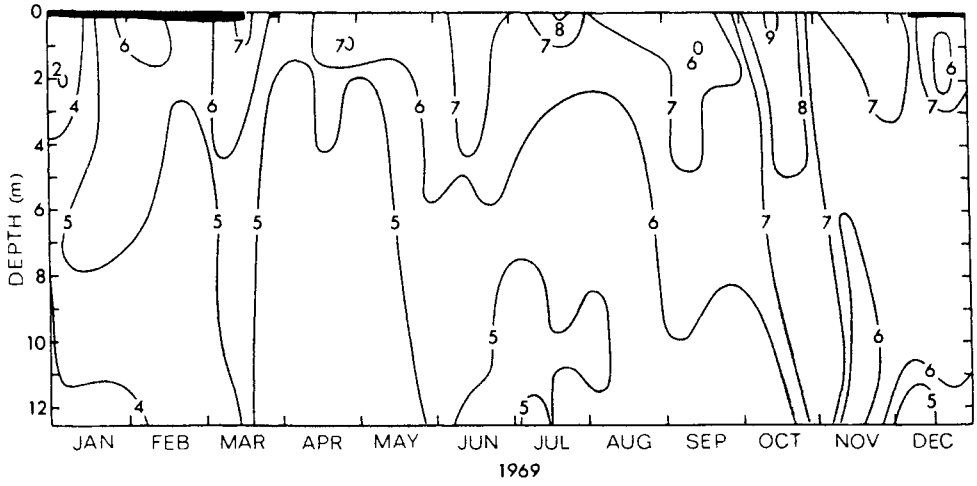

FIGURE 23-7 Depth–time diagram of isopleths of dissolved organic carbon (mg C liter^{-1}), Lawrence Lake, Michigan, 1969. (From Wetzel, R. G., Rich, P. H., Miller, M. C., and Allen, H. L.: Metabolism of dissolved and particulate detrital carbon in a temperate hard-water lake. *Mem. Ist. Ital. Idrobiol.* 29(Suppl.):185–243, 1972.)

added to the pool through secretions and lysis of cellular contents; (2) allochthonous DOC, composed largely of humic substances originating from terrestrial and wetland/littoral higher plant tissues that are recalcitrant to rapid bacterial degradation; and (3) bacterial degradation and chemosynthesis of organic matter with subsequent release of DOC. Very much smaller amounts, usually quantitatively negligible but qualitatively of potential importance, include (4) DOC from excretions of secondary producers, zooplankton and higher animals, that have ingested living or detrital organic matter.

Phytoplanktonic productivity and allochthonous sources from the drainage basin are the primary sources of the DOC pool of oligotrophic waters. In moderately large or very large bodies of water, phytoplanktonic photosynthesis can constitute a major contributor to the DOC pool. However, most lakes are small, and the ratio of littoral to pelagic photosynthetic productivity greatly increases as the mean depth of the basin decreases.

With increasing fertility, the relative contributions to system productivity by phytoplankton, submerged and emergent littoral/wetland macrophytes, and eulittoral algae are altered (Chaps. 18 and 19; see Fig. 19-21). The shift in dominance with respect to the productivity of these major groups results in differential contributions to the DOC pool (Fig. 23-8). If the drainage basin is not manipulated extensively by human activities, allochthonous inputs of DOC to a lake are defined by characteristics of its drainage basin and are relatively constant on a long-term annual basis; their relative contribution to the ecosystem consequently decreases as autochthonous sources increase

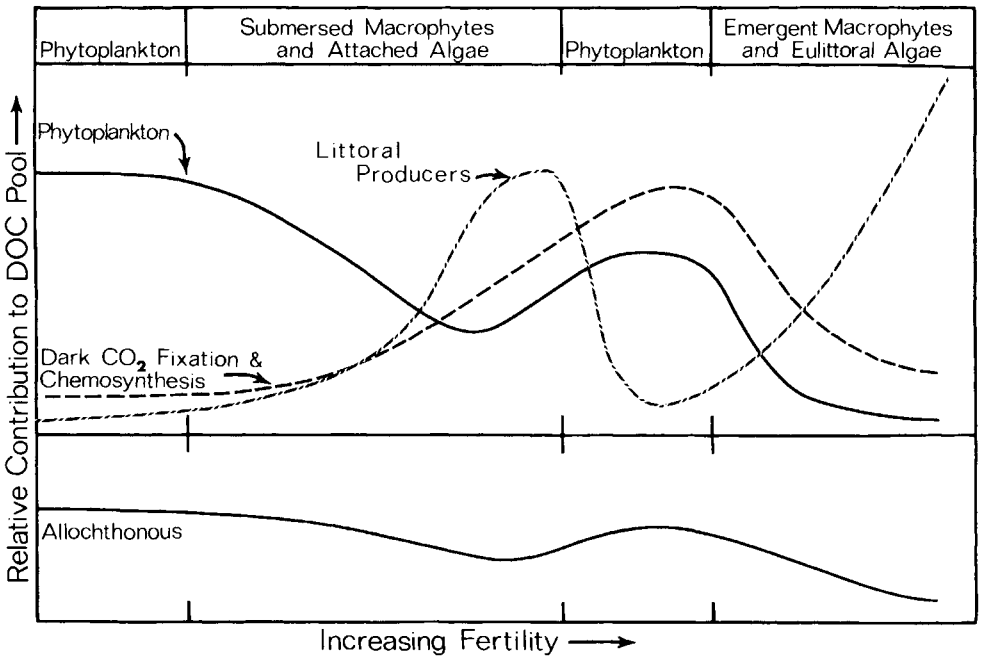

FIGURE 23-8 Generalized relative contributions of phytoplankton, littoral producers, dark and chemosynthetic CO_2 fixation, and allochthonous sources of dissolved organic carbon (DOC) to lakes of increasing fertility in the progression of dominating pelagic and littoral flora. Upper panel of generalized changes in dominating productivity by autotrophic flora refers to those changes detailed in Figure 19-21. In the final stages, highly productive emergent plants subsume all other inputs of organic matter (cf. Chap. 25).

(Fig. 23-8). A partial dissolved organic carbon budget of acidified Lake Gårdsjön, Sweden, demonstrated that over half of the DOC entered the lake from precipitation, surface runoff, and seepage (Broberg and Persson, 1984). Nearly half of the dissolved organic carbon was respired, photooxidized, or precipitated and sedimented. High-molecular-weight DOC compounds tend to prevail in the open water, with long chemical turnover times (Cole *et al.*, 1984). In reservoir systems, allochthonous inputs of DOC can exceed by several times the amounts of POC and DOC produced autochthonously (e.g., Romanenko, 1967).

Temporal variations in DOC among streams are large and often irregular. Clearly, most of the DOC in rivers is usually dominated by recalcitrant organic compounds of terrestrial and floodplain origins (Meyer, 1986; Moore, 1987; Burney, 1990; Grieve, 1990). DOC commonly reaches maximum values during low-flow summer and autumn periods, likely the result of concentration effects during summer periods of low precipitation and high evapotranspiration, as well as increased rates of decomposition with higher temperatures. In larger rivers, concentrations of DOC and total export of DOC is coupled to high-flow periods when flood plains are inundated, often in the winter. In very large rivers, primary production by phytoplankton and periphyton may contribute appreciably to the DOC during low-flow periods. Production is rapidly reduced as a result of turbidity and light attenuation during high-flow periods. In tropical rivers, DOC concentrations are much more variable owing to reduced seasonality of temperature, variable precipitation and flooding periods and the duration of flooding of the flood plain. Although the initial flush of DOC from the land or wetlands can be large following snowmelt or a large precipitation event, the sustained DOC concentrations in the runoff is often rapidly reduced by the dilution with large amounts of water.

Human disturbances can markedly alter releases of DOC to streams. Nonseasonal inputs of domestic and industrial organic wastes can radically alter discharge-corrected loads of DOC. Following clear-cutting of forest within the drainage basins of small streams, DOC concentrations of streams were reduced with little downstream accumulation (Kaplan *et al.*, 1980; Meyer and Tate, 1983; Grieve, 1990). Streams within undisturbed drainage basins had much higher levels of DOC with summer maxima and concentrations increasing downstream. In steep-drainage river basins, seasonal differences in DOC levels were small among streams draining forested and deforested sections of the drainage basin.

Therefore, in summary, a large portion, usually >90%, of the organic matter imported from allochthonous and littoral/wetland sources to these aquatic ecosystems is predominantly in dissolved or colloidal form. Although a portion of the dissolved organic compounds may aggregate and shift to a particulate and hence gravitoidal form that may sediment out of the water, most of the imported dissolved organic matter is dispersed within the water and is moved about with the hydrodynamic movements within the water body. That dispersion of DOM is important owing to its retention in zones of utilization or modification by physical processes (e.g., photolysis) within the aquatic ecosystems, which may not be the case with particulate organic matter subject to gravitoidal sedimentation. Great seasonal and daily variations can occur in those hydrodynamics, particularly in streams and rivers. In lakes, daily and seasonal variations are generally appreciably slower and smaller than in rivers. Retention times, which are important for effective utilization by enzymatic hydrolysis, tend to be longer in lakes than in streams.

Furthermore, massive microbial degradation of DOM occurs within lakes and streams despite the general recalcitrance of the organic matter. Many examples were detailed earlier (Chaps. 17 and 21) and are being further verified experimentally (e.g., Wehr *et al.*, 1999). Because of limited accessibility of large portions of these predominantly humic and fulvic acid molecules to enzymatic hydrolysis, degradation rates are slow. Thus, many of these commonly acidic macromolecules have long turnover times and relatively long residence times once within the lakes or streams. Dissolved macromolecules are often of considerable age (years) but are mixed with variable and rapidly changing inputs of younger humic and nonhumic substances of more recent synthesis. Recent studies are indicating that humic substances, particularly relatively recalcitrant fulvic acids, are generated by algae and contribute to the multitude of diverse compounds that constitute the collective dissolved organic matter (McKnight *et al.*, 1991, 1994). This source is potentially important in littoral areas, where attached and sessile algal productivity is often several orders of magnitude greater than that of phytoplankton (e.g., Wetzel, 1990a, 1996). Because of the recalcitrance of these dominating dissolved organic compounds, the dissolved organic matter can reside *within* lakes and rivers for long periods of time (months or years).

Strong budgetary evidence in early lake studies indicated both that, despite continual loading, the dissolved organic matter did not accumulate and losses by aggregation and sedimentation were small. However, large quantities of CO_2 evade to the atmosphere, even among oligotrophic lakes where rates of production and heterotrophic microbial respiration are low (e.g., Otsuki and Wetzel, 1974; Kling *et al.*, 1992;

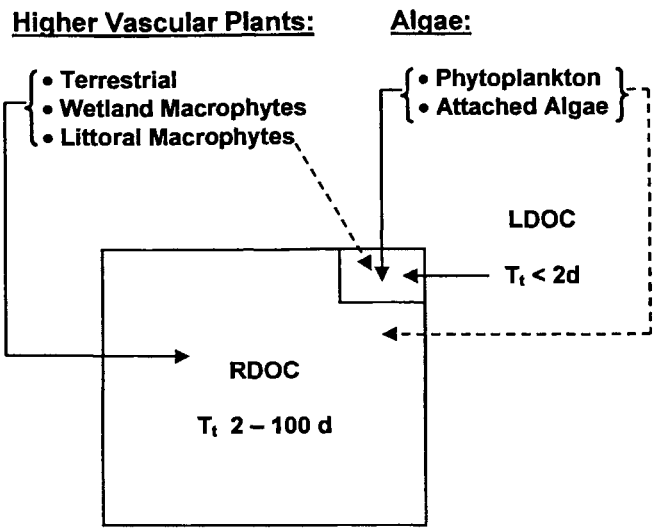

FIGURE 23-9 Common sources of organic carbon and rates of mineralization of labile (LDOC) and recalcitrant (RDOC) dissolved organic carbon in lakes and streams. (After Wetzel, 2000a.)

recently verified globally, cf. Cole *et al.*, 1994; Dillon and Molot, 1997a). Even though at certain times of the year, CO_2 (levels may indicate a small invasion) during periods of high primary productivity, total CO_2 evasion to the atmosphere is always in excess, usually greatly in excess, of autochthonous photosynthetic organic carbon production by phytoplankton on an annual basis.

For decades in aquatic ecology, the apparent chemical recalcitrance of humic substances that dominated the instantaneous bulk DOC of lakes and streams led to the belief that these compounds were poorly used by microbiota. Recent evidence clearly shows that bacterial production depends to a great extent upon humic materials from allochthonous sources and is stimulated by high-flow events that deliver humic organic influxes into the lakes and streams (e.g., Geller, 1985; Meyer *et al.*, 1987; Gremm and Kaplan, 1988; Kairesalo *et al.*, 1992; Straškrabová *et al.*, 1993; Volk *et al.*, 1997; Tranvik, 1998; Bergström and Jansson, 2000; cf. Chap. 17). Utilization of the imported DOC is enhanced by the longer retention times and exposure to higher temperatures and to light. To be sure, loss rates are slow, but consistently in the range of 0.5–2% per day under many different environmental conditions (Fig. 23-9). Often, rates of degradation of total dissolved organic matter are faster than 2% per day.

B. Particulate Organic Carbon (POC)

Examination of the general spatial and temporal distribution of pelagic POC of lakes of varying degrees of productivity permits a few generalizations. In oligotrophic to moderately productive lakes, the observed depth–time distribution of pelagic POC follows the productivity and biomass distribution of phytoplankton rather closely during stratified periods. When Lawrence Lake, for example, is stratified, the POC maxima lags behind highs in productivity from several days to about two weeks, especially when sedimentation of plankton is slowed in thermal density gradients of the metalimnion (Fig. 23-10). During the period of ice cover, one can frequently observe reduced primary production, lower inputs of allochthonous POC, and

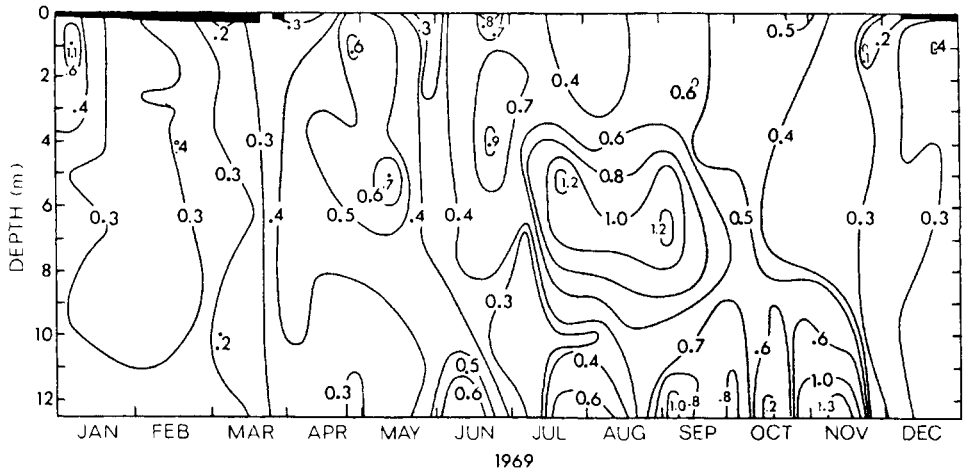

FIGURE 23-10 Depth–time distribution of pelagic particulate organic carbon (mg C liter^{-1}), Lawrence Lake, Michigan, 1969. (From Wetzel, R. G., Rich, P. H., Miller, M. C., and Allen, H. L.: Metabolism of dissolved and particulate detrital carbon in a temperate hard-water lake. *Mem. Ist. Ital. Idrobiol.* 29(Suppl.):185–243, 1972.)

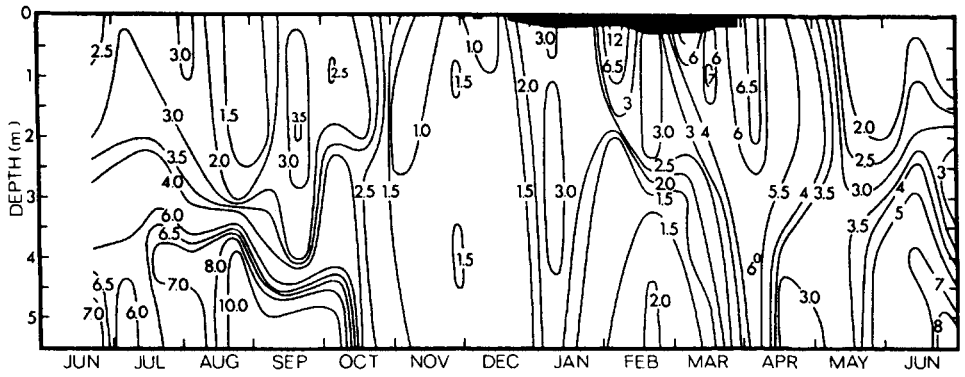

FIGURE 23-11 Depth–time distribution of pelagic particulate organic carbon (mg C liter^{-1}) of hypereutrophic Wintergreen Lake, Michigan, 1971–1972. (From Wetzel *et al.*, unpublished.)

a gradual reduction in concentrations of POC. An increase in POC generally is observed during periods of circulation when surficial sediments are disturbed and resuspended into the water column. In less productive lakes, hypolimnetic POC generally does not increase greatly unless the lower hypolimnion becomes anaerobic—for example, in the latter portions of summer stratification when specialized bacterial populations or algae (e.g., euglenophytes) may develop in profusion. In hypereutrophic lakes that receive large inputs of planktonic and littoral POC, the hypolimnia are rapidly rendered anoxic (as exemplified by Wintergreen Lake, Fig. 23-11) and bacterial productivity contributes to marked increases in POC.

The amounts of pelagic POC of a lake are relatively constant from year to year (Table 23-11), as long as the lake system is not disturbed by external influences such as enrichment from human activities. The ratio of DOC to POC is rather constant at about 10:1 in most unproductive to moderately productive lakes but is lower (ca. 5:1 to 3:1) and more variable in streams (e.g., Moeller *et al.*, 1979; cf. Table 23-1). Deviations from this 10:1 ratio with depth and season are small in less productive waters (cf., e.g., Figs. 23-7 and 23-10). As lakes become more eutrophic, the DOC:POC ratio fluctuates greatly with season and depth. In the Wintergreen Lake example (Fig. 23-11), the annual average is about 5:1; but during periods of intensive algal (epilimnetic) and bacterial (metalimnetic and hypolimnetic) growth, the ratio decreases to 1:1 or less and then increases to about 10:1 during the fall period of circulation (see also Weinmann, 1970; Pendl and Stewart, 1986). In riverine lakes and in reservoirs with high allochthonous loading of POC, DOC:POC ratios fluctuate and have lower than the global average values (ca. 4:l; Rai and Hill, 1981).

TABLE 23-11 Particulate Organic Carbon of the Pelagic Zone of Lawrence Lake, Michigan, 1968–1981[a]

Years	*Mean g C*$^{-2}$	*Mean kg C lake*$^{-1}$

1981	1.84	91.5
Average, 14 yr	2.18	108.1

[a] Data of Wetzel (unpublished).

In a productive lake in Michigan, Saunders (1972) found that the particulate organic detritus constituted from 1.3 to 16.9 times the phytoplanktonic biomass and made up >50% of the seston. The remainder of the seston was dominated by inorganic matter, such as particulate $CaCO_3$ and silica.

Estimates of the replacement of algal cell carbon in the pelagic POC have been made from measurements of the biomass of algalcell carbon and the rates of net primary production (Miller, 1972). Compensating for respiratory loss of carbon, the daily net accumulation of POC can be estimated from net primary production. The total suspended epilimnetic POC of Lawrence Lake had an average replacement time (turnover) of 40.7 days (range, 8.1–544 days). In the POC pool, a mean of 83 mg C m^{-2} (range, 30–241 mg C m^{-2}) was algal cell carbon that was replaced by primary productivity in 1.1 days (range, 0.30–2.55 days) during the

ice-free seasons. The algal cell carbon had an annual mean replacement time of 3.6 days.

Generalizations on the cycling of organic carbon among phytoplanktonic populations are difficult to make because of the paucity of data under natural conditions. POC concentrations of the pelagic zones usually are considerably larger (double or greater) in eutrophic lakes than in infertile waters (Fig. 23-12). Differences in concentrations of DOC are less marked in the transition from oligotrophic to highly eutrophic waters. Algal cell carbon commonly increases nonlinearly with increasing fertility, and a slight tendency towards algal cells of greater size is found in eutrophic lakes. Replacement times of algal cell carbon by net primary production are usually larger (slower turnover times) in eutrophic than in oligotrophic waters, but the increases in replacement times are not proportional to increases in cell carbon. Hence, in less fertile waters, the algal cells are photosynthesizing more per unit cell carbon; i.e., they have a greater carbon flux per cell.

All indications point to the importance of autochthonous primary production by the phytoplanktonic and littoral flora as major contributors to the POC of natural lake systems. Allochthonous POC is relatively small in contrast to major inputs of DOC, except for special cases (e.g., in small lakes or ponds in heavily forested areas or reservoirs that are small in volume in relation to inputs and flowthrough). The sources of POC shift in their relative contributions to the total POC pool as the aquatic ecosystems frequently progress through stages of increasing fertility when exposed to enhanced nutrient loading or as seen among a series of lakes at different stages of development (Fig. 23-13). Generalizations are again problematic because of the high degree of lake individuality. The importance of the littoral components to the production of POC in a given series of lakes increases greatly and changes markedly in the transition from nutrient-limited conditions of oligotrophic lakes to light limitations imposed by biogenic turbidity, to dominance by emergent macrophytes and associated littoral microflora.

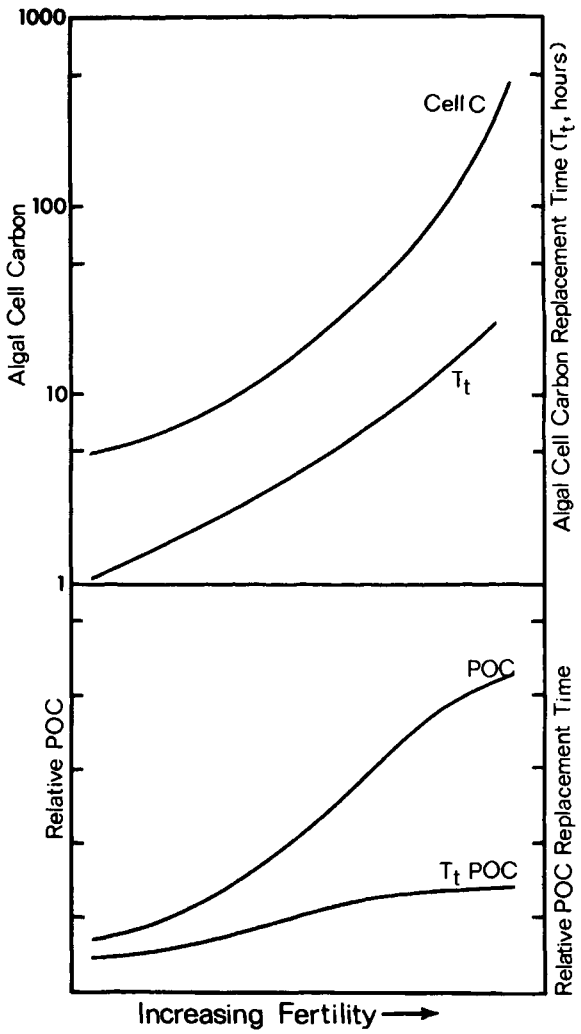

FIGURE 23-12 Generalized relationship of pelagic algal cell carbon and particulate organic carbon (POC) and their relative replacement times (T_t) in lakes of increasing fertility. (From Wetzel, R. G., and Rich, P. H.: Carbon in freshwater systems. *In* Woodwell, G. M., and Pecan, E. V. (eds.): *Carbon and the Biosphere*. Springfield, Va., National Information Service, 1973.)

C. Chemosynthesis and Nutrient Regeneration

In many cases, only low intensities of light reach the sediments within the pelagic zone; this fact, combined with the continual sedimentation of predominantly dead POC, ensures that benthic metabolism is primarily heterotrophic and detrital (Rich and Wetzel, 1978). The low rate of diffusion of oxygen into saturated sediments and its rapid utilization there mean that much metabolism is anaerobic, even when hypolimnetic oxygen depletion does not occur. Hutchinson (1941) termed this metabolism "pelometabolism" and describes its importance relative to "hydrometabolism" that occurs in the free water of the lake. Carbon dioxide produced by anaerobic detrital pelometabolism represents the escape of the oxidized product of an oxidation–reduction reaction (Fig. 23-14). The continued production of CO_2 during anaerobiosis indicates that the respiratory quotient (CO_2 release/O_2 uptake) of benthic metabolism is >1 and that alternate electron acceptors are being reduced instead of molecular oxygen. Thus, alternate electron acceptors are receiving energy originally captured during photosynthesis and transferred to carbon as water is oxidized to oxygen and CO_2 is reduced to carbohydrate (cf. Chap. 21).

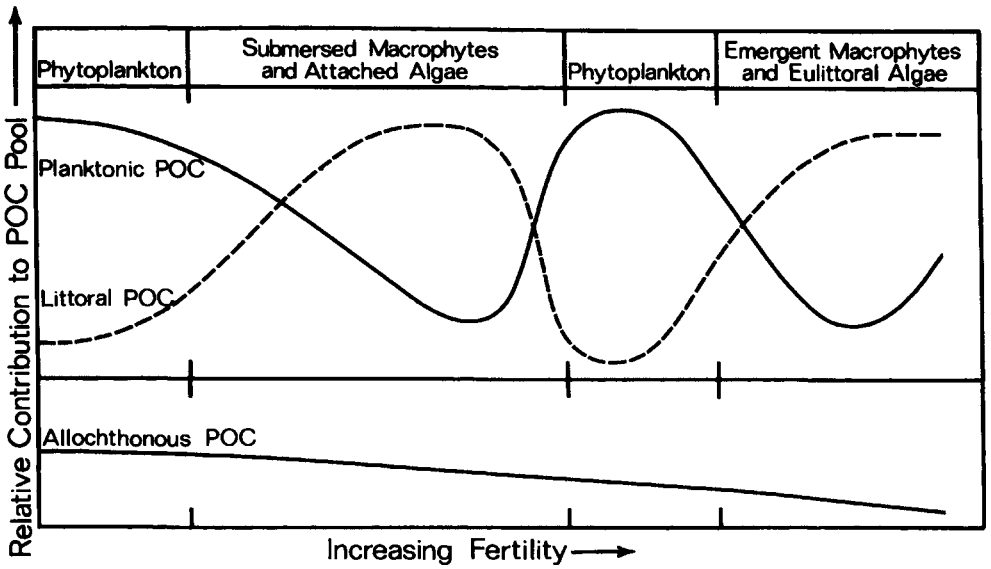

FIGURE 23-13 Generalized relative contributions of planktonic, littoral, and allochthonous sources of particulate organic carbon (POC) to lakes of increasing fertility as the dominance of pelagic and littoral primary productivity shifts (as detailed in Fig. 19-21). (From Wetzel, R. G., and Rich, P. H.: Carbon in freshwater systems. *In* Woodwell, G. M., and Pecan, E. V. (eds.): *Carbon and the Biosphere*. Springfield, Va., National Information Service, 1973.)

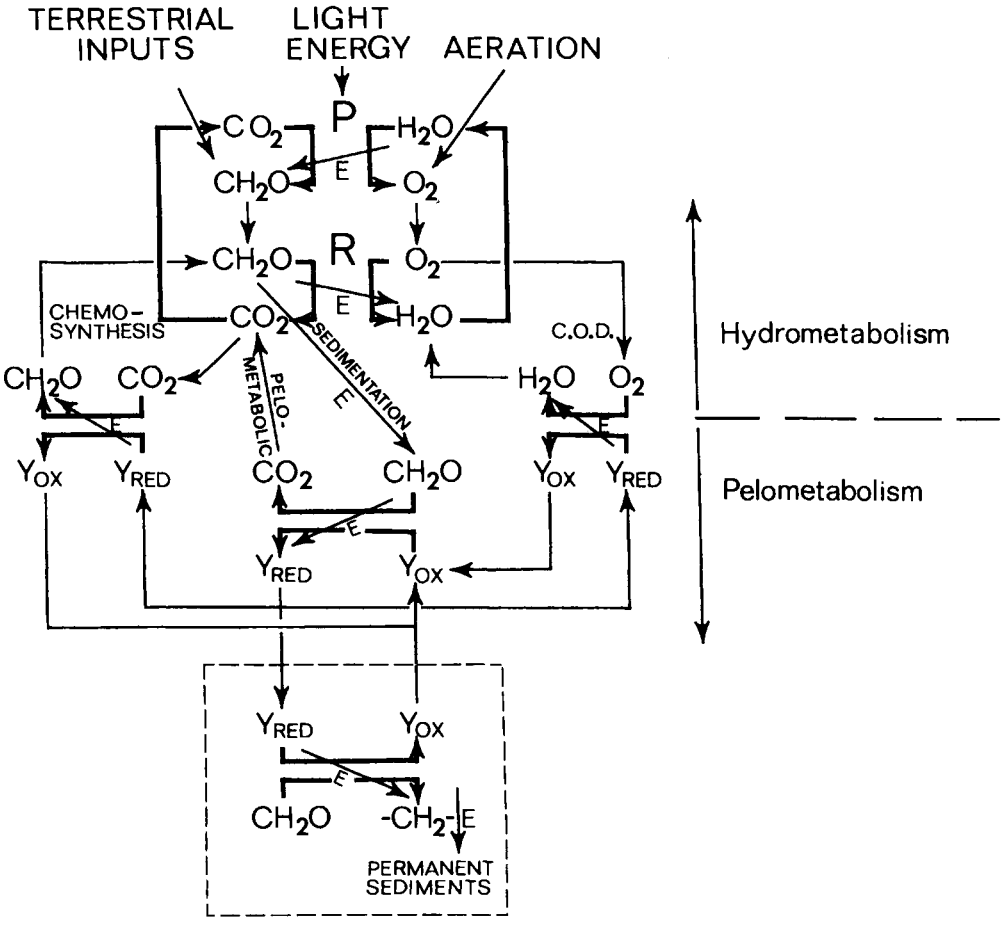

FIGURE 23-14 Oxidation–reduction reactions associated with benthic detrital electron flux from sediments. *P* = photosynthesis; *R* = respiration; *E* = electrons; red = reduced; ox = oxidized; C.O.D. = chemical oxygen demand. (Modified from Rich and Wetzel, 1978.)

This accumulation of electrons in the sediments must be interpreted as functional with respect to the ecosystem (Wetzel *et al.*, 1972; Rich and Wetzel, 1978). The ***detrital electron flux*** into and ultimately out of the sediments originates from the same photosynthetic energy source as does a predator's food and is a much larger proportion of the total source. Presumably, evolution, or at least integration, of the ecosystem has incorporated this energy flow into its overall function to the same extent as the more recognized flow through predator–prey systems. Reduced ions, radicals, and molecules are generally more soluble than their oxidized form; as a result, the reducing conditions favor an increase in the net rate of diffusion out of the sediments. Upon entry of these products into the oxidized layers of the lake, further oxidation may proceed either chemically or biologically. If the original detrital reduction involved a nutrient (sulfate, nitrate, or ferric phosphate) or a fermentation product, the detrital energy has effected both nutrient regeneration and translocation. If the subsequent "hydrometabolic" oxidation is biological (chemosynthesis), the detrital energy has been reintroduced into the biota. The energy thus transferred must be considered heterotrophic rather than synthetic in that it is originally derived from primary production (cf. Sorokin, 1964, 1965).

In order to further understand the consequences of the benthic detrital electron flux, some basic considerations of the possible alternatives of benthic metabolism are worth evaluating. Material enters the sediments by sedimentation because it is particulate—that is, it is relatively insoluble. If it remains insoluble it will enter the permanent sediments of the lake and decrease the volume of the lake—that is, reduce the lifespan of the lake. In order to escape the sediments, it must become more soluble, gaseous, or both.

Presumably, cellulose and similar materials constitute much of the organic material that enters the sediments. The intermediary metabolic products of such compounds are increasingly soluble and culminate in carbon dioxide that is both gaseous and highly soluble. Very reduced carbon compounds—for example, methane—are also gaseous and volatile, soluble, or both. The loss of dissolved organic carbon from the lake sediments is not well understood, but organic acids, acetic acid in particular, are significant products (Chap. 21). A carbohydrate (e.g., cellulose) requires one molecule of oxygen for each carbon atom in order to be oxidized to CO_2 and water. The removal of a molecule of oxygen will release two carbon atoms when the product is methane. However, oxygen represents the heaviest atom in cellulose, and the simple removal of oxygen via the production of CO_2 reduces the mass of the molecule appreciably and results in less potential sediment.

As we have seen, CO_2 and methane are the major gases escaping from benthic metabolism. Highly reduced carbon compounds are also well-known products of long-term sedimentation—that is, coal and petroleum—and increasing concentrations of carbon, in excess of that found in carbohydrates, are measurable in lake sediments over much shorter time periods (Shiegl, 1972). Given this format, at least two additional ecosystem-level consequences of the benthic detrital electron flux may be hypothesized.

The redox potential in lake sediments brought about by anaerobic metabolism represents a measure of electron activity that has been dissociated from biochemical (enzymatic) "constraints" or reaction specificity (Rich and Wetzel, 1978). Consequently, these electrons may diffuse out of the sediments in association with a number of inorganic and organic compounds, as has already been described. The exhaustion of a particular class of electron acceptors causes the benthic redox potential to become more negative relative to molecular oxygen; this continues until new acceptors precipitate back into the sediments following hydrometabolic oxidation as highly insoluble compounds (e.g., FeS or CuS). On the other hand, the carbon and oxygen in the form of CO_2 are the relatively massive products of the oxidized component of the anaerobic oxidation–reduction reactions. Thus, the net diffusion of reduced compounds out of the sediments is controlled by redox potential, and the net diffusion controls the export of mass—that is, carbon and oxygen—from the lake sediments. In this manner, the lifespan of the lake is affected directly by reduction of mass through losses of large quantities of gases of carbon and oxygen. The rate of the detrital electron flux is fundamental to eutrophication rates of lake systems.

The importance of detrital electron flux in benthic metabolism is reflected further by the changes in ratios of CO_2 evolution to consumption of molecular oxygen in hypolimnia over an annual period. The oxygen uptake by benthic sediments in lakes generally is considered to exceed the concomitant evolution of CO_2. Oxidations of proteins and fats result in respiratory quotients (RQ = CO_2 released/O_2 consumed) of less than unity, as has been demonstrated often by caloric combustions of benthic organisms. An RQ value of 0.85, generally accepted as an average value (Ohle, 1952; Hutchinson, 1957), has been used in estimates of lake productivity by hypolimnetic CO_2 accumulation (Chap. 11). Anaerobic bacterial fermentative metabolism produces excess CO_2, a positive CO_2 anomaly, and volatile organic compounds, such as methane, that diffuse out of the sediments.

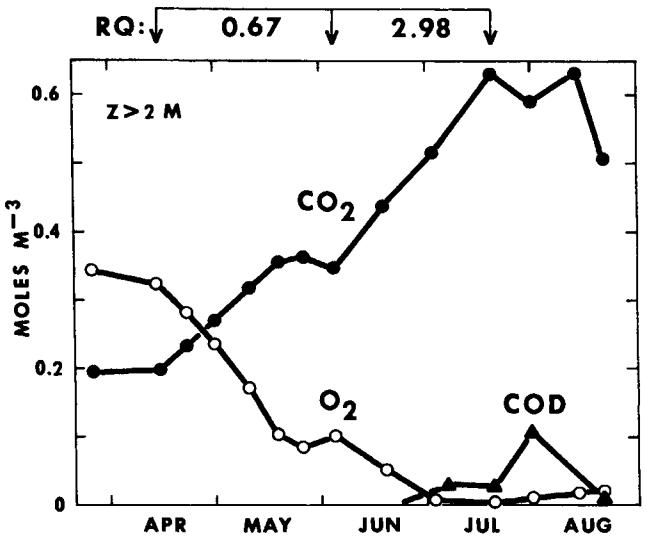

FIGURE 23-15 Changes in the hypolimnetic concentrations of CO_2, O_2, and chemical oxygen demand (COD) and the benthic respiratory quotients, Dunham Pond, Connecticut. (From data of Rich, 1975.)

Lake sediments have an "oxygen debt" that is indicated by low and negative redox potentials and nonbiological chemical uptake of molecular oxygen by reduced substrates that were formed under anaerobic conditions (Rich, 1975). This suggests that microbial metabolism involving glycolysis and reactions in the tricarboxylic acid cycle are continuing, while oxidative reactions using molecular oxygen as the terminal electron acceptor (i.e., the respiratory cytochrome system) are impeded by limited O_2 diffusion (Wetzel *et al.*, 1972). Viewing the *RQ* concept at the benthic community level, which would include the anaerobic bacteria that utilize electron acceptors other than molecular O_2, the benthic respiratory quotients would be greater than those of organisms undergoing aerobic metabolism. Additionally, the *in situ RQ* values would be expected to vary seasonally with water circulation periods at overturn and changes in redox gradients in response to varying rates of oxygen diffusion. Such was the case in Dunham Pond, Connecticut, in which Rich (1975) found during stratification that respiratory quotients of the hypolimnion varied inversely with the availability of oxygen (Fig. 23-15) from <1 after spring circulation and oxygen renewal. The respiratory quotients increased, however, to nearly 3 under anoxic conditions during the latter portion of summer stratification. Similar results have been found in a number of other lakes (Rich and Devol, 1978; Rich, 1980; Mattson and Likens, 1993). Under anaerobic conditions, high respiratory quotients are the result of the oxidation of organic carbon to CO_2 during the reduction of alternate electron acceptors, which then appear as oxidizable substrates. Reductions in sediment mass also result from this process, because soluble and gaseous products are formed that increase diffusion of reduced matter out of the sediments. Further, the removal of oxygen (reduction) from permanently sedimented carbon compounds represents the removal of more than half their mass.

To conclude, the alternate role of detrital electron flux suggests that existing lakes can be viewed as temporarily sedimenting energy rather than mass, which permits an extended existence. Simultaneously, benthic detrital electron flux tends to close the carbon and particularly the oxygen cycles of lakes.

V. DETRITUS: ORGANIC MATTER AS A COMPONENT OF THE ECOSYSTEM

Studies that address detrital origins and its metabolism directly, including the nonplanktonic and terrestrial components of the lacustrine ecosystem, are few. The heterogeneity and diversity of lacustrine detritus are reflected in the compound nature of most lake ecosystems. The role of allochthonous inputs in the metabolism and trophy of streams has been emphasized by numerous investigations (Ross, 1963; Hynes, 1963; Darnell, 1964; Cummins, 1973). Similarly, pelagic metabolism can be strongly influenced by edaphic factors and terrestrial metabolism in small lakes with high drainage-area-to-volume ratios. The importance of very high wetland and littoral productivity and extensive loading of organic matter and nutrients from the drainage basin disputes Forbes's (1887) statement that a lake. . . "is an islet of older, lower life in the midst of the higher, more recent life of the surrounding region." Further, it is simply untrue, as Shelford (1918) proposed, that "one could probably remove all the larger plants from a lake and substitute glass structure of the same form and surface texture without greatly affecting the immediate food relations." Most lakes are small with high shoreline-to-surface-area ratios, and pelagic metabolism is modified by littoral metabolic activities and inputs. Moreover, sedimentation of organic matter from both littoral and pelagic sources in the relatively static waters of lakes results in a displacement of much of the lake's metabolism to the sediments. Prerequisite to a study of aquatic ecosystem structure is a complete representation of the productivity inputs of all components. The metabolism of detrital organic matter results in a complex carbon cycle that dominates both the structure and function of lake and river ecosystems.

A. Definitions of Detritus and its Functions

Organic detritus or "biodetritus" was described by Odum and de la Cruz (1963) as dead particulate organic matter inhabited by decomposer microorganisms. The existence and importance of detritus in many habitats have since become the subject of a large and widespread literature. However, the position of detritus in relation to the trophic dynamic concept of Lindeman (Chap. 8) was not clarified until recently. Balogh (1958) demonstrated that detritus, as egested material, can constitute an important fraction of total metabolism in several terrestrial soil and litter communities. On the other hand, Odum (1962, 1963) and others have emphasized that detritus originating as ungrazed primary production supports a "detritus food chain" that is essentially parallel to the conventional "grazer food chain" at succeeding trophic levels.

The importance of the divergence between the concepts of the grazer food chain and the detritus food chain has been emphasized and clarified by Wetzel and co-workers (1972; Rich and Wetzel, 1978; Rich, 1984). Part of the difficulty stems from the concept of ecological efficiencies as it grew out of the original statement of the trophic dynamic model by Lindeman (1942; cf. Kozlovsky, 1968). Lindeman's trophic dynamic concept indeed offers explanations for Eltonian pyramids of numbers and biomass. The postulated trophic levels estimated predation and concluded that energy transmitted by predation influences the amount of biomass at each trophic level. In this way, productivity included biomass and turnover dynamics by respiration, predation, and nonpredatory losses. Lindeman estimated predation or trophic transfers at every trophic level simply by biomass plus respiration at each trophic level. Thus, his corrected productivity was the sum of biomass, respiration, and inferred predation and decomposition. Decomposition was egestion (defecation) by a predator or ingested but unassimilated prey by simple difference (decomposition of trophic level n material was egestion by trophic level $n + 1$). Other nonpredatory losses, such as prey not killed or prey killed or that died but were not eaten, were ignored as trivial, which they are not.

Efficiency is a ratio of product over reactant, or, in the case of an ecological efficiency, the productivity of a predator over predation upon its prey. Lindeman defined trophic efficiency as the ratio between assimilation by one trophic level and the assimilation of the preceding trophic level (i.e., Λ_n/Λ_{n-1}). This formulation recognizes neither the existence of material egested or otherwise lost by trophic level n nor postassimilatory, nonpredatory losses at Λ_{n-1}, which may be lost to those trophic levels and to the grazer food chain but which *are not lost to the ecosystem as a whole.* Although later studies on ecological efficiencies have used different formulae (e.g., $\text{Ingestion}_n/\text{Ingestion}_{n-1}$) (Slobodkin, 1960, 1962), discrimination between egestion and other nonpredatory losses from respiration is commonly not done (Burns, 1989; Hairston and Hairston, 1993). Therefore, most empirically derived aquatic ecological efficiencies that do not specify respiration are in reality agricultural or grazer food chain efficiencies and not applicable to complete ecosystems in which detrital organic matter is the significant trophic pathway.

A more realistic system operation is integrated diagrammatically in Figure 23-16. Here autochthonous organic matter represents all carbon fixed by autotrophs living within the lake or river ecosystem, minus their respiratory losses. The actual immediate form of organic matter productivity may be living cellular material (primary POM), which may become detrital secondarily, or dead particulate or dissolved organic carbon, or both.

A three-phase system of organic carbon is operational: dead organic matter, both particulate and dissolved (Fig. 23-16, *left*); living particulate organic material (*right*), which has the potential of entering either the POC or DOC pool upon death and whose metabolism may either create or destroy all three phases; and CO_2. Nonliving equilibrium forces are also present (e.g., photooxidation and hydrolysis of organic compounds). As is discussed later, these processes potentially represent turnover rates that can equal biological metabolism and certainly can enhance rates of microbial utilization. Therefore, metabolism represents the organizing force in the structure of the organic system, and it is metabolism that determines to a large extent the kinds and magnitudes of transformations that occur between the oxidized and reduced forms of carbon. The top of the diagram represents the zone of reduced carbon inputs, the middle portion the zone of oxidation to CO_2, and the lower portion represents losses of organic matter from boundaries of the system. The two parallel dynamic pools of organic carbon (dead, *left*; living, *right*) originate photosynthetically and are depleted by oxidation to CO_2 and exports. Although bacteria are shown in association with detritus, they function as biota. Odum's detritus food chain is really a link between the two pools in the direction of the biota. From the standpoint of the ecosystem, however, microbial and photochemical utilization of organic matter is a major utilization of organic matter that totally dwarfs utilization by higher organisms. Moreover, nonpredatory losses are in reality "nonpredatory productivity"—that is, productivity that is available to organisms other than predators, namely bacteria.

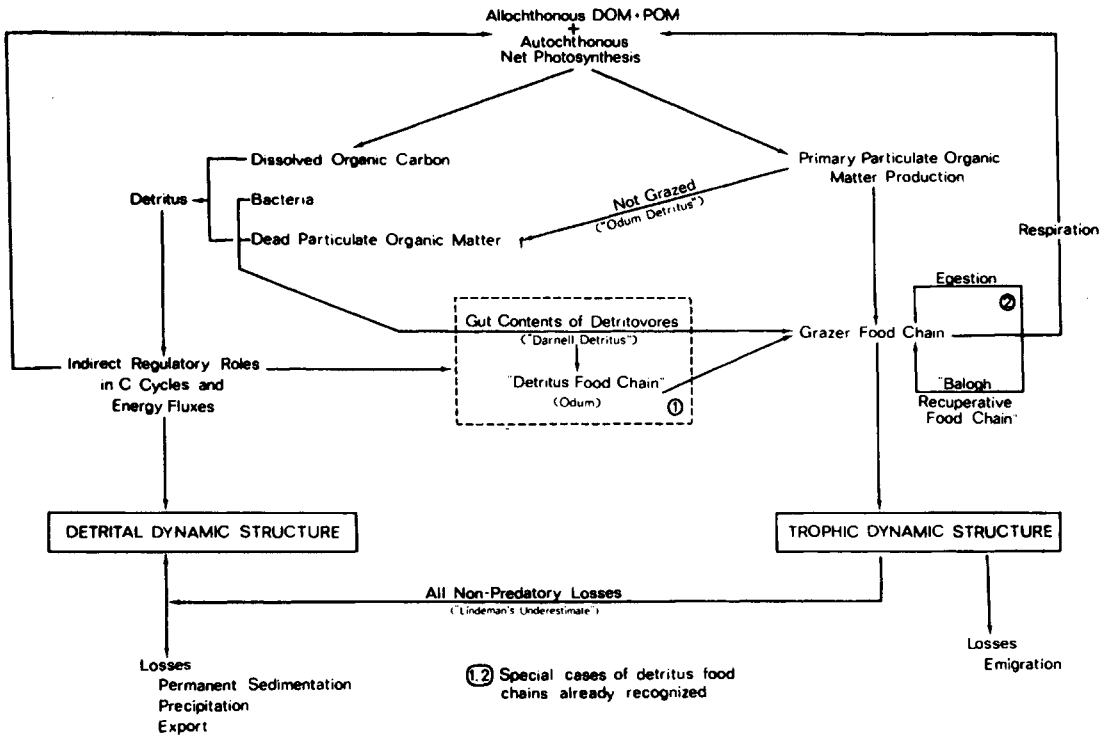

FIGURE 23-16 Generalized integration of the trophic and detrital dynamics of aquatic ecosystems. (From Wetzel *et al.*, 1972.)

A major point to be emphasized is that frequently >90% of the organic matter entering the system from photosynthetic sources is not utilized in the grazer and detrital food chains. Among studies of the trophic dynamic food cycle relationships, lack of appropriate recognition of nonpredatory losses from autotrophs ("Odum's detritus") and nonpredatory losses from heterotrophs ("Lindeman's underestimate"; see Fig. 23-16) represents a major void in contemporary system analyses.[3] As noted earlier (Table 16-12), Richman (1958) and Slobodkin (1962) demonstrated that a large amount of ingestion is not assimilated and that egestion can be 80% or more of what is ingested, instead of the 10–20% estimated by Lindeman. Ingestion and the percentage of egestion increase markedly with increasing food availability.

Detritus and associated terms have been redefined (Wetzel *et al.*, 1972; Rich and Wetzel, 1978) in an attempt to make current terminology consistent with the ecosystem concept and to avoid perpetuating the oversight of nonpredatory pathways. The new definitions do not contradict the old, but are defined more broadly so as to avoid some of the ambiguity inherent in the concepts of the ecosystem and trophic-level efficiencies espoused by earlier investigators and perpetuated by many recent ones.

Detritus *consists of organic carbon lost by nonpredatory means from any trophic level (includes egestion, excretion, secretion, and so forth) or inputs from sources external to the ecosystem that enter and cycle in the system (allochthonous organic carbon).* This definition removes the highly arbitrary "particulate" restriction from existing definitions of detritus. In terms of the ecosystem, there is no energetic difference between DOC lost from a phytoplankter or feces or other exudates lost from an animal. Rates of utilization may differ, but functionally the organic carbon and energy are the same. Detritus is all dead organic carbon, distinguishable from living organic and inorganic carbon.

Second, the bacterial component is not combined with detritus ("biodetritus" = POM plus bacteria of Odum and de la Cruz, 1963) because this interferes with the general applicability of the term to situations in which detritus is not simply ingested. Such cases include the use of detrital energy in the regeneration of nutrients such as CO_2, N, and P; algal heterotrophy; losses by adsorption; flocculation; precipitation with $CaCO_3$; chelation of elements, and so forth. In some

[3] Notable exceptions are the theoretical analyses and models of Patten (1985), who has shown the important thermodynamic relationships of detritus and how the ecosystems must operate.

cases, plant and algal materials can pass through the digestive tracts of animals and not be completely killed before being released in feces (e.g., Porter, 1973, 1975; Velimirov, 1991). Growth can continue with these living cells or plant fragments after gut passage and even be enhanced by exposure to concentrated nutrient supplies en route. This material would be excluded from the definition of detritus. Detritus is dead, and therefore living egested material is not detritus.

The ***detritus food chain*** *is any route by which chemical energy contained within detrital organic carbon becomes available to the biota.* Detrital food chains must include the cycling of detrital organic carbon, both dissolved and particulate, to the biota by direct heterotrophy of DOC, chemoorganotrophy, or absorption and ingestion. The definition of "detritus food chain" emphasizes the actual trophic linkage between the nonliving detritus and living organisms and recognizes the metabolic activities of bacteria attached to detrital substrates as a trophic transfer. *The special case of a detrital food chain in which detrital energy is subsequently transferred by noncarbon substrates in an anaerobic environment has been termed* ***detrital electron flux.*** As discussed in the previous section, such energy may reenter the biota (chemosynthesis) or mediate chemical or physical phenomena, or both, such as increasing the availability of inorganic nutrients in an anaerobic hypolimnion or in the sediments. The term *flux* specifies the flow of electrons, not carbon, to alternate electron acceptors in the absence of molecular oxygen.

Detritus, as a component of the environment, *can also affect facets of the chemical and physical milieu without clear, defined energetic transformations of the detritus itself.* In this situation, reference is made to effects of detritus that do not involve oxidation–reduction reactions. Examples include several indirect effects by which detrital organic carbon can influence and regulate the total energy and carbon flux of an aquatic system. Adsorption onto the surfaces of and coprecipitation of dissolved organic compounds with inorganic particulate matter (clays, $CaCO_3$, and others), and complexing of inorganic nutrients by dissolved organic substances (e.g., humic compounds) are examples of this interaction.

Physical processes, such as partial or complete photochemical modification of organic macromolecules, can result in major alterations in biological availability of portions of complex, heterogeneous dissolved organic compounds. These processes can affect the decomposition, utilization, and effects of dissolved organic matter in many ways. Examples include:

a. *Alterations of enzymatic accessibility by the macromolecules.* In particular, cross-linking of polypeptide chains with polyphenolic humic substances can lead to enzymatic inhibition or reduction of activity (e.g., Wetzel, 1991, 1993; Haslam, 1998; Boavida and Wetzel, 1999).

b. *Partial photolysis of humic macromolecules,* particularly with the generation of volatile fatty acids and related simple compounds that serve as excellent substrates for bacterial degradation (e.g., Stewart and Wetzel, 1981; Wetzel *et al.*, 1995; Moran and Covert, 2001; discussed in detail in Chap. 17). It is important to recognize that of the total photolytic irradiance, about half of the partial photolysis of organic substrates results from UV-B (285–300 nm) and UV-A (320–400 nm) irradiance. Transmittance and photolytic activity from UV-B and UV-A is restricted largely to the surface waters. In contrast, photosynthetically active radiation (PAR, 400–720 nm), although much weaker energetically than UV, penetrates into water to much greater depths. Although photolysis of organic compounds is appreciably less than that induced by UV at surface waters, the photolytic generation of simple substrates is appreciable by PAR as well as by UV (Fig. 23-17). Results of such studies are indicating that over half of labile organic substrates are generated by PAR irradiance of dissolved humic substances.

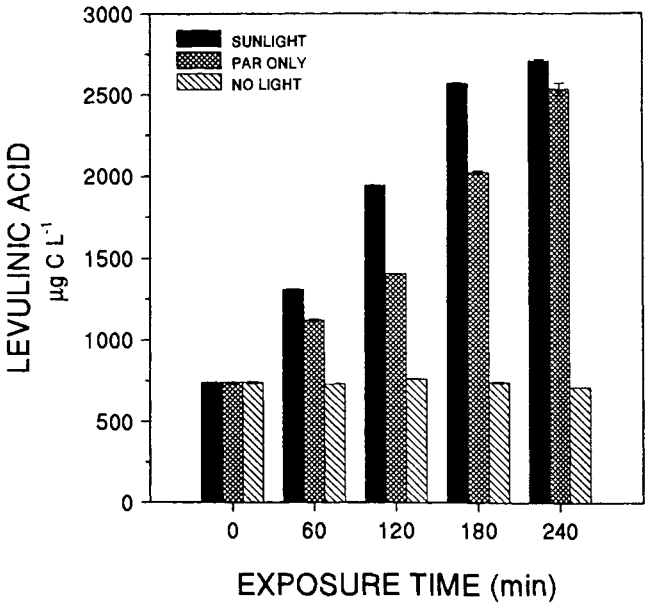

FIGURE 23-17 Net generation of levulinic acid from the partial photolysis of sterile whole leachate (0.2-µm pore-size filtrate) of the emergent macrophyte *Juncus effusus* (10 mg DOC liter^{-1}) after four weeks of microbial decomposition at 20°C in the dark. Exposed to full natural sunlight of UV-B, UV-A, and photosynthetically active radiation (PAR) (13.05 mol m^{-2} over the 4-h period), to PAR only, and incubated simultaneously in the dark. Error bars = SD, $n = 3$. (Modified from Wetzel, 2000d.)

If the photodegradation continues to the point that most of the chromophoric humic compounds are photolysed and utilized biologically or converted to CO_2, the residual nonchromophoric DOC appears to be fairly resistant to appreciable biological degradation. For example, in very shallow wetland pools and saline lakes, chromophoric DOC can be reduced appreciably (Tranvik and Kokalj, 1998; Arts *et al.*, 2000). In many shallow saline lakes, the nonchromophoric DOC concentrations can be very high (to 30 mg C liter^{-1} or more). The specific nature of the recalcitrance of nonchromophoric DOC to bacterial degradation is unclear. Exposure of dissolved humic substances to strong UV-C (254 nm) reduced subsequent growth of bacteria (Lund and Hongve, 1994). These authors suggested that radicals induced by radiation mediated the negative growth effects. However, most of the identified nonabsorbing photodegradation products are good substrates for bacteria (e.g., Wetzel *et al.*, 1995).

c. *Partial photodegradation of dissolved organic nitrogen and phosphorus compounds* to release inorganic nutrient compounds such as nitrate, ammonia, and phosphate (e.g., Manny *et al.*, 1971; review of Moran and Zepp, 1997).

d. *Complete photolysis of humic substances to CO and CO_2*, with some dissociation to dissolved inorganic bicarbonate as well as evasion of some CO_2 to the atmosphere. Photochemical oxidation by sunlight of natural dissolved organic carbon compounds to both carbon monoxide (CO) and dissolved inorganic carbon (DIC) has been known for some time (e.g., Miller and Zepp, 1995). Depending on the dissociation conditions, some excess CO_2 will evade to the atmosphere. Early studies on the photolytic degradation of dissolved organic matter suggested that the dominant component of solar irradiance was UV-B and UV-A and that PAR above 400 nm was of little consequence. Many of these studies, however, were not performed under sterile conditions, and as a result findings were confounded by nearly instantaneous microbial utilization of the organic compounds generated with rapid degradation and generation of CO_2. Moreover, many of the DOM sources of these studies had been exposed to natural sunlight for long (e.g., weeks) and noncomparable periods of light. Contemporary research is indicating that although UV-B and UV-A are significant and can contribute to more than half of photochemical mineralization, photosynthetically active radiation (PAR, 400–720 nm) is also a major photolytic agent (Vähätalo *et al.*, 2000; Wetzel, 2000c,d). For example, from nearly 200 separate photolytic experiments on DOM from different waters and plant sources under different conditions of decomposition, the UV-B portion of the spectrum was always most effective in complete photodegradation to CO_2, but

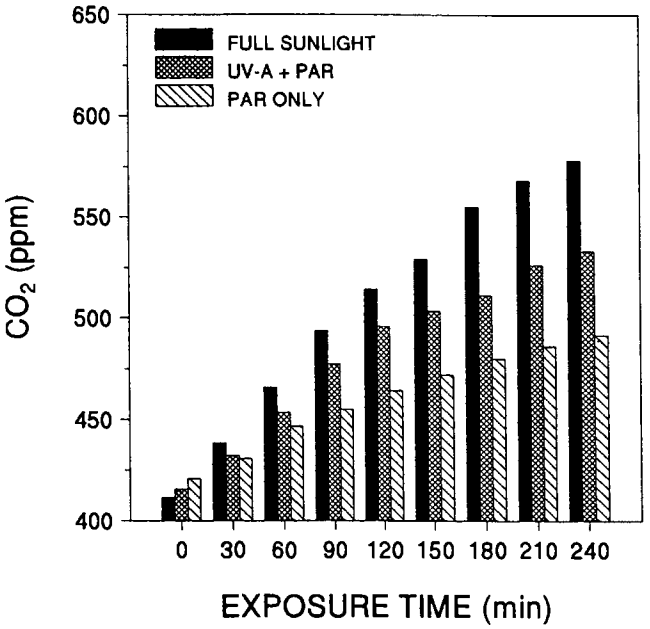

FIGURE 23-18 Photolytic degradation of sterile dissolved organic matter (leachate from *Juncus effusus*, 0.2-μm pore-size filtrate) to CO_2 under replicated, aseptic conditions exposed to full sunlight (UV-B, UV-A, and PAR) of 15.53 mol m^{-2} over the 4-h period, to UV-A + PAR, and PAR only. (From Wetzel, 2000a.)

UV-A was also highly effective, with small differences from the photolytic capacities of UV-B (Fig. 23-18). PAR is also highly effective in photolytic degradation of DOM to CO_2, and about one-quarter (23.4%) of the collective photolysis can be attributed to the largely blue portion of the PAR spectrum (400–700 nm) and ca. 68% to UV-A (320–400 nm) (Fig. 23-19).

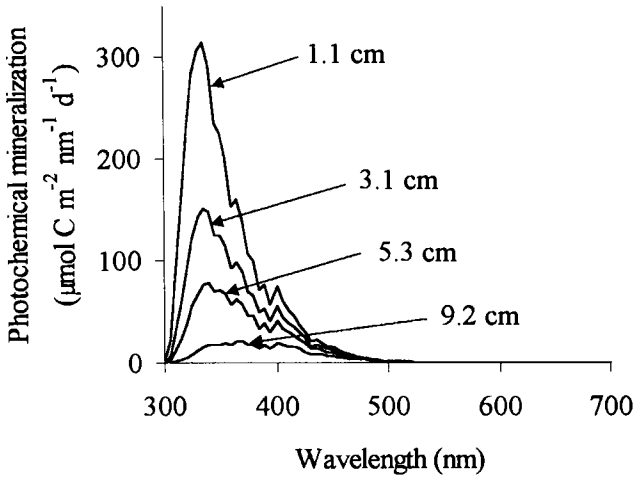

FIGURE 23-19 Photochemical mineralization of chromophoric dissolved organic matter at different depths in humic lake Valkea-Kotinen, Finland, 26 July 1994, indicating the increasing proportion of mineralization with greater depth resulting from irradiance in the visible range. (Modified from Vähätalo *et al.*, 2000.)

Approximately half of the collective photolysis was induced by natural light of a wavelength >360 nm. The relative importance of PAR as a mineralizer to that proportion increases with greater depths.

Both partial photolysis to the generation of volatile fatty acids and other simple organic substrates, as well as complete photolysis with the generation of large quantities of CO_2 by PAR, are important findings because of the much lower extinction rates of PAR in water in comparison to those of ultraviolet irradiance. Photolytic processes, so important to nutrient cycling, are therefore not restricted to the uppermost strata of a few centimeters of aquatic ecosystems, but rather can affect much of the variable volume of the photic zone.

Furthermore, the photolytic responses are very rapid. For example, when natural sunlight was attenuated very rapidly, as by a severe thunderstorm (Fig. 23-20, *middle*), the rate of photolytic degradation of DOC to CO_2 declined precipitously, but the photolytic capacities of PAR declined more rapidly than did the effects of UV-B (Fig. 23-20, *lower*). The precise chemical degradation processes involved in photolysis of dissolved macromolecules, particularly the helical humic substances, represent a major void in our understanding. Interdisciplinary collaboration among chemists and biologists is essential to progress effectively in our understanding of biological implications of organic molecular structure.

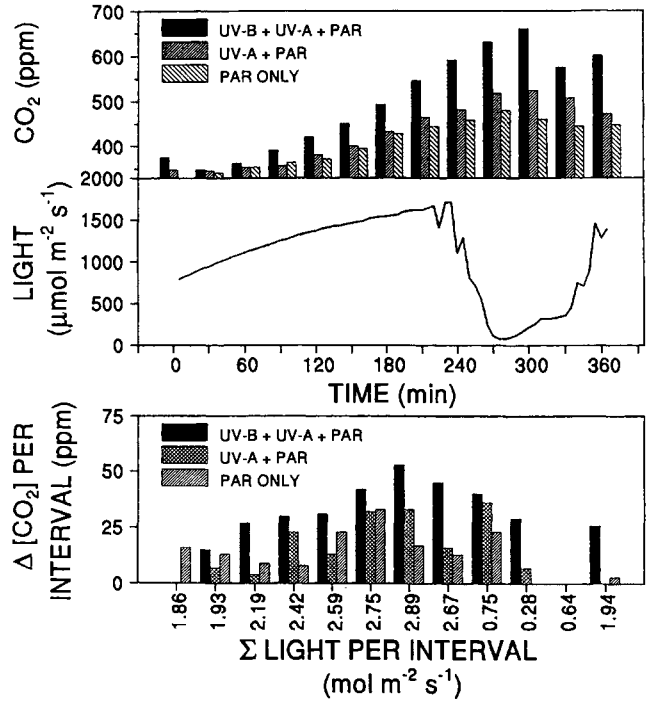

FIGURE 23-20 Photolytic degradation of sterile dissolved organic matter (aquatic plant leachate, *Juncus effusus*, 0.2-µm pore-size filtrate after 20 weeks of microbial decomposition) to CO_2 under replicated, aseptic conditions exposed to full sunlight (UV-B + UV-A + PAR), UV-A + PAR only, and PAR only (*upper*). A heavy rainstorm occurred during the incubations, which reduced light severely for an hour (*middle*). The net change in CO_2 production per amount of light received per interval under these conditions (*lower*). (From Wetzel, 2000a.)

Less direct but important biogeochemical interactions of dissolved organic matter in aquatic systems are also important but poorly studied at the ecosystem level. Natural dissolved organic substances, particularly humic compounds, in aquatic ecosystems can interact with other important metabolic components. For example, dissolved organic compounds can:

a. *Interact with inorganic compounds,* particularly in complexation reactions such as chelation, as discussed earlier (Chap. 14; see also Perdue, 1998). Depending on the concentration ratios of the complexing DOM to inorganic elements, the mode of organic complexation, biological availability, and, in some cases, elemental toxicity can be increased or decreased.

b. *Interact with other organic compounds*, such as peptidization, and alter biological susceptibility to enzymatic hydrolysis. Bonding of proteins, glycoproteins, and carbohydrates to polyphenolic humic macromolecules is a common process and results in macromolecules of considerable size (1500–90,000 D) (Münster, 1985). Membrane properties, such as lipid hydrophobicity, can be altered by such interactions with humic substances and in turn affect enzyme hydrolysis rates and nutrient transport mechanisms (e.g., Lemke *et al.*, 1995, 1998). In a most interesting interaction, humic substances can complex with proteins, particularly enzymes both freely soluble and membrane-bound, with noncompetitive inhibition (Wetzel, 1992, 1993; Münster and De Haan, 1998). Enzymes can be stored for long periods (days or weeks) in this complexed, inactive state, be redistributed in the ecosystem with water parcel movements, and be reactivated by partial photolytic cleavage by ultraviolet irradiance (Fig. 23-21) (Wetzel, 1991, 1995, 2000c; Boavida and Wetzel, 1999).

In addition, dissolved humic substances can sorb hydrophobic organic chemicals and thereby reduce their bioconcentration and toxicity (Kukkonen, 1999; Steinberg *et al.*, 2000). The binding capacity is linearly related to the hydrophobicity of the contaminant. The detoxifying capacity of humic substances is directly correlated with the quotient between aromatic and aliphatic carbons in the humic substances.

c. *Alter chemical properties such as redox and pH*; for example, exposure of natural dissolved organic matter to UV of sunlight can result in a photochemical

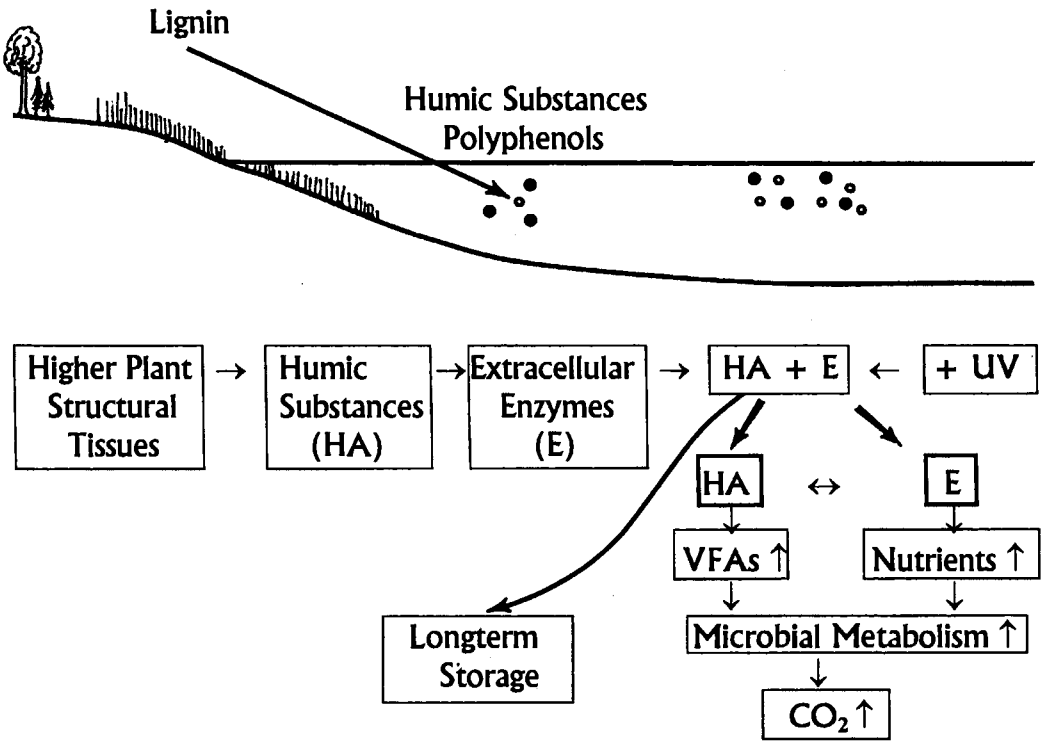

FIGURE 23-21 Potential interactive pathways and processes of humic substances emanating from decomposition products of higher plant tissues with extracellular and surface-bound enzymes and photolytic reactions, particularly with UV irradiance. Humic acid–enzyme complexes can be stable for long periods (weeks or months) and subsequently reactivated upon exposure to weak UV light. Further photolysis can cleave simple compounds from the macromolecules for subsequent utilization. (From Wetzel, 2000a.)

formation of reduced oxygen species, particularly hydrogen peroxide (H_2O_2) (Cooper *et al.*, 1988; Scully *et al.*, 1994). H_2O_2, with a half-life of several hours in natural waters, can radically alter redox cycling of metals (Moffet and Zika, 1987).

Humic substances may buffer against acidification but may also add natural acidity to surface waters when in very high concentrations in waters of low ionic strength. Organic carboxylic and phenolic acids provide a pH buffer when the pH is between 4 and 5 and the carbonate buffering capacity is absent (Kullberg *et al.*, 1993; Lydersen, 1998). Organic acids can modify the acidity of surface waters and depress water from 0.5 to 2.5 pH units when the acid-neutralizing capacity is in the range of 0–50 μeq liter^{-1}. Thus, a predominance of humic acids can result in an organic acidity that can influence, and at times exceed, inorganically derived acidity form natural or anthropogenic sources (cf. Chap. 11). However, usually organic anions represent <10% of the total anions and contribute little to acidity except in waters of extremely low ionic strength (Henriksen *et al.*, 1988; Urban *et al.*, 1988; Driscoll *et al.*, 1989; David *et al.*, 1992). Strong acids, particularly H_2SO_4, can exceed the buffering capacities of organic acids and shift surface water acidification by organic acids to total dominance by strong acids. High production of organic acids in peat wetlands and similar environments are often neutralized within the fens and bogs.

d. *Microbially reduced humic substances can*, upon entering less-reduced zones of sediments, *serve as electron donors* for the microbial reduction of several environmentally significant electron acceptors (Lovley *et al.*, 1999). Once microbially reduced, humic substances can transfer electrons to various Fe(III) or Mn(IV) oxide forms abiotically and recycle the humic compounds to the oxidized form, which can then accept more electrons from the humic compound-reducing microorganisms.

e. *Altered physical properties* such as selective modifications of light penetration. The well-known selective attenuation of light by chromophoric dissolved organic matter (cf. Chap. 5) can further modify biogeochemical cycling in numerous ways. Increasing light extinction can result in increased temperatures of surface strata with steep thermal discontinuities in the metalimnion and strong isolation of the colder hypolimnetic waters. The mixed layer depth decreases, which results

in reduced total heat content of the lake or reservoir (Hocking and Straškraba, 1999). Modifications of the spectral penetration of light from dissolved organic matter can alter rates of photosynthesis, hormonal activities, and migratory distribution and reproductive behaviors (see Chaps. 15 and 16). Absorption of ultraviolet irradiance by humic substances can protect organisms from genetic damage as well as modify macromolecules and enhance bioavailability of organic substrates.

B. Detrital Dynamic Structure of Carbon in Lakes and Reservoirs

There have been very few attempts to examine the dynamics of detrital organic carbon on a functional basis. Such studies require measurements of all nonpredatory losses of organic carbon from any trophic level within the ecosystem as well as inputs from sources external to the ecosystem that enter and cycle in the system. Obviously, a number of simultaneously interacting components are operational. It is clear, nonetheless, that most of the organic metabolism of lake systems involves the detrital dynamic structure and that an understanding of this functional system is a prerequisite for meaningful evaluation of control mechanisms of the whole ecosystem. Stated another way, we must understand carbon flux rates among all components at the same time that we seek an understanding of parameters or human disturbances important in regulating metabolism.

Quantitative analyses of the major organic carbon transformations in lake systems have shown the following general characteristics: (1) The central pool of organic carbon is in the dissolved form; (2) Three major sources of particulate organic carbon occur: allochthonous, and two distinct major zones of autochthonous carbon flux, the littoral and the pelagic of lakes or the channel water of rivers; (3) Allochthonous inputs from the drainage basin and exports from the lake or river occur largely as dissolved organic carbon and represent a major flow of carbon through the metabolism of the system; and (4) Detrital metabolism occurs principally in the benthic region, where a majority of POC is decomposed in many lakes and rivers, and the pelagic area during sedimentation in lakes. Secondary metabolism thus is displaced from sites of production and input, by sedimentation in the case of POC and by aggregation and coprecipitation with inorganic matter in the case of DOC.

Examples in support of these generalizations can be obtained from analyses of an arctic tundra pond and of the pelagic zone of a eutrophic temperate lake for a single day, of a large reservoir over a 30-day period of the summer, and of a softwater and a hardwater temperate lake over an annual period. Because of the complexity of these studies and the insights they offer into the central questions on metabolism, these analyses warrant closer scrutiny than has been given to other examples in this discussion.

The instantaneous carbon mass of the major components and transfer rates of carbon between them were evaluated for a typical midsummer day in a small arctic tundra pond by Hobbie *et al.* (1972, as modified and corrected in Hobbie 1980). These small ponds cover the northern tundra by the thousands, lying in depressions between low ridges formed above ice wedges; beneath them lies permafrost, which prevents any outflow. Most of the ponds are very shallow (<40 cm) and are frozen solid for nine months of the year. The tundra vegetation surrounding the ponds is dominated by two sedges (*Carex aquatilis* and *Eriophorum angustifolium*) and a grass (*Dupontia fischeri*). The dominant herbivore of the area is the brown lemming, which clips this vegetation close to the ground. Litter from these clippings and lemming feces form a significant source of particulate and dissolved matter reaching the ponds.

The DOC pool represented most of the total carbon present in the aqueous portion of the system because the inorganic carbon content was quite low (Fig. 23-22). Although the primary productivity on an annual basis was very low, 50% of the total was contributed by the macrophytes, 47% by the benthic algae, and 3% by the phytoplankton. The most active transfer path was the movement of detrital organic carbon from the aquatic plants to the sediments, where decomposition resulted in major respiratory loss as CO_2. The flux rates were much smaller in the water than in the sediments, and the transfer of organic carbon between POC and the zooplanktonic crustacea was small but significant. The photooxidation of dissolved organic compounds to CO_2, although small, is significant in this shallow habitat, as has been indicated for certain streams and lakes (cf. Gjessing, 1970; Gjessing and Gjerdahl, 1970; Stewart and Wetzel, 1981a; Wetzel, 2000a).

The organic carbon cycle of a shallow (1.5 m) tundra lake of the Northwest Territories of Canada was analyzed for five weeks of the open-water period by examination of CO_2 fluxes through benthic respiration and anaerobic decomposition, photosynthesis of benthic and phytoplankton communities, and gas exchange at the air–water interface (Ramlal *et al.*, 1994). The annual carbon budget estimate for the lake indicated that 50% of the carbon was produced by the benthic community, 20% by phytoplankton, and 30% by allochthonous organic matter. Benthic respiration dominated heterotrophic utilization of the organic matter.

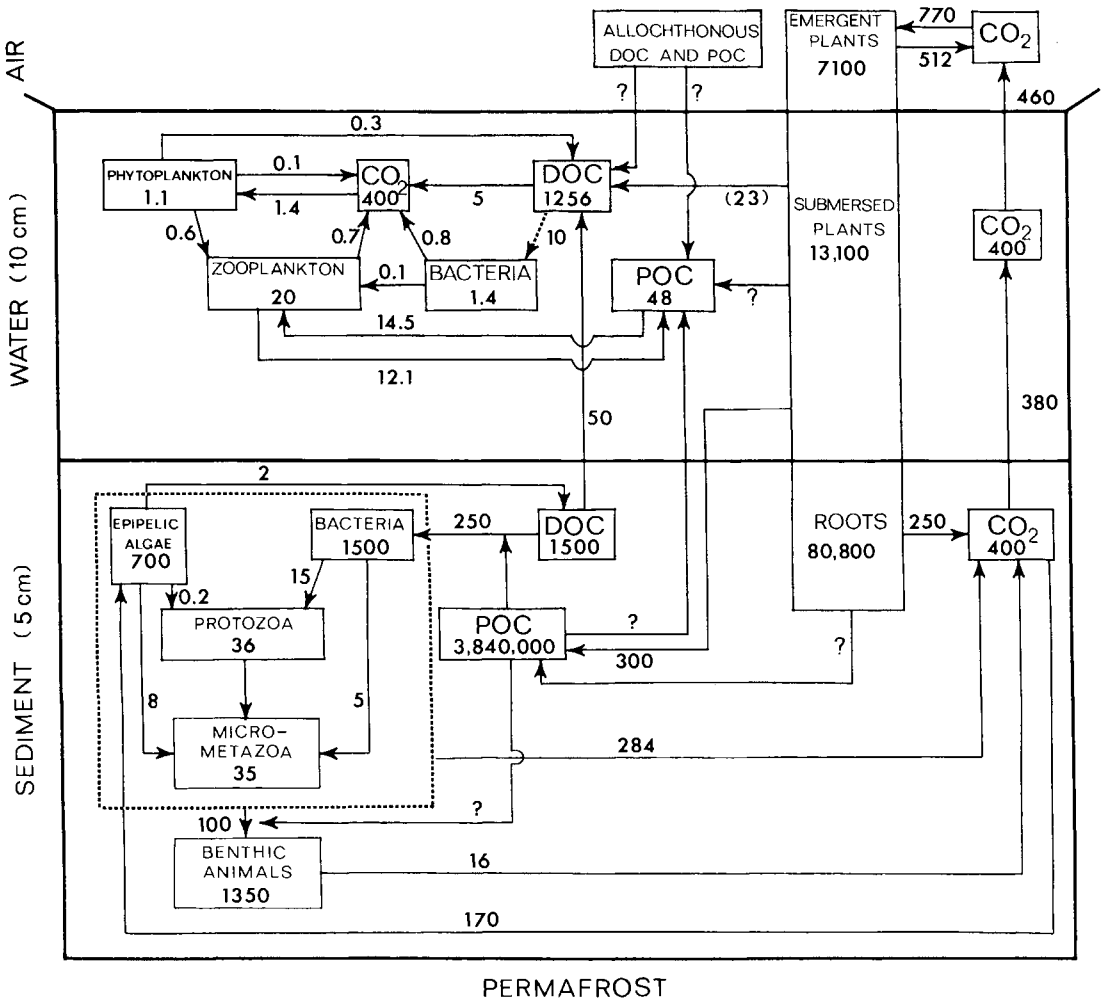

FIGURE 23-22 Carbon flow among components of a tundra pond ecosystem representative of approximately average midsummer conditions at coastal Barrow, Alaska (lat. 71°N). Data from Pond B on 12 July 1971 are used in the water portion of the diagram and those for Pond J on the same date for the sediment portion. Numbers in boxes refer to organic carbon mass (mg C m^{-2}), while arrows indicate the transfer rates (mg C m^{-2} day^{-1}). DOC = dissolved organic carbon; POC = particulate organic carbon. (Modified from Hobbie *et al.*, 1972, as corrected by Hobbie, 1980.)

The carbon flux in the pelagic zone at midsummer in the surface water of eutrophic Frains Lake, southeastern Michigan (Saunders, 1972a) demonstrates an analogous relationship (Fig. 23-23). Within a 24-h period, fluctuations in DOC ranged from two to six times more than DOC released extracellularly by the phytoplanktonic algae. Particulate organic detritus, ordinarily five to ten times greater than that of the phytoplankton, constituted a much larger potential source of DOC than living phytoplankton and was dispersed both in the photic and aphotic zones. Similarly, detrital particulate carbon was, at this time and depth, much more important energetically than phytoplankton as a food source to the crustacean zooplankton. Clearly, the organic detrital matter is quantitatively a major constituent of this system, in terms of both mass and metabolism. Its importance increases markedly from the photic to the tropholytic zone.

An approximate organic carbon budget for a shallow hypereutrophic lake exhibited very high productivity of phytoplankton, submersed macrophytes (predominantly *Myriophyllum spicatum*), and epiphytic algae (Table 23-12). Benthic respiration dominated in this shallow lake, in which the organic sediments were resuspended constantly during the ice-free period.

Another example of the relationships among pools of organic matter, living components, and fluxes among components emerges from investigations of the pelagic zone of Dalnee Lake, eastern Russia (Sorokin and Paveljeva, 1972). This lake receives a major influx of

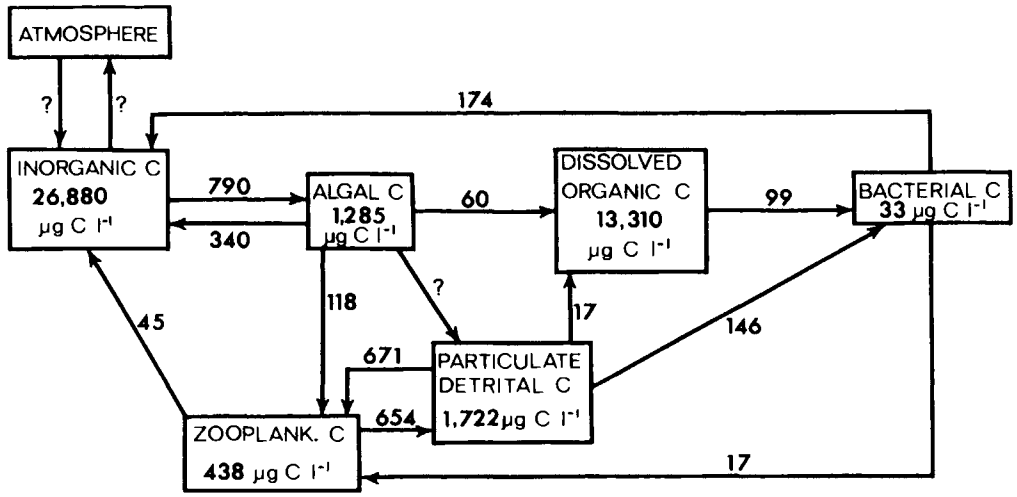

FIGURE 23-23 Pelagic carbon flow at 1-m depth in Frains Lake, Michigan, on 22 July 1968. Numbers on arrows refer to transfer rates in μg C liter^{-1} 24 h^{-1}; numbers in blocks refer to carbon concentration in μg C liter^{-1} at sunrise. (Modified from Saunders, 1972a.)

organic matter from allochthonous sources, equal to at least one-third of the total organic input (Fig. 23-24). During the month of July, the average flux rates of organic matter, expressed as calories m^{-2} per 30 days, indicated that the planktonic bacterial populations were consumed mainly by protozoa. Most of the protozoan organic matter entered the nonpredatory organic matter pool and underwent mineralization. Zooplankton and higher organisms utilized only a very small portion of the total organic base of detritus and microflora. About one-third of the zooplanktonic utilization of the microflora was by the rotifer *Asplanchna*, which was predatory on protozoa at this time of year. It was estimated that well over 70% of the organic matter entering the system from autochthonous photosynthetic and allochthonous sources became part of the nonpredatory organic matter pool and was subsequently decomposed or lost from the system by sedimentation and outflow without entering the animal components of the system.

[a] Extracted from estimates of Adams and Prentki (1982).

A detailed evaluation of the carbon budgets of a whole-lake system at meter depth intervals over several years was undertaken on a hardwater lake in southwestern Michigan (Wetzel *et al.*, 1972). In this system, organic carbon inputs and utilization were evaluated over an annual period for allochthonous inputs, exports, and dynamics in the littoral, pelagic, and benthic zones (Fig. 23-25). Even though the littoral flora of this lake is not well developed in comparison to most lakes of similar morphometry, the single largest flow of organic carbon originated as primary particulate production of the littoral zone (Table 23-13). This material was transported to the deeper sediments, where it was supplemented by additional particulate organic carbon sedimenting from the pelagic zone (Table 23-14). Allochthonous POC input to the sediments was a fraction of the POC sedimenting in the pelagic zone and is included there. Benthic microbial metabolism of the sediments released a major amount of the sedimented

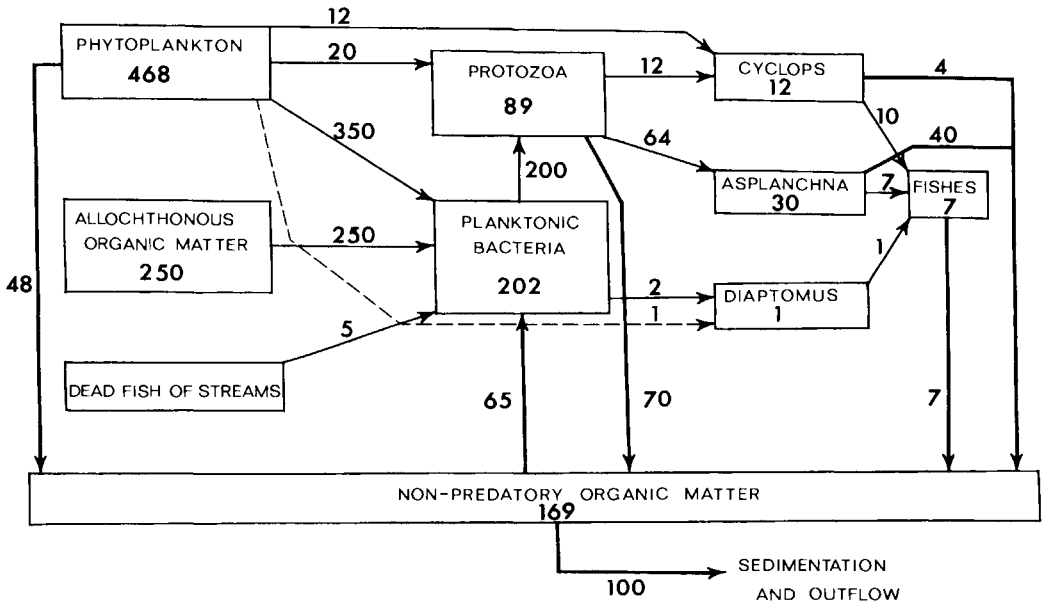

FIGURE 23-24 Generalized relationships of the average energy flow in the pelagic zone of Dalnee Lake, Kamchatka, Russia, during the month of July. Data expressed in calories m^{-2} per 30 days. (From data of Sorokin and Paveljeva, 1972.)

organic carbon to the dissolved CO_2—HCO_3^-—CO_3^- pool in respiration (Table 23-15). CO_2 released by microbial respiration was the primary flow of carbon to the photic zone, and much of it evaded to the atmosphere. A much smaller amount of benthic organic carbon was directly utilized by the pelagic community, and approximately an equivalent amount was lost by permanent sedimentation. Utilization of benthic detrital carbon (resuspension of Fig. 23-25) was almost equivalent to sedimentation losses from the pelagic zone and represented an important contribution to pelagic productivity of material originating from the littoral zone.

[a] From Wetzel *et al.* (1972). Estimates are based on a lakewide areal basis rather than on an arbitrarily defined littoral zone. Values for epiphytic algal productivity are larger based on a subsequent detailed analysis (Burkholder and Wetzel, 1989a), but the conservative value here is used for illustration of the points discussed.

An integration of these budgets of inputs and outputs permits an evaluation of the annual carbon fluxes in a whole-lake system in which the allochthonous, littoral, benthic, and pelagic organic carbon flows are considered (Table 23-16). The whole-lake budget is within 5% of being balanced, which is very good considering the magnitude of variances involved in the analyses under *in situ* conditions. Analyses of zooplanktonic grazing by serially increasing animal concentrations to 200-fold *in situ* (Wetzel *et al.*, 1972) and *in situ* measurements of grazing of phytoplankton (Haney, Wetzel, and Manny, unpublished; Crumpton and Wetzel, 1982) yielded maximal values of 25% (nighttime) and <5% (daytime) of the epilimnetic volume grazed per day during the period of maximum development of zooplanktonic populations. At other times of the year, the values were lower and therefore were considered negligible in this lake. Without question, zooplanktonic grazing can cause marked alterations in algal species composition and succession within the phytoplanktonic community at certain times of the year (see critical analyses of Lawrence Lake algal populations in Crumpton and Wetzel, 1982; Taylor

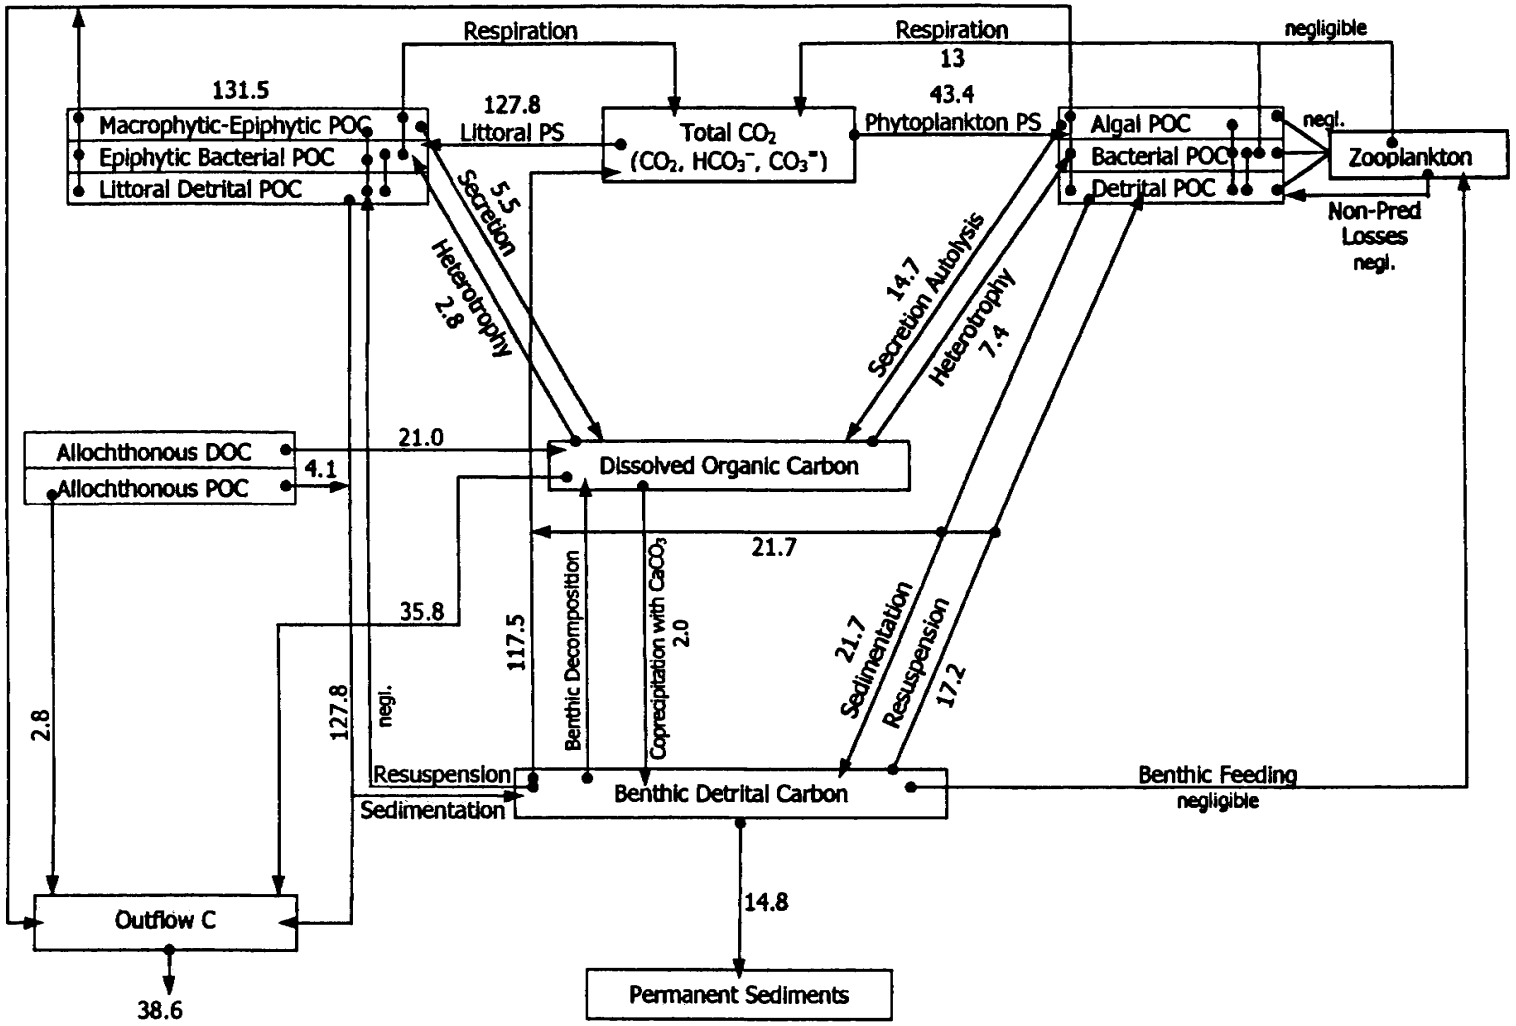

FIGURE 23-25 Detrital structure and flux of organic carbon (g C m^{-2} y^{-1}) of Lawrence Lake, southwestern Michigan. DOC = dissolved organic carbon; POC = particulate organic carbon; PS = photosynthesis. (After Wetzel *et al.*, 1972.)

Total pelagic net production (DOC + POC) = +2.8 g C m^{-2} yr^{-1}

[a] From Wetzel, R. G., *et al.*: Metabolism of dissolved and particulate detrital carbon in a temperate hardwater lake. *Mem. Ist. Ital. Idrobiol.* 29(Suppl.):185–243, 1972.

and Wetzel, 1988). These analyses, as well as others (e.g., Jewson *et al.*, 1981), however, demonstrated the importance of algal losses by sedimentation out of the photic zone; on an annual basis, sedimentation losses were much greater than losses from grazing. Sedimenting algae, as well as detritus egested by zooplankton, enter the detrital portion of the carbon cycle.

Analyses of the dynamics of the annual carbon fluxes in Lawrence Lake, of which only summary values are given in Tables 23-13 through 23-16, demonstrate the major inputs from the littoral flora and the dominance of respiration in the sediments, where this

TABLE 23-15 Annual Benthic Particulate Carbon Budget of Lawrence Lake, Michigan[a]

material is decomposed. When macrophytes are minor contributors to the total autochthonous organic inputs, as is the case in Mirror Lake, New Hampshire (Table 23-17), the respiratory metabolism of the sediments is still a major site of decomposition. In Mirror Lake (Table 23-17), phytoplankton dominate the inputs of organic carbon; the output percentages of Mirror Lake are nearly identical to those of Lawrence Lake (Table 23-16), in which the littoral inputs dominate. The importance of dissolved organic detritus in the inputs from allochthonous sources and in the outflow is in the same relationship to the whole in both lakes. The decomposition of photosynthetically fixed carbon by microflora of the littoral and the sediments, which probably dominates in most lakes of the world since a vast majority of lakes are small to very small, relegates the role of animals as "decomposers" to a lesser category, and the burden of heterotrophic metabolism is shifted to the microflora. In large lakes in which the inputs from littoral sources are proportionately low or in hypereutrophic lakes in which phytoplanktonic densities reduce light to the point of excluding much of the littoral flora, animals may assume a somewhat greater importance in the degradation of POC. The bulk of organic carbon is dissolved, however, and decomposition of that organic matter is almost completely microbial and by physical photolysis.

C. Detrital Dynamic Structure in River Ecosystems

The structure of biomass or carbon fluxes in flowing waters is much less well documented. From a detailed budget of the average daily biomass flow in a temperate woodland stream, it was estimated that 25–30% of the particulate biomass input flowed through and was decomposed by the benthic animals, assuming an average assimilation rate of 40% for nonpredators (Cummins, 1972). Allochthonous and autochthonous inputs of dissolved organic matter, which constitute at least 5 times and probably 10 times that of the POC, were not considered in this budget.

The dissolved organic matter, as in lakes, drives the metabolism of streams and rivers. It is common for >90% of the annual organic carbon movement in streams and rivers to be in the dissolved form (e.g., Table 23-18). Experimental analyses in artificial streams have demonstrated that a large portion (>50%) of this DOM can be rapidly degraded (24–48 h) by planktonic and attached bacteria under optimal conditions. Under natural conditions, some of the DOC being transported is photolysed by natural sunlight either completely to CO_2 or partially with the generation of substrates available for bacterial degrada-

tion. The amount of DOC that is converted to POM via flocculation, especially in hardwater streams as discussed earlier, or that enters bacterial biomass that is then partially degraded by animals is unclear. This area is of great interest and is in need of further research. Less than 1% of detrital organic inputs was estimated to be metabolized by macroinvertebrate fauna of a mountain stream in New England (Fisher and Likens, 1973). The role of animals in comparison to microflora in decomposition of POM varies widely, and may be even more variable in streams than in lakes, but is certainly small.

These relationships are exemplified in an annual organic carbon budget for a section of a small river in Japan (Table 23-19). Dissolved organic matter and fine particulate organic matter made up >88% of the inputs of organic carbon. Total community respiration constituted for <5% utilization of the organic matter loading. The remainder was either stored briefly or largely exported as fine POC and mostly as DOC.

It is of the utmost importance to emphasize that these examples of the functional structure of lake and stream ecosystems are only preludes to the important underlying questions of what parameters control the observed structural integrity of the system. Analyses of structure and dynamics of ecosystems are a prerequisite to analyses of factors regulating the observed and changing structure. But such analyses must not become an end in themselves. Sufficient underlying similarities between the structure and dynamics of ecosystems probably exist that will permit generalizations to emerge with less rigorous analyses. As a result, more effort could be devoted to experimental evaluation of control mechanisms. It is critical that the regulatory mechanisms of natural ecosystems be understood before human perturbations of the systems can be effectively evaluated and minimized. Meaningful applied research and wise management of aquatic resources cannot be undertaken effectively without a basic understanding of functional control mechanisms.

D. Death and Organic Cycling

Therefore, in summary, the observed heterotrophic biotic productivity of most lakes and rivers, as estimated in the detailed organic carbon budgets just discussed, could not possibly be supported by the autochthonous organic carbon generated by pelagic primary productivity within these waters. The aquatic heterotrophic productivity must be supplemented by external allochthonous organic matter imported from terrestrial and land–water interface regions. From the standpoint of the lake or a river per se, bounded by the shore line, the lake or river is a net heterotrophic ecosystem that decomposes much more organic matter than is produced within those boundaries.

Furthermore, the annual time period is the only interval of relevance in comparative analyses of productivity and utilization of organic matter (Wetzel, 1995). A significant portion of the total autochthonous annual photosynthetic production, even in the pelagic regions, occurs during cold, low-light periods when consumption by zooplankton and higher animals is reduced or virtually absent. Although that noningested production may be of little immediate consequence to the higher animal heterotrophs, it is of major importance and usually dominates energy flows within the pelagic region. Furthermore, nonpredatory heterotrophic metabolism completely dominates energy flows of the whole-lake or river ecosystem. Large amounts of dissolved and noningested particulate organic matter enter the detrital pool for the dominant microbial heterotrophy.

Utilization of organic matter by metazoan predation, however, represents only a small portion of the total organic carbon pool of the ecosystem and a very small source of DOM. Material and energy fluxes of egested particulate and soluble organic matter within the pelagic zone and the rest of aquatic ecosystems by nonmetazoan heterotrophs are largely ignored or discussed in terms of conversion back to particulate organic matter of sufficient size for ingestion by predation of metazoans (Wetzel, 1995). The common thesis that living net production in organisms, particularly algae and microbes as well as metazoans, that die largely by ingestive predation is not only unsubstantiated but also unreasonable. Predation by animals functions in the facilitation of detritus turnover, expediting the transfer rates of a small portion of organic matter by microbes in the conversion to CO_2.

Many if not most organisms—particularly bacteria, fungi, algae, as well as higher organisms—simply mature physiologically, senesce, and die, and then enter the combined particulate and dissolved organic detrital pool for utilization by microbial heterotrophs. Biochemical death of many cells and organisms is genetically programmed and fixed within relatively narrow physiological sequences. Turnover of dissolved organic matter occurs many times, with large conversions of portions of the organic matter to CO_2 heterotrophically, before predation, with much slower generation times, can respond to changes in particulate organic matter.

Senescence and mortality of bacteria, algae, and other microbes from viral infections is large (40 to >50%). Clearly, viral mortality leads to major evasions of dissolved organic matter as cellular integrity is compromised (e.g., Suttle, 1994; Fuhrman, 2000; Wommack and Colwell, 2000). Average virus-to-bacteria ratios of 50:1 have been observed with a high direct correlation between abundance of viruses and bacteria (Thingstad, 2000; Wetzel, 2000b). Most estimates indicate viral phages lyse about one-fourth of the bacterial production per hour (Heidal and Bratbak, 1991). Phage-induced mortality of bacterioplankton in Lake Konstanz, Germany, for example, was estimated to vary between 1 and 24% of total mortality over an annual period (Simon *et al.*, 1998). Other viral mortality estimates of bacterioplankton and phytoplankton are in a similar or higher range (11–66%) for lakes, coastal waters, and rivers (e.g., Suttle, 1994; Fuhrman and Noble, 1995; Mathias *et al.*, 1995). One can view the viral mortality as an important component of the microbial loop that accelerates the dissipation of organic carbon to CO_2.

Loss of cellular integrity upon senescence or viral parasitism results in a rapid large loss of soluble cellular organic matter, often exceeding 40% of the total organic carbon within the first 24 h (e.g., Krause, 1962; Otsuki and Wetzel, 1974b). DOM lost at this stage often consists of simple, nonstructural organic compounds of relatively high energy and availability to microbes. Similarly, ingestion of bacteria and pico- and ultraplankton by protists, which purportedly although erroneously was proposed to "short circuit" metabolism in the "microbial loop", is a major diversion of organic carbon away from animal higher trophic levels. A much more realistic food-web ecosystem structure properly places appropriate metabolic emphasis on the microbial communities from viruses through protists (Fig. 23-26). Clearly, the metabolism and energetic fluxes associated with dead detrital organic matter as DOM dominates in all these ecosystems. Among some communities, such as higher aquatic plants and their attached periphytic microbial

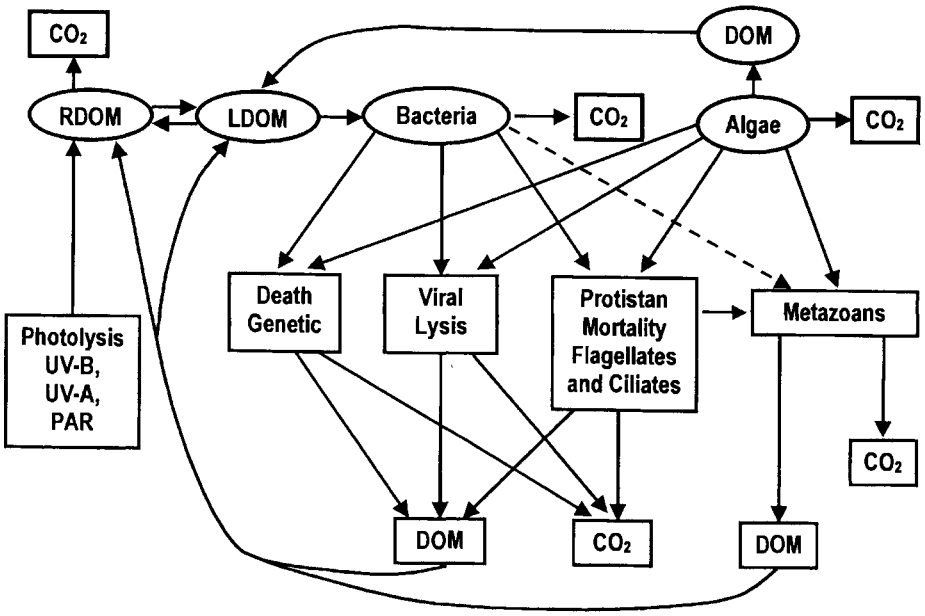

FIGURE 23-26 Food-web structure of predominantly pelagic components of aquatic ecosystems that reflects the importance of the microbiota, the microbial loop, and physical processes by which most of the organic matter inputs are metabolized heterotrophically or degraded *by physical processes.* DOM = dissolved organic matter, with labile (LDOM) and recalcitrant (RDOM) components.

complex, most (>90%) of the total organic matter production (foliage, sloughed tissues, excreted DOM, rooting tissues, and others) never enters a metazoan digestive tract, analogous to the situation in terrestrial ecosystems (Wetzel, 1990a, 1995). Functionally, organic carbon cycling in terrestrial and inland aquatic ecosystems is similar.

VI. NET ECOSYSTEM PRODUCTION

The dissolved organic carbon pool of lakes receives inputs from both pelagic and littoral photosynthesis. In the Lawrence Lake example, an equivalent amount was received allochthonously from the drainage basin. The major loss of dissolved organic carbon through outflow represented most of the net ecosystem production of Lawrence Lake relative to the surrounding environment (Table 23-20). This estimate of *net ecosystem production* yields essentially a measure of export from the system, for example, by outflow, sedimentation, and emigration.

Woodwell and Whittaker (1968) originally defined net ecosystem production (NEP) as

$$\text{NEP} = GP - [RS_{(A)} + RS_{(H)}]$$

when GP = gross production
$RS_{(A)}$ = respiration of autotrophs
$RS_{(H)}$ = respiration of heterotrophs

or simply NEP = (gross production)−(respiration of the ecosystem). The essential feature of NEP is that it accounts for importation and losses via respiration. The original expression was modified by Woodwell *et al.* (1972) to account for the import and export of organic material:

$$NEP = (GP + NP_{in}) - [RS_{(A)} + RS_{(H)} + NP_{out}]$$

when NP_{in} = net production imported from another ecosystem
NP_{out} = net production exported

Both formulations interpret *NEP* as the positive or negative increment of organic matter, either as living biota or dead organic storage, after total respiration within the ecosystem. The latter definition of *NEP*, which specifically subtracts organic exports, limits application of the term to only that material which remains inside ecosystem boundaries.

VII. BIOTIC STABILITY AND SUCCESSION OF PRODUCTIVITY

The mechanisms and couplings of detrital metabolism, as elaborated in the three-phase system (allochthonous, littoral, and pelagic) and exemplified in the dynamics of whole-lake ecosystems, as exemplified in Lawrence and Mirror lakes, provide a fundamental stability to the entire biotic dynamics of lakes and streams. Living components of the system generally undergo rapid oscillations of productivity in an opportunistic series of competitive responses to changes in availability of constraining nutritional and physical factors governing their growth. However, the overall metabolism of both lakes and streams is dependent to a major extent on the detritus components of dead DOC and POC that form a primary source of utilizable energy.

Much of the present emphasis on DOM of aquatic ecosystems correctly addresses how this abundant reservoir of recalcitrant dissolved organic carbon can be utilized in microbial metabolism and respiration and can influence microbial nutrient regeneration. The commonly observed incomplete photolysis of DOC is critical to accelerated utilization of these macromolecules

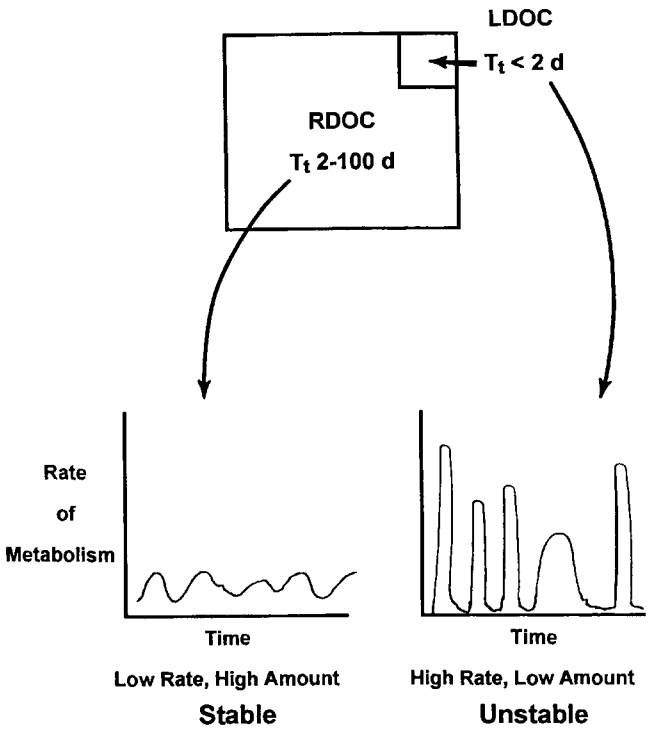

FIGURE 23-27 Relative rates of metabolism of the large, dominating pool of recalcitrant dissolved organic carbon (RDOC) vs. the small instantaneous pool of labile dissolved organic carbon compounds that are largely under the supply control of highly ephemeral algal communities. (From Wetzel, 2000a.)

but is clearly not mandatory. Portions of the complex DOM pools, including fractions of humic and fulvic acid compounds, are degraded, but total degradation rates are clearly slow. Such chemical organic recalcitrance of DOM is instrumental in providing a thermodynamic stability to metabolism within lake, reservoir, wetland–littoral land–water interface, and river ecosystems (Wetzel, 1983, 1984, 1992, 1995, 2000a). The chemical recalcitrance is truly a "brake" on ecosystem metabolism, and that brake is critical for the maintenance of stability.

Most of the detrital organic pool, both in particulate and dissolved phases, of inland aquatic ecosystems consists of residual organic compounds of plant structural tissues. The more labile organic constituents of complex dissolved and particulate organic matter are commonly hydrolysed and metabolized more rapidly than more recalcitrant organic compounds that are less accessible enzymatically (Fig. 23-27). The result is a general increase in concentration of the more recalcitrant compounds, commonly exceeding 80% of the total, with slower rates of metabolism and turnover. These recalcitrant compounds, however, are metabolized at rates slowed and regulated in large part by their molecular complexity and bonding structure.[4]

In every detailed *annual* organic carbon budget of lake and river ecosystems, the heterotrophic metabolism of the ecosystem cannot be supported by organic matter generated by phytoplankton. At least several-fold support of the total metabolism is from organic subsidies from the land–water interface communities and allochthonous production. From the standpoint of metabolic stability, it is particularly important that most of the organic carbon is dissolved and relatively recalcitrant, which ameliorates the violent oscillations so characteristic of the pelagic particulate components of the ecosystem. The relatively slow utilization rate of this detrital reservoir gives stability to aquatic systems, tiding the system over during periods of low detrital carbon inputs and recharging the reserve during excessive inputs.

In addition, much of the particulate organic matter formed in the dominating land–water interface regions of lake and river ecosystems is displaced to reducing, anoxic environments of the littoral and profundal sediments. The dissolved organic carbon, largely of higher plant origins, provides the stability and is the currency for the quantitatively more important detrital pathways in aquatic ecosystems (Fig. 23-28). The same underpinnings of that stability prevail in terrestrial ecosystems and likely much of the marine ecosystem. The trophic dynamic structure is almost totally dependent energetically upon the detrital dynamic structure. The manner in which it is manifested differs in fine detail among systems, but functionally, it must be the same in all ecosystems.

Detritus includes nonliving particulate, colloidal, and dissolved organic matter, and metabolically, size only affects rates of hydrolytic attack (Wetzel, 1995). Inland aquatic ecosystems collect organic matter, particularly in dissolved forms, from terrestrial, wetland, and littoral sources in quantities that supplement if not exceed those produced autochthonously. Rates of utilization of that organic matter are slowed by a combination of chemical recalcitrance as well as displacement to anoxic environments. As a result, inland aquatic ecosystems are heterotrophic and functionally, detrital bowls, not algal bowls.

A. Human Influences

In long-term evolutionary scales, humans now have the abilities to intervene rapidly in this interdependent relationship and alter the stability of the rates

[4] On the basis of disequilibrium thermodynamics, the chemical recalcitrance functions to regulate and balance dissipation of energy (entropy) at a high level, which is needed to maintain stability.

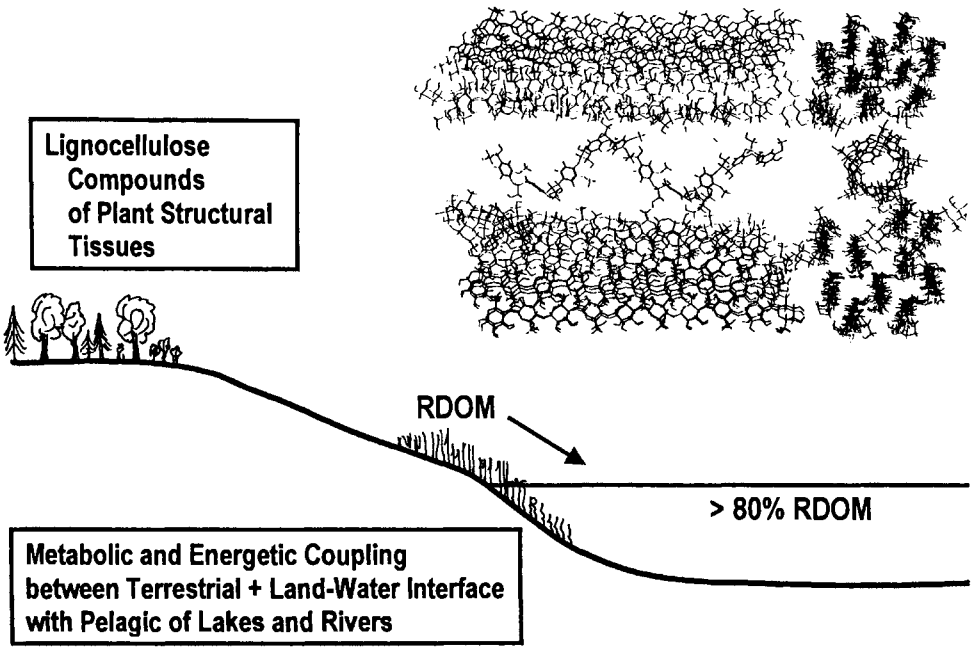

FIGURE 23-28 Lignocellulose compounds of higher plant structural tissues from terrestrial and land–water interface regions form a major source of recalcitrant dissolved organic matter (RDOM) within aquatic ecosystems and a major metabolic coupling between the drainage basin and aquatic ecosystems. (From Wetzel, 2000a.)

of metabolism of organic matter. For example, reduction of ozone in the stratosphere and associated increased UV irradiance could lead to accelerated photolytic degradation of macromolecules of DOM by both abiotic[5] and biotic pathways to CO_2. The photolytic enhancement of substrates for bacterial metabolism by UV photolysis of recalcitrant humic substances can result in accelerated rates of biogeochemical cycling of nutrients and stimulated productivity of the ecosystems. In addition to decreasing the metabolic stability of the lakes and streams, the enhanced microbial respiration will certainly lead to enhanced generation of CO_2 and evasion to the atmosphere.

Moreover, as the concentrations of CO_2 in the atmosphere increase, largely from anthropogenic combustion of fossil fuels, plant growth commonly accelerates. For example, CO_2 concentrations will double to ca. 720 ppm yet in the present century. Experimental doubling of CO_2 leads to increased rates of photosynthesis and growth by about 20–35% above rates at ambient CO_2 concentrations. The increased growth also commonly leads to nitrogen limitations. As a result, C:N ratios increase and commonly structural tissues, particularly lignin content, increase. As these plants grown in enriched CO_2 decay, DOM leached into the surface waters contain larger amounts of dissolved humic substances. Photolysis of this DOM from those plants grown under enriched atmospheric CO_2 resulted in a conspicuous increase in CO_2 release among both terrestrial plants (Fig. 23-29) and emergent aquatic plants (Fig. 23-30). Clearly, photodegradation of dissolved organic substrates is a major process that can alter rates of biogeochemical cycling in aquatic ecosystems.

The stability is afforded in part by the recalcitrant chemical structure of the organic substrates and in part by the displacement of much of the organic matter to anoxic environments. When oxygen is absent or its diffusion rate into a habitat is insufficient to fulfill the requirements of aerobic microflora, the rate of carbon mineralization is slower and the number of microbial cells formed per unit of substrate is less than when oxygen is abundant (Alexander, 1971; J. B. Hall, 1971). Complex and often simple organic compounds, such as fatty acids and amines, can accumulate when the quantity of readily fermentable carbon is large, as in the sediments. The low redox conditions lead to the generation of anaerobic fermentative products, including gases (CO_2, CH_4, H_2, and H_2S), that simultaneously inhibit

[5]Although the contribution of UV-B to photochemical mineralization of DOC is small in comparison to UV-A and blue portions of PAR (see Fig. 23-19), UV-B has high impact for photochemical damage to DNA. Therefore, the implications of increased UV-B are likely higher for availability and metabolism of organic substrates and for reproduction of biological organisms than for abiotic photochemical reactions that convert DOC to CO_2.

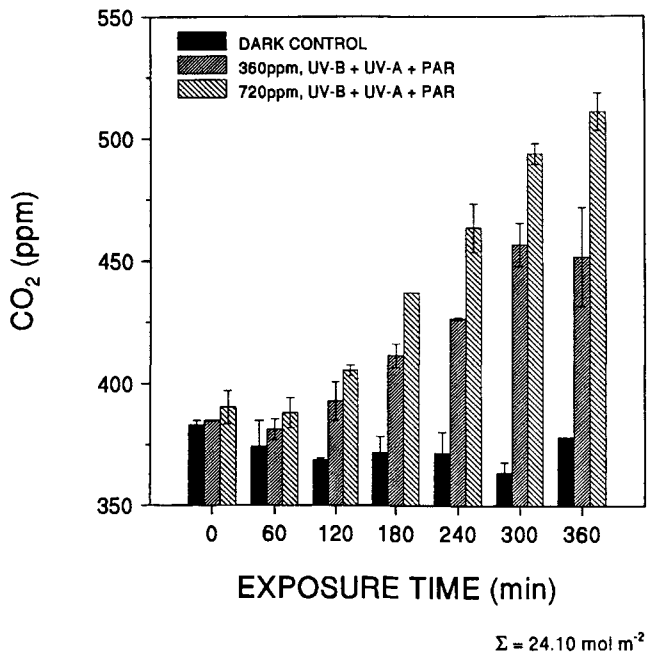

FIGURE 23-29 Release of CO_2 above saturation by complete photolytic degradation of sterile leachate from leaves of the riverine popular tree (*Populus tremuloides*), grown under ambient atmospheric CO_2 and doubled CO_2 concentrations, after one week of microbial decomposition. (From Wetzel, 2000a.)

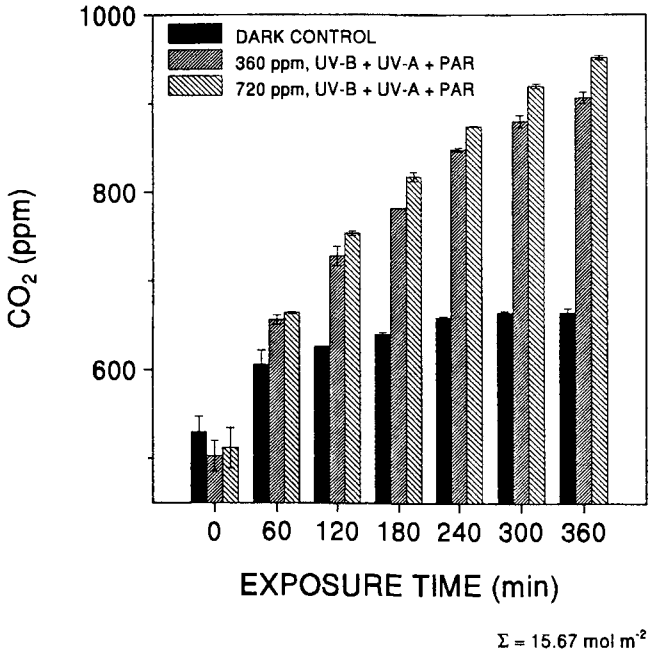

FIGURE 23-30 Release of CO_2 above saturation by complete photolytic degradation of sterile leachate from leaves of the cattail (*Typha latifolia*), grown under ambient atmospheric CO_2 and doubled CO_2 concentrations, after one week of microbial decomposition. (From Wetzel, 2000a.)

many forms of microbial growth and under aerobic conditions serve as a major sink for molecular oxygen. Degradation under these conditions is slowed and limited largely to utilization of intermediate compounds of anaerobic microflora. When oxic conditions are in close juxtaposition to anaerobic degradation, intermediate products are more completely and efficiently degraded. Inhibitory conditions caused by low E_h and toxic gaseous products are then greatly diminished. The trophic dynamic structure is almost totally dependent energetically upon the detrital dynamic structure. The manner in which it is manifested differs in fine detail among systems, but functionally, it must be the same in all ecosystems.

Within the operation of the detrital dynamic structure, the sources, quantities, and composition of detrital inputs are important and are related to lake eutrophication. As has been discussed in detail earlier (Chaps. 18 and 19), the littoral plant complex of macrophytes and their associated microflora dominate autochthonous productivity of many lake and most river ecosystems. The contributions by phytoplankton, submersed and emergent macrophytes, and attached and eulittoral algae change with increasing fertility. Dominance by the sessile flora is usually the case, except for certain extremely oligotrophic lakes, lakes of very large area and volume, or hypereutrophic lakes, where biogenic turbidity severely attenuates submersed light conditions (see Fig. 19–21).

The detrital dynamic structure functionally controls metabolism in a majority of lakes, in part because nutrient regeneration is controlled by detrital dynamics. Wetland and littoral plants are implicated as a major metabolic force driving detrital dynamics in most lakes, where they are dominant sources of allochthonous and autochthonous organic matter. Moreover, the detrital inputs of particulate and dissolved organic substrates vary with the flora adapted to individual lake conditions. For example, in hardwater marl lakes, DOC interacts with inorganic components such as $CaCO_3$, which effectively suppresses subsequent pelo- and hydrometabolism. These suppressing mechanisms can be loaded to saturation, resulting in rapid transition to highly eutrophic conditions, geologically speaking. In other cases, the succession of certain macrophytes can lead to a community dominated by *Sphagnum* and other mosses that function as effective ion exchangers with simultaneous release of refractory organic compounds (cf. Chap. 25), creating conditions in which detrital metabolism is slowed and permitting accumulation of organic matter in particulate form. Detrital metabolism and the rates and cycling of dissolved organic matter underlie the entire metabolic and trophic structures of all ecosystems.

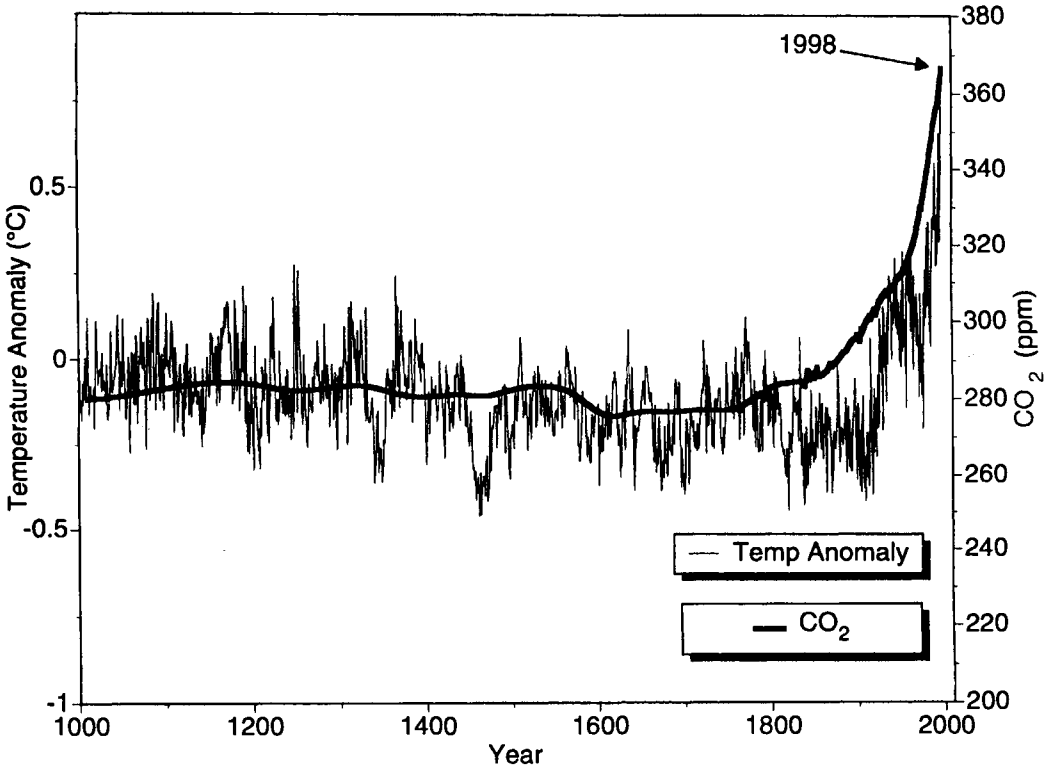

FIGURE 23-31 Long-term determinations of CO_2 concentrations of the atmosphere, directly for the past half century and from paleorecords earlier and average paleo-temperature estimates of deviations from the average over the past 1000 years. VIII. SYNERGIES AMONG DISSOLVED ORGANIC MATTER, SUNLIGHT, CLIMATIC WARMING, ENHANCED ATMOSPHERIC CO_2, AND ACIDIFICATION

Reduction of ozone in the stratosphere, in part associated with releases of chlorofluorohydrocarbon compounds used in refrigeration and propellant devices, has resulted in large increases in the amounts of UV-B and, to a lesser extent, UV-A reaching the surface of the Earth (Kerr and McElroy, 1993; Madronich, 1994). The increases vary with atmospheric conditions but are in the range of 1% per decade near the equator and >13% per decade at latitudes greater than >45°.

Atmospheric concentrations of CO_2 have progressively increased markedly in the past century, largely as a result of human combustion of fossil fuels (Fig. 23-31) and are anticipated to double to approximately 720 ppm in the present century. The increases in CO_2 concentrations can stimulate plant productivity, as discussed earlier, but additionally result in a "greenhouse effect," in which back radiation of heat from the Earth is reduced. As a result, a gradual warming of the average temperatures occurs that is directly correlated with rising CO_2 concentrations (Fig. 23-31).

The primary thesis of this chapter is that dissolved organic matter is a primary component of aquatic ecosystems that regulates biogeochemical cycling and provides a fundamental thermodynamic stability to lakes and streams. Alterations of the atmospheric and climatic environment by human activities can impact the biogeochemistry of organic matter cycling and flux rates in aquatic ecosystems. A number of processes are already evident:

1. *Reduction in DOC Concentrations.* A general trend has been observed among long-term data sets that DOC concentrations are declining gradually (Schindler *et al.*, 1991; Schindler and Curtis, 1997). Particularly in oligotrophic lakes where DOC concentrations are often low, UV light penetrates to depths of several meters and can negatively influence organisms by genetic damage, diverting production to increased synthesis of protective pigments, and other ways. In lakes of alpine regions or in high latitudes where higher plant source materials are few, allochthonous loading

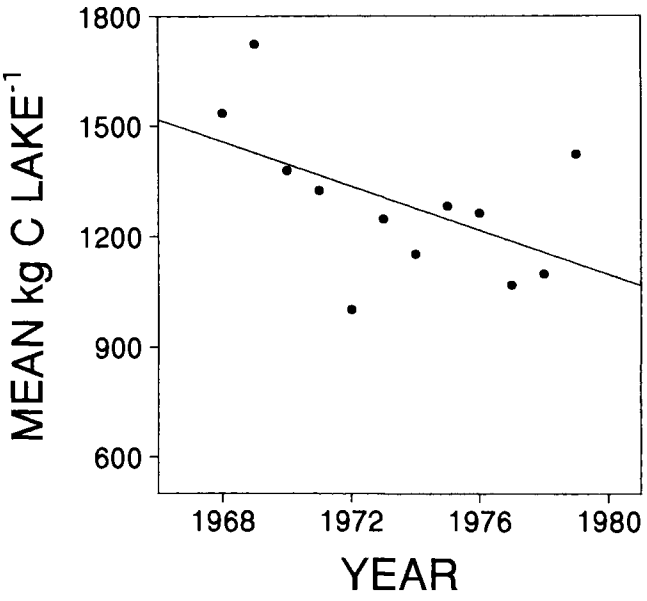

FIGURE 23-32 Decline ($r^2 = 0.28$) of mean annual dissolved organic carbon in Lawrence Lake, southwestern Michigan, determined by analyses at each meter depth at weekly or biweekly intervals over the 12-yr period and weighted for volume in each meter stratum of water. (Data of Wetzel, unpublished.)

of chromophoric organic matter is low. Organisms in such lakes can be exposed to high intensities of ultraviolet irradiance (McKnight *et al.*, 1997). Even in lakes with higher concentrations of DOC, the long-term trends are often toward slowly decreasing concentrations of DOC (Fig. 23-32).

2. *Climatic Warming and Droughts.* There is little question that both temperature and carbon dioxide concentrations of the atmosphere are increasing (Fig. 23-31). Rising temperature has also influenced precipitation patterns and particularly has led to large regions in which rainfall and snow accumulations have been reduced. Droughts are a cumulative result of numerous meteorological factors affecting precipitation, evapotranspiration, and losses. Droughts usually do not become severe until after long periods of deficient rainfall and unrestrained water use.

DOC in some lakes has declined appreciably over the last quarter century coincident with substantial warming (Fig. 23-32 and in the Ontario lakes, Schindler *et al.*, 1992). Reduced precipitation and increased evapotranspiration in the drainage basin result in reduced stream flows and lower DOC loading to the stream and lake. Transparency of lake water to UV photolysis increases under these conditions. Similar reductions in DOC in streams have been observed (e.g., Dillon and Molot, 1997). The decrease in annual DOC yields of streams occurs in spite of higher concentrations in storm flows following periods of prolonged drought (Schindler *et al.*, 1992; Hinton *et al.*, 1997).

3. *Effects of Acidification.* As poorly buffered softwater lakes are acidified (cf. Chap. 11), the concentrations of DOC decline and transparency of the water increases (Driscoll and van Dreason, 1993; Dillon and Molot, 1997; Gjessing *et al.*, 1998). The fate of the DOC upon acidification is unclear. Some DOC may be mineralized and evade to the atmosphere, and some may flocculate and sediment. Under drought conditions, reoxidation of previously deposited reduced sulfur in wetland and littoral sediments can yield strong acid pulses during intermittent rainfall events following drought periods (Bayley *et al.*, 1992).

4. *Increased Rates of Bacterial Metabolism and Nutrient Recycling.* As discussed earlier in this chapter, the increased penetration of UV-B, UV-A, and PAR irradiance can result in the acceleration of partial photolysis of organic macromolecules. Simple organic substrates generated by this process accelerate bacterial metabolism, simultaneously generating CO_2 and enhancing nutrient regeneration. The decrease in the metabolic buffering capacity from DOC results in reduced stability of the ecosystem.

5. *Increased Rates of CO_2 Evasion to the Atmosphere.* The photolytic mineralization of organic substances to CO_2 directly by UV-B, UV-A, and PAR irradiance increases as the amounts of DOC decline. With the decline of chromophoric DOC, penetration of light increases in a positive feedback mechanism.

IX. SUMMARY

1. Nearly all of the organic carbon of natural waters consists of dissolved organic carbon (DOC) and dead particulate organic carbon (POC). The ratio of DOC to POC is commonly between 6:1 and 10:1, both in lacustrine and running water ecosystems (cf. Table 23-1).
2. Living POC of the biota constitutes a very small portion of the total POC; most POC and all DOC is dead detrital organic matter. The metabolism of the biota, however, is important in mediating reversible fluxes of carbon between the dissolved and particulate phases of organic carbon.
3. Organic matter consists almost totally of a mixture of plant, microbial, and animal products in various stages of decomposition.
   a. *Nonhumic substances* are low-molecular-weight organic substances, such as carbohydrates, proteins, amino acids, fats, waxes, resins, pigments, et cetera. These substances are relatively labile, are easily degraded by microorganisms (hours),

and exhibit rapid flux rates. Instantaneous concentrations are relatively low.

b. *Humic substances* are naturally occurring heterogeneous organic substances recalcitrant to rapid biological utilization (days to weeks) and are high in molecular weight (most 700–5000 D). Humic substances are derived largely by microbial degradation from cellulose and lignin of plant structural materials and constitute 70–80% of the organic matter of water and soils.

c. Fungi and certain specialized bacteria degrade plant materials and form humic substances.

d. Dissolved organic carbon moves with the water and will sediment if it adsorbs to inorganic or organic particulate matter or if it undergoes polymerization to particulate form. Only a small percentage of DOC aggregates, flocculates, and shifts to colloidal and particulate states; these organic particles are of relatively high nutritive value.

4. The distribution of DOC within lakes and streams is relatively constant, with changes in season and in depth.
5. Particulate organic matter tends to remain near sites of production. In the soils and hydrosoils, POC undergoes degradation, with the release of DOC of partial degradation by microbes.
6. DOC of allochthonous origin (terrestrial and wetland marsh sources) constitutes the primary source of external organic carbon loading to fresh waters. This DOC is extensively modified by microbial metabolism in soils, streams, wetlands, and littoral areas as it flows toward recipient lakes.
   a. Dissolved organic matter (DOM) that enters lakes via surface runoff or groundwater seepage contains a low percentage of nitrogen (organic C:N approximately 50:1). The high C:N ratio results from a large proportion of structural compounds from terrestrial and higher aquatic plants and from the selective decomposition of more labile compounds by microflora as the DOM is transported by water flow.
   b. DOM derived from algal and cyanobacterial production within water bodies has a higher initial nitrogen content, with a C:N of about 12:1.
   c. The molecules of many humic compounds of DOM absorb solar radiation >290 nm. Photochemical reactions from absorption of irradiance by these chromophoric compounds (CDOM) can modify the compounds to render them more bioavailable to bacteria and, in some cases, degrade them entirely to CO_2.
7. There are three major sources of particulate organic carbon (POC):
   a. Allochthonous sources of POC, which consist primarily of plant materials. This POC is transported by water drainage and by air movements to recipient streams or lakes. Rates of decomposition of POC in recipient waters vary greatly with the organic composition of the material but are usually much slower (e.g., leaves in weeks; woody material in years) than those of DOC (days to weeks).
   b. Most of the POC of streams and rivers is produced in the soils of the drainage basin and in the floodplain areas adjacent to the channels. POC inputs can be seasonal, particularly among heavily forest-canopied streams (cf. Chap. 21).
   c. Much of the POC in lakes originates from autochthonous production in (i) the pelagic zone and (ii) the littoral zone. Because most lakes are small and shallow, much of the POC originates in littoral areas from aquatic macrophytes and associated attached algae. In reservoirs, the proportion of autochthonous POC production to allochthonous POC loading is more equal, although it can be quite variable (particularly seasonally).
8. The spatial and temporal distribution of pelagic particulate organic carbon is commonly closely correlated with the productivity and biomass distribution of phytoplankton and bacteria during periods of thermal stratification. The inputs from littoral productivity to the POC pool of lakes increase in relative importance in the transition (e.g., in a series of lakes) from the nutrient-limited conditions of oligotrophic lakes to more fertile conditions of eutrophic lakes (see Fig. 23-13).
9. Much functional insight into the operation of freshwater ecosystems has been obtained from quantitative analyses of the dynamics of carbon cycling among the biotic communities and the inorganic and organic carbon reservoirs. From several examples of organic carbon budgets discussed in detail, those general properties discussed earlier were verified. In addition:
   a. Detrital particulate organic carbon from allochthonous, littoral, and pelagic components is often metabolized under anoxic conditions largely in the sediments. Detrital dissolved organic matter is dominated by recalcitrant organic substances, largely of allochthonous and littoral sources, that chemically suppress rapid degradation. These degradability characteristics

provide a fundamental thermodynamic stability to ecosystems. Many components of the biotic (living), trophic dynamic structure of freshwater ecosystems generally undergo rapid oscillations in relation to an array of dynamic factors governing growth and reproduction, while detrital metabolism is slower and more evenly sustained by a much larger organic reserve.

b. Increases in autochthonous organic carbon inputs in relation to allochthonous inputs result in progressively greater decomposition in the sediments than occurs in the water column.

c. The trophic dynamic structure of freshwater ecosystems is almost totally dependent for its energy upon the detrital dynamic structure. In many lakes and reservoirs, the littoral and allochthonous components are the dominant sources of synthesized organic carbon; these two components also dominate inputs of detrital organic carbon and are implicated as the major driving force of the ecosystems.

10. The major sites of detrital metabolism are the benthic region, where most particulate organic carbon is decomposed in many lakes, and the pelagic region largely of dissolved organic carbon. Considerable secondary metabolism is thus displaced from sites of production to sites of decomposition by sedimentation in the case of POC and by aggregation and coprecipitation with particulate matter in the case of DOC.
11. Detrital organic matter functions in several pivotal roles:
    a. Although the specific nature of detritus molecules modifies their behavior and effects upon the environment, detritus inevitably carries most of the energy of the ecosystem from its points of origin to its places of transformation.
    b. Essentially, all lakes and streams are heterotrophic net CO_2 producers with massive evasion of CO_2 to the atmosphere in excess of autochthonous production.
    c. Most benthic metabolism is heterotrophic, microbial, and anaerobic, even when hypolimnetic oxygen depletion does not occur. The continued production of CO_2 by anaerobic benthic metabolism, and release of this oxidized product (synthesized using alternate electron acceptors) to the overlying water, results in benthic and hypolimnetic respiratory quotients (CO_2 released/O_2 uptake) >1.
    d. The reduction of alternate electron acceptors (nitrate, iron and manganese oxides, sulfate, or various organic substrates) instead of molecular oxygen results in an accumulation of electrons in the sediments and the receipt of energy originally transferred during photosynthesis (where CO_2 was reduced to carbohydrate and water was oxidized to oxygen). This flow, termed *detrital electron flux*, into and ultimately out of the sediments (i) derives its energy from photosynthesis, just as a predatory animal does from its food, and (ii) is a much larger proportion of the total energy inputs and transfer processes because most organic matter becomes detrital in the ecosystem without ever passing through an animal. Thus, the ecosystems incorporate detrital energy flow into their overall functioning to an extent that is similar to, and usually much greater than, that occurring through the well-recognized energy flow of predator–prey processes.
    e. From a functional standpoint of ecosystem operation, *detritus* consists of all organic carbon (DOC and POC) lost by nonpredatory means from any trophic level (by egestion, excretion, secretion, autolysis, et cetera.) or inputs from sources external to the ecosystem that enter and cycle within the system (allochthonous organic carbon). The *detritus food chain* is any pathway by which the chemical energy contained within detrital organic carbon compounds becomes available to the biota.
    f. Recent experiments demonstrate microbial degradation of DOC manifoldly greater than could be derived from autochthonous primary production and that utilization of this recalcitrant allochthonous and littoral DOC is mediated by partial photolysis by UV-B, UV-A, and photosynthetically active (PAR) radiation.
    g. Relatively small portions of the allochthonous and autochthonous organic matter reach higher trophic levels. Degradation of allochthonous and autochthonous organic matter is largely by physical photolytic and by microbial processes.
    h. A functional commonality exists in the way organic matter is utilized; differences emerge in sources of organic matter, which affect the rates of utilization, not the process of utilization. Freshwater ecosystems are heterotrophic and are functionally detrital bowls, not algal bowls.
12. Natural dissolved organic substances, particularly humic substances, can interact with other important metabolic components.
    a. These compounds can complex, often by chelation, with inorganic elements and alter biological availability.

b. These compounds can complex with other organic compounds, such as enzymes, and reduce their availability and utilization by biota.
c. Humic substances can buffer against acidification but also may add acidity when in high concentrations to surface waters of very low ionic strength.
d. Microbially reduced humic substances can serve as electron donors and a redox shunt between oxidized and reduced compounds under anaerobic conditions.
e. Dissolved organic substances can modify light penetration severely and thereby affect photoreception, organism behavior, and thermal cycles and coupled stratification.

IV. Summary

In the past, alterations of aquatic ecosystems have been brought about by changes in climatic conditions; more recently, changes have been greatly accelerated by human activities. These changes have affected conditions of the drainage basins, water budgets, nutrient loading and budgets, and the resultant productivity of fresh waters.

Lakes function as natural traps for sediment. Once materials entering or produced in the lake settle to the lake bottom, energy levels and hydrodynamics are usually insufficient to transport materials out of the basin. Records of climatic and human-induced changes in the environment have been left in the sediments of lakes and certain reservoirs. These records represent relatively static derivatives of the dynamic ecosystems that are constantly changing over short-term (e.g., seasonal) and long-term periods. Paleolimnology focuses on the interpretation of sedimentary sequences and on diagenetic processes that can alter that record. The ultimate goal is to gain insights into past conditions, productivity, and changes in regulatory parameters that have caused aquatic ecosystems to enter a different stage of productivity. In addition, insights can be gained toward a prediction of the trajectory that an ecosystem may take in future time (Deevey, 1984).

A lake is at the receiving, downgradient end of a drainage basin. Lake sediment is derived from both external and internal sources. Allochthonous materials are transported by water movements from its surrounding drainage basin or enter from the air as particulate precipitates (e.g., leaf fall or dust). Autochthonous materials settle from materials generated within the lake (dead organic matter, chemical precipitates such as carbonates, and siliceous diatom frustules). Organic accumulation within the sediments of a lake results from a positive balance between production and loading to the sediments and diagenesis within the sediments. It is generally assumed that the rate of change of organic deposition provides a record of past productivity levels. Such assumptions, however, are based on the premise that the rates of diagenesis have been constant or can be estimated and that most of the organic matter has been produced autochthonously within the lake basin.

Most of the bulk of lake sediments is mineral detritus released and imported from the drainage basin. This proportion increases with decreasing size and volume of lakes and is very high in reservoirs, where river influents are a much larger proportion of the total reservoir volume than is the case in most natural lakes.

Biota and biotic structure within the lake are derived biogeochemically largely from these materials. The sediments provide a partial record of both the biota within the lake and chemical and biotic materials imported from the drainage basin. Some changes occurring in the drainage basin but recorded by mineral, chemical, or biotic (e.g., pollen) importations to the sediments can be very useful (Binford *et al.*, 1983). For example, climatic changes, recorded directly by changing mineralogy or indirectly by changing terrestrial plant pollen assemblages found in the lake sediments, are important in the interpretation of environmental conditions to which lake biota were exposed, parts of which may also be preserved in the sediment.

I. STRATIGRAPHY AND GEOCHEMISTRY

A. Sedimentary Record

The fossil record of sediments includes both biochemical substances produced by organisms, or resulting from their degradation, and morphological remnants of specific organisms. The subject is large and the literature is voluminous. Particularly instructive reviews on paleolimnology, from which much of the following résumé was drawn, include Vallentyne, 1960; Frey, 1964, 1969a,b, 1974, 1988; Swain, 1965; Juse, 1966; Korde, 1966; Binford *et al.*, 1983; Smol, 1990, 1992; and Anderson, 1993.

Sediments that accumulate in lake basins originate from numerous source materials. The composition is influenced to a great extent by the geomorphology of the lake basin and the drainage basin. Although many lakes were formed between the intervals of cyclic glaciation and deglaciation, most lakes of earlier glacial periods have been obliterated by succeeding glaciations, by filling with sedimentary materials or by draining. It is only because of the very recent retreat of the last major glaciation phase that so many lakes exist at the present time. With the notable exceptions of some very ancient lakes, particularly in rift areas in Africa and Asia (Livingstone, 1975), most lakes are very young ($<20{,}000$ years).

The primary sedimented materials are controlled by regional geology and climate and are modified by biological processes of both the drainage basin of the lake and the lake itself. Water movements such as wave action and currents sort particulate matter according to its size and density and the energy available for displacement. Movement of particles to the central depression of a lake basin that leads to sediment focusing (cf. Chap. 21, pp. 633–635) in the lake results from three major processes (Hilton, 1985): (a) peripheral wave action that generates turbulence and resuspends sediments in littoral areas that are subsequently redeposited in deeper areas; (b) intermittent, random redistribution of sediments of the entire basin when the lake is not stratified, particularly during autumnal overturn; and (c) movement of sedimentary material parallel to a sloping bed (sliding) or movement initiated by a rotational failure of the sediment (slumping), resulting in material being transported by flows from shallow regions to deeper waters. Little sediment will accumulate on slopes $>14\%$, and $<4\%$ slope has little effect (Håkanson, 1981). The morphometry of the lake basin dictates the dominant process of sediment redistribution.

The result is a general gradient from coarser particles near shore regions to finer particles in sediments under deeper waters. This gradient can be disrupted by various mechanisms that often are related to the morphology of the lake basin. For example, deposits of sediments in littoral regions or river deltas can accumulate until they become gravitationally unstable and slump in landslide fashion or move as turbidity flows to deeper portions of the basin where they come to overlie finer, often younger, sediments.

B. Dating of Sediments

Several methods have been used to determine the age of sedimented materials in lake deposits. In postglacial lakes, the most important method has been to evaluate the age of organic material by measuring its content of radioactive carbon (^{14}C). Radiocarbon is formed in the upper atmosphere by the reaction of nitrogen (^{14}N) with neutrons (n): $^{14}N + n \rightarrow {}^{14}C + {}^{1}H$. The production of ^{14}C has been nearly constant over time but has varied because of changes in the supply of neutrons produced by cosmic radiation. Neutron quantity is thus dependent upon the intensity of cosmic radiation. The cosmic-ray flux in the upper atmosphere is influenced by (a) the intensity of the Earth's magnetic field and (b) short-term changes in solar wind magnetic properties (Ralph and Michael, 1974; Stuiver and Quay, 1979). When the Earth's geomagnetic field is strong, fewer cosmic rays reach the upper atmosphere; when it is weak, the inverse occurs. These geomagnetic changes cause about an 8% change in atmospheric ^{14}C over a period of approximately 6000 years. The short-term solar magnetic variations of ^{14}C production occur in cycles of a few hundred years or less and superimpose small deviations upon the long-term geomagnetic trends. Radioactive carbon decays back to ^{14}N with the emission of a β^- particle and has a half-life of 5568 years.

The ^{14}C of the atmosphere is a very small part of Earth's CO_2 reservoir (approximately 1 in 10^{12} parts).

For purposes of ^{14}C dating, it is assumed that ^{14}C produced in the atmosphere is in rapid equilibrium with these CO_2 reservoirs and that the balance among the carbon reservoirs has been constant over time. During photosynthesis, $^{14}CO_2$ is photosynthetically incorporated into organic matter in proportion to its availability in the atmosphere. When the organisms die and are interred in sediments, the ^{14}C contained in the organic matter continues to decay back to ^{14}N with the emission of a β^- particle. The half-life of ^{14}C disintegration is constant, and when the residual specific activity of ^{14}C in the carbon of old organic matter is accurately radioassayed, it provides an estimate of the age of the organic matter. The decay rate of ^{14}C should permit age determinations back to a limit of about 75,000 years. Technical detection limitations of assaying for negative beta radiation of ^{14}C above background radiation usually limit ^{14}C-age determinations to 40,000 years, although techniques have improved (e.g., Grootes, 1978; Stuiver, 1978b).

Much effort has been devoted to evaluating the accuracy of ^{14}C dating of organic deposits, including potential errors caused by variations of ^{14}C production within the atmosphere and ^{14}C incorporation into plant organic matter (e.g., reviews of Ralph and Michael, 1974; Krishnaswami and Lal, 1978; Stuiver, 1978a; Stuiver and Quay, 1979). Recent changes in past atmospheric ^{14}C levels can be determined by measuring the present-day ^{14}C activity of wood laid down in trees (e.g., Douglas fir, Sequoia redwoods, and bristlecone pine) and accurately dated by counting tree rings. Calibrations of ^{14}C dating measurements of older samples have been made by careful comparisons with other dating techniques ($^{230}Th/^{234}U$ ratios, thermoluminescence, magnetic dating). In hardwater lakes containing appreciable quantities of geologically old, ^{14}C-deficient carbonates, inorganic carbon fixed in photosynthesis is not in equilibrium with atmospheric ^{14}C activity, but includes carbon dissolved from carbonates of the drainage basin. This old ^{14}C-deficient carbon dilutes contemporary carbon originating from atmospheric sources. Organic matter from sediments of calcareous lakes thus gives dates that are spuriously old. Corrections are only approximate, and often the radiocarbon-dating values from these lakes must be compared with independent chronological measures (MacDonald *et al.*, 1991).

The dating of very recent sediments can be problematic with ^{14}C methodology. More recent dates of sediment deposits have been obtained by analyses of lead-210 (^{210}Pb). Radium-226 in soils decays to radon-222, which escapes to the atmosphere, where it decays to ^{210}Pb. This ^{210}Pb enters a lake via precipitation and is eventually incorporated into the sediments; it is termed "unsupported" ^{210}Pb, since it was produced from radium located outside the sediments. Dating by ^{210}Pb relies on the difference in the total ^{210}Pb in the sediment and the "supported" ^{210}Pb resulting from the presence of ^{226}Ra and produced within the sediments. The difference is the concentration of "unsupported" ^{210}Pb resulting from atmospheric deposition. "Unsupported" ^{210}Pb will decrease with depth in the sediments because of radioactive decay, provided the input of ^{210}Pb to a lake is constant, its residence time is constant, and there is no significant migration within the sediment (Robbins and Edgington, 1975; Pennington *et al.*, 1976; Oldfield and Appleby, 1984; El-Daoushy, 1988; Turner and Delorme, 1996). The age of the sediment at any particular depth can be calculated from its activity of unsupported ^{210}Pb relative to that at the surface, since the radioactive half-life (22.26 years) is constant. Because of the short half-life of ^{210}Pb, this dating technique is limited to about 150 years. Caution is needed in interpretations because of differential rates of accumulation and of remobilization of Pb in the early diagenesis of sediments, particularly in relation to differences in iron and manganese cycling within the sediments (Appleby and Oldfield, 1978; H. E. Evans, 1984; Oldfield and Appleby, 1984; Benoit and Hemond, 1988; Binford and Brenner, 1988; R. D. Evans, 1991; Wan, 1993).

The distribution in sediments of cesium-137, which has been present in the atmosphere since 1954 because of atomic bomb testing, has been a useful method of dating sediments deposited within the last 50 years. More recently (1986), the nuclear accident at Chernobyl created a new maximum in ^{137}Cs that has been used as a marker for short-term accretion rate and transfer coefficient estimates in sediments (Mitchell *et al.*, 1983; Appleby *et al.*, 1993; Callaway *et al.*, 1996). This method assumes that ^{137}Cs fallout with rain became attached to particles and that these particles were quickly (<1 year) transported from the drainage basin to lake deposits (Ritchie *et al.*, 1973). ^{137}Cs falling directly upon the lake surface is adsorbed onto suspended particulate matter and sedimented. There is evidence (Davis *et al.*, 1984) that downward molecular diffusion and adsorption of ^{137}Cs and biological recycling can greatly confound the application of this method for dating recent sediments.

In both the ^{210}Pb and ^{137}Cs dating techniques for recently deposited sediments, it is assumed that disturbance of the sediment stratigraphy is small. In some cases, disturbance by water movements and biological redistribution of sediments by benthic macroinvertebrates (cf. Chap. 21) can be sufficient to obscure dating chronology (e.g., Robbins *et al.*, 1977; McCall and Fischer, 1980). In other cases, careful interpretation of recent dating analyses, combined with other

paleolimnological data, provides much insight into reconstruction of recent lake events (e.g., Pennington *et al.*, 1976; von Damm *et al.*, 1979).

After sediments are deposited in a lake, properties of magnetic intensity and geomagnetic declination (direction) are retained in the sediments as ***remnant magnetism.*** These magnetic characteristics reflect past, relatively short (approximately 1000 years) variations in the direction of the Earth's magnetic field. Much of the magnetic remanence is carried by hematite (Fe_2O_3) (Mackereth, 1971, Creer *et al.*, 1972). Initial studies carried out in Lake Windermere, England, showed that the direction of the horizontal magnetization oscillates about a mean direction with an amplitude of approximately $\pm 20°$ and a frequency of 2700 years. Remnant magnetism was similarly demonstrated in sediments of a number of other lakes, although with somewhat different periods of oscillation (e.g., Yaskawa *et al.*, 1973; Tolonen *et al.*, 1975; Creer *et al.*, 1976; Oldfield *et al.*, 1978a,b; Thompson *et al.*, 1980). This method assists in rapidly dating sediments by nondestructive methods once the detailed chronology has been established within a given lake or continental region (Creer, 1982).

A further magnetic property of sediments, their ***magnetic susceptibility,*** is useful in evaluating probable sources of sedimented materials in lakes (Thompson *et al.*, 1975; Oldfield *et al.*, 1978, 1983; Thompson, 1978; Appleby *et al.*, 1985). Magnetic susceptibility is simply the magnetizability of sediment (i.e., its degree of attraction to a magnet). The most magnetically susceptible sediments contain the highest amount of allochthonous inorganic material washed into the lake from the drainage basin. From the paleomagnetic secular variations the chronology of sedimentation rates can be coupled to deforestation, afforestation, and agricultural changes in the drainage basin. Magnetic susceptibility also assists in evaluating spatial differences in stratigraphy within a lake basin. These differences result from variations in the deposition in different places, including the slumping of deposits from shallower areas over deeper deposits.

Many recent lake sediment profiles contain atmospherically derived fly ash and various particles from industrial processes. These particles include a magnetic fraction that can be characterized and approximately quantified by magnetic remanences preserved in the sediments (Oldfield and Richardson, 1990). Sediment profiles from lakes in industrially developed regions show widespread increases, steeply so in recent decades, in magnetite and hematite deposition beginning from the mid-nineteenth century onwards.

Airborne ***soot spherules*** are small (ca. 30 μm) carbonaceous particles generated during coal and oil combustion and released into the atmosphere. Soot particles are preserved in lake sediments, and the content in the sedimentary record is proportional to the history and intensity of coal and oil combustion (Renberg and Wik, 1984). Soot particle deposition increased in the middle of the nineteenth century and has risen progressively since, with some optimistic suggestions for reduced loading coincident with emission controls in recent times.

Some lake deposits exhibit distinct ***laminations*** in which temporal differences in the composition and quantities of suspended matter laid down create fine alternations of light- and dark-colored layers. When a pair of laminae (a dark and a light) represent a time period of one year, the lamination is called a ***varve*** (DeGeer, 1912; Nipkow, 1920; Sturm, 1979; Renberg and Segerström, 1981). Varves are generally restricted to sediments of lakes that have not been physically disturbed during deposition. In such lakes, varves provide a means of dating sediments at annual intervals and can be used to interpret former conditions of climate, mineralogy of the drainage basin, water level, the succession of certain organisms, and trophic conditions as evaluated by other sediment parameters and from biotic remains (e.g., Merkt, 1971; Renberg, 1978; Satake and Saijo, 1978; Sturm and Matter, 1978; Renberg and Segerström, 1981; Edmondson, 1991b).

Whether the deposition of sediments occurs in distinct laminations or varves depends upon the timing of lake stratification in relation to the timing of inputs of suspended matter from sources to the basin (from river runoff, deposition from the atmosphere, autochthonous production of organic matter or inorganic precipitates (e.g., $CaCO_3$), resuspension of deposited matter, or importation of suspended matter from ground water) (Sturm, 1979). Often, inputs are not sufficiently coordinated with quiescent stratified conditions; as a result, deposition is chaotic and distinct annual laminations are not formed. Bimodal sedimentary varves occur if the seasonal (discontinuous) influx of suspended matter coincides with thermal stratification of the water column in annually stratified lakes and no appreciable bioturbation of the sediments erases the pattern subsequently.

In glacial environments, relatively coarse sediments are brought to recipient lakes with the inflow of meltwater in the spring and summer and are deposited during the period of thermal stratification. Finer sediments are deposited over these during the winter when the lake is ice covered. Similar bimodal deposition is often found in temperate lakes, particularly in meromictic lakes in which the sediments are not disturbed by water circulation (e.g., Tippett, 1964; Brunskill, 1969; Digerfeldt *et al.*, 1975; Ludlam, 1976; Simola, 1977). In these cases, records of seasonal differences can be

found in the deposition of diatoms, tree pollen, clay, iron oxides, and/or calcium carbonate.

C. Inorganic Chemistry

External source materials in dissolved and particulate forms that leave the drainage basin and enter the recipient lake basin are influenced markedly by the terrestrial vegetative cover. Numerous examples were discussed quantitatively in the preceding chapters and need not be reiterated here. The long-term effects on the productivity of lakes are influenced by climatic variations as well as by human-induced changes in the vegetation and weathering processes (e.g., Mackereth, 1965, 1966; Bradbury *et al.*, 1975; McColl and Grigal, 1975; Dean and Gorham, 1976; Likens *et al.*, 1977; Engstrom and Wright, 1984; Likens and Bormann, 1995). An example of the effect of climate on weathering was demonstrated in some endorheic lakes of East Africa (Hecky and Kilham, 1972). Lakes in humid areas that had high weathering rates of the drainage basin received greater inputs of silica and were largely bicarbonate dominated. In more arid regions, sodium chloride originating from precipitation dominated the inorganic composition, and inputs of silica were low. The chemistry and climate changes of these endorheic lakes were reflected in the sedimentary record as well as in the extant diatom populations.

Chemical constituents of the sediments have been used variously to interpret rates of both limnological activities of the lake as well as changes in climate and alterations of the drainage basin (Engstrom and Wright, 1984). For example, the relative intensity of soil erosion is generally reflected in the concentrations of elements primarily associated with clastic minerals (Na, K, and Mg). Estimates of soil weathering based on the level of these elements in the mineral matter (inorganic ash) may be confounded by variations in sedimentation of biogenic silica and autochthonous biochemically precipitated oxides. Phosphorus occurs in lake sediments as sorbed components of amorphous iron oxides, in discrete mineral phases, and as organically bound phosphorus (Chap. 13). The inorganic phosphorus–iron complex is largely responsible for the exchange of dissolved phosphorus in many sediments. If iron content and other sedimentological conditions remain constant, a record of changing phosphorus levels in the water may be preserved in the sediments. As discussed earlier (Chap. 13), the retention of phosphorus in lake sediments is affected by redox conditions, sediment mixing, and pH. Thus, because of the changes in retention capacities of the sediments for phosphorus, only long-term major changes or abrupt pollutional loading alterations are conspicuous.

The analyses assume that the chemical chronology represents, at least on a long-term basis, the composite changes in inputs to the lake and metabolic transformations that have occurred within the lake. For example, comparison of the chemical composition of numerous elements, mostly biologically nonessential, in lake sediments as well as in rock and soils of the drainage basins permits an effective evaluation of the chronology of erosion and rates of leaching (Cowgill, Hutchinson, and collaborators, 1963, 1966a,b, 1970, 1973). Inputs of extremely inert, conservative elements, such as titanium, permit another evaluation of erosion rates of the lake basins. Depending on the geology of the area, other elements may indicate disturbances of drainage basins. In Laguna de Petenxil, a small lake in Guatemala, sediment concentrations of calcium, strontium, potassium, and, to some extent, sodium increased during periods of active Mayan agricultural activity in the drainage basin. Manganese, iron, and phosphorus followed the fluctuations of agriculturally determined alkalies and alkaline earths in an analogous way (cf. Deevey *et al.*, 1979).

Detailed investigations of the paleolimnology of a small, closed lake of volcanic origin in Italy, Lago di Monterosi, demonstrated the marked effects of alterations to the drainage basin area by the construction of a road alongside the lake in early historical times (Hutchinson *et al.*, 1970). The lake was quite productive shortly after its formation for a period of about 2000 years, probably related to initial easy leaching of materials rich in potassium and of fairly high phosphorus content. By 20,000 years BP[1], sedimentation rates were very low. Low rates of deposition of inorganic constituents and organic matter, indicative of very low productivity, continued until at least about 5000 years BP and the Roman period. This interval was marked by a period of cold, dry conditions following the last glacial retreat from the area. A slight increase in productivity was discernible during the latter portion of this interval and a more recent period, most likely related to slight climatic amelioration and some human activity. A very large increase in nutrients and productivity occurred slightly over 2000 years BP (Fig. 24-1). The changes in the sedimentary records coincided rather precisely with the major disturbance of the drainage basin by the construction of a Roman road, the Via Cassia, in about 171 BC. A great increase in inputs of phosphorus and alkaline earths, particularly calcium, resulted, and the lake rapidly became eutrophic, causing the deposition of much organic matter. The productivity of the lake since the period of major disturbance has declined as land uses in the area have changed.

[1] BP = before present.

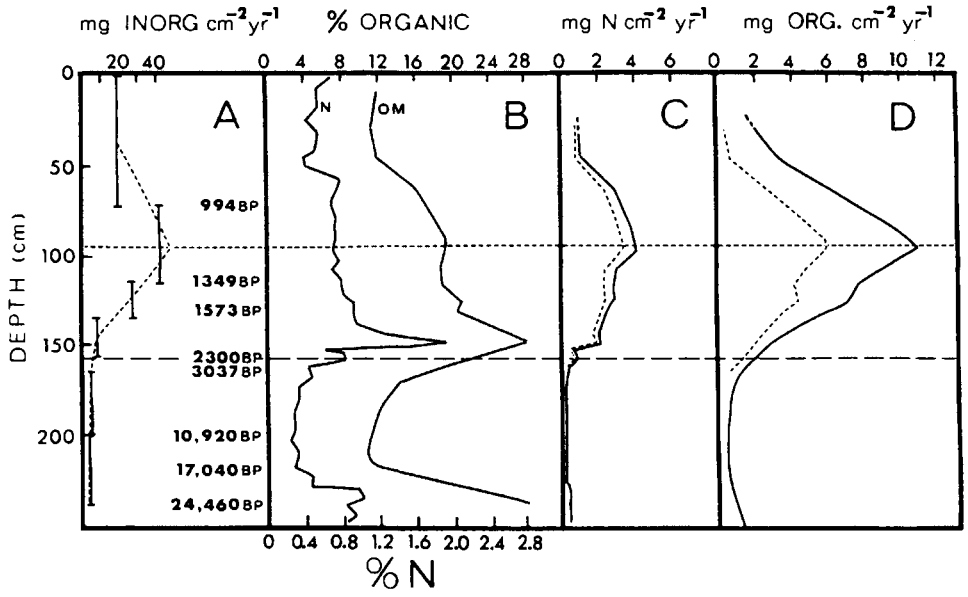

FIGURE 24-1 Stratigraphy of organic matter and nitrogen in the sediments of Lago di Monterosi, Iraly. (a) Estimation of sedimentation rates as a function of sediment depth and radiocarbon dates; (b) ignitable organic matter and nitrogen as percentages of dry sediment; (c) estimated rate of deposition of nitrogen, the broken line being corrected for organic nitrogen brought in by erosion; and (d) estimated rate of deposition of organic matter, the broken line being corrected for organic matter brought in by erosion. (Redrawn from Hutchinson *et al.*, 1970.)

Sedimentary records of such disturbances in the drainage basin are common. For example, the productivity of Grosser Plöner See in northern Germany was increased markedly in the early thirteenth century by the construction of a mill dam that raised the water depth a few meters and flooded portions of the surrounding catchment basin (Ohle, 1972, 1979; Averdieck, 1978). In more recent times in the New World, the total clearance of forests over large portions of North America has led to marked changes, usually increases, in the productivity of lakes, which recorded in the chemical stratigraphy of sediments deposited during the last two centuries. Often, the increased leaching and nutrient loading leads to a marked acceleration of productivity. In contrast, when this increased leaching occurs in calcareous regions, extreme loading of calcium and carbonates can result in a negative effect on productivity owing to carbonate interactions and sedimentation of essential inorganic and organic nutrients (Wetzel, 1970; Manny *et al.*, 1978; Wetzel and Manny, 1978; cf. Livingstone, 1957; Livingstone and Boykin, 1962).

The paleolimnological conditions and productivity of a eutrophic hardwater lake in southern Michigan were reconstructed by combined analyses of the sedimentation rates of organic carbon, nutrients, fossil pigments, pollen, and diatoms (Manny *et al.*, 1978). During the late glacial period (14,075 to 10,200 years BP), algal productivity was low under boreal conditions of low temperatures and competition for nutrients, particularly phosphorus, which was coprecipitated with $CaCO_3$. A long period of relatively constant but slowly increasing productivity followed from about 10,200 to 5900 years BP. During this period, the surrounding vegetation shifted from pine to oak dominance as the climate ameliorated. From about 5900 to 140 years BP, several lines of evidence indicated a gradual increase in areas suitable for the growth of submersed littoral macrophytes, until littoral productivity likely exceeded that of the phytoplankton. Alternating shifts between littoral algal and macrophytic dominance and then to phytoplanktonic dominance occurred repeatedly, which suggested fluctuations in water levels in response to alternating moist and dry periods. During this period, evidence also indicated that the hypolimnion became anoxic each year. As the land surrounding the lake was deforested by humans who settled into the region approximately 140 years BP, sedimentation rates increased sevenfold. The increase in sedimentation rates occurred concomitant with markedly increased sediment concentrations of carbonates and phosphorus and decreased organic matter, nitrogen, and plant pigments. Littoral diatoms increased over planktonic diatoms during this period. In 1926 (some 75 years BP), a bird sanctuary with extensive waterfowl populations was established on the

lake in conjunction with a reforestation program designed to stabilize eroding soils around the lake. These actions rapidly resulted in reduced carbonate loading and markedly increased concentrations of organic nitrogen, pigments, organic matter, and particularly phosphorus. During this period, diatoms of the sediments were dominated by eutrophic, planktonic species. The hypereutrophic conditions continue to the present time, with exceedingly high sedimentation rates (approximately 6 mm yr^{-1}).

The old concept that lakes progress from states of oligotrophy to eutrophy is not necessarily universal (Deevey, 1955; Hutchinson, 1973). As has been demonstrated repeatedly from chemical analyses of sediment stratigraphy, coupled with other indices of past productivity, lake productivity responds to changing nutrient incomes, climate, and morphometry. Accumulation rates of nitrogen, phosphorus, and organic matter in sediments are commonly high in early postglacial times, a period of high availability of nutrients. Accumulation rates typically then decline as leaching gradually impoverishes the drainage basin. In recent times, increases or decreases in lake productivity are usually directly related to disturbances caused by human activities.

D. Organic Constituents

Examination of the organic compounds in sediments must address the problem of origin: Did the organic compound originate within or outside of the lake basin? Furthermore, many organic compounds undergo degradation both during and after sedimentation. The extent of preservation is not always uniform with geologically changing conditions at and within the sediments. However, certain organic constituents of sediments, especially pigment degradation products and certain lipids, are relatively stable and very helpful in the interpretation of past episodes of productivity, particularly when coupled with other indices.

Total amino acid, carbohydrate, and chlorophyllous and flavinoid pigment residues in lake and bog sediments typically increase toward the surface (Swain, 1965). Carotenoid pigments also commonly increase upward in more recent lake sediments but decrease markedly in the developmental transition from a lake to a bog (see discussions further on). Maxima of many organic compounds occur just beneath the surface of the sediment, probably associated both with increased microbial metabolism at the interface and with redox-mediated adsorption phenomena.

Much information is available on organic compounds and their distribution in sediments (Vallentyne, 1957b, 1960, 1969; Cranwell, 1976; Philp *et al.*, 1976). With improved analytical technology in the last decade, a shift has occurred from simple measurements, such as the amount and distribution of total organic matter, carbon, or nitrogen, to molecular characterization of individual compounds. Many organic compounds are not very stable and tend to be hydrolyzed enzymatically and chemically; they may then be metabolized microbially. It is often very difficult to distinguish the time, origin, and mechanism of synthesis of many organic compounds. Significant progress has been made in the association of specific compounds with specific organisms, particularly with certain pigment products (see the following discussion) and with lipid derivatives (e.g., Mermoud *et al.*, 1981, 1982; Cranwell, 1990; Buchholz *et al.*, 1993).

The distribution patterns of fatty acids, hydroxy-acids, and total neutral lipid constituents of sediments allow identification of biological sources of a significant percentage (ca. 50%) of the lipids (Cranwell, 1973, 1990; Robinson *et al.*, 1987). For example, analyses of carbon-chain lengths of *n*-alkanes derived from plant lipids showed that sediment could be characterized by the type of humic material from which it was derived. In higher plants, *n*-alkanes consist of largely odd-numbered carbon chain lengths of C_{23} to C_{35}, whereas lower plants contain *n*-alkanes of both odd- and even-numbered carbon chains. Humic derivatives in sediments from acidic peat areas around a lake contained predominantly C_{31} *n*-alkanes, whereas those from deciduous forested areas had mostly C_{27} and C_{29} *n*-alkanes. Investigation of monocarboxylic unsaturated fatty acid components in lake sediments, soil, and peat indicated that autochthonous material was the main source of C_{12}–C_{18} *n*-alkanoic acids, while terrestrial sources provided the C_{22}–C_{28} *n*-alkanoic acids (Cranwell, 1974, 1979, 1990). The relative contribution of these two sources could be related to the trophic conditions (greater C_{12}–C_{18} acid content in the sediment of productive lakes) and to the rate of erosion of the drainage basin. High abundance of branched/cyclic alkanoic acids, typically occurring in lipopolysaccharides of gram-negative bacteria, was correlated with a large autochthonous contribution from algae and bacteria, whereas a low abundance was correlated with a high terrestrial contribution to the *n*-alkanoic acids. High amounts of alkanoic acids were also found in productive, eutrophic lake sediments that were strongly reducing.

These and similar organic chemical approaches hold much potential and deserve intensified investigation. Problems associated with diagenetic changes in organic compounds after deposition, about which little is known, are serious because these transformations can be confused with those resulting from succession or

other changes in the organisms that synthesize the compounds. Controlled experimental analyses, however, can provide insight into the mechanisms and rates of diagenesis involved.

II. BIOLOGICAL INDICATORS

A. Morphological Remains

Paleolimnology has a long history that began with analyses of morphological remains of aquatic and terrestrial organisms. Preservation of dead organisms in the sediments is typically incomplete, and the extent of preservation depends both upon the type of organism and the environmental conditions that prevail at the time of sedimentation. Pollen and spores of terrestrial plants are most abundant, as are frustules of diatoms and chrysomonad cysts (Frey, 1974, 1988). Remnants of some other groups of algae can occur, but many are not represented. The Cladocera and chironomid midges have the most abundant and diversified of animal remains, although all groups of animals are represented to some extent. Many remains can be matched to species, particularly among the diatoms, desmids, Cladocera, ostracods, and beetles. When only a stage in the life cycle is represented (e.g., cysts of chrysomonads or resting eggs of rotifers), features allowing specific identification are lacking and differentiation often is possible only to the point of the genus or family level.

Of the dominant organisms found in sediments, each group consists of two separate communities, one in the warm littoral zone and the other pelagic. As we have seen with the focusing effects of sediment particles and organic matter, remains of inshore organisms are moved offshore by wind-generated water movements and currents. The amount of such movement and displacement varies widely with different drainage basin and lake basin characteristics.

B. Pollen and Spores

Plant pollen and spores are produced in great abundance, but only a few of those produced fulfill their reproductive function. As pollen types are dispersed, they are well mixed by atmospheric turbulence in proportion to the quantity and composition of the parent vegetation in and surrounding lakes. Most pollen grains have a heavy protective layer (exine) and are resistant to decay if deposited in nonoxidizing sites, such as occur in the sediments of most standing waters. The taxonomy of pollen, based largely on the exine structure and sculpture, is relatively well known for vegetation of many parts of the world. Since pollen is relatively abundant in sediments, small aliquots of sediment are sufficient for analysis. As a result, analyses can be performed at very close intervals within the stratigraphy of sedimentary deposits. The pollen assemblage in sediments of known age, which can be determined by various dating techniques, provides an index of vegetation in and surrounding the lake in the past and also reflects changes that have occurred in the vegetation and drainage basin through time.

A number of detailed works are available on the principles of pollen analysis, including pollen identification and interpretation of pollen data. A good summary of these analyses is given in Birks and Birks (1980). Although many earlier analyses depicted the stratigraphy of pollen as relative percentages of the different pollen types, much greater interpretative power is gained from determinations of the absolute pollen frequency (number of pollen grains cm^{-3}). Then, with determinations of the sediment accumulation rates obtained from dating measurements, the absolute pollen accumulation rate (grains cm^{-3} yr^{-1}) can be determined for the different types or species.

Absolute pollen accumulation rates (pollen influx), unlike percentages, provide independent rates for each species in proportion to its densities and its past population dynamics. Careful interpretation is required, however, because pollen influx into lakes and their sediments can vary with factors not associated with the population and community dynamics of the surrounding vegetation. For example, some lakes are more efficient than others in collecting pollen because of differences in their morphology, their position within the landscape, and the quantities of pollen influx received from inflowing streams versus that received from the atmosphere (Davis *et al.*, 1973, 1984; Pennington, 1973, 1979; Bonny, 1976).

Within a lake, sediments and pollen can be resuspended and moved from shallow to deep parts of the basin (Lundqvist, 1927; Davis, 1968, 1973). This process of sediment focusing often can result in a greater net accumulation of sediment in the deeper parts of the lake basin (e.g., Lehman, 1975; Likens and Davis, 1975; Davis and Ford, 1982; Davis *et al.*, 1984). Additionally, the rate of sediment focusing can differ in different areas of a lake basin, and analyses of several sediment cores are required to resolve spatial and temporal patterns of deposition. The intensity of sediment focusing can change over time. For example, focusing can decrease as the basin fills. This reduction may be erroneously interpreted as a decrease in apparent rates of accumulation per unit area (when measured at a single point), because more recent deposits are being spread more thinly over a greater area than was the case previously.

The stratigraphy of pollen and spores provides a chronology of the vegetation from which presumptive evidence for climatic changes can be obtained. These vegetational changes of the landscape and catchment area provide insight into temperature and rainfall changes, soil development, and changes in the drainage basin caused by human activities. Rapid changes in vegetational succession, such as caused by catastrophic forest pathogen outbreaks in the past or recently by human introduction of exotic pathogens, is readily seen in the pollen record in laminated lake sediments (e.g., Allison *et al.*, 1986). Knowledge of the detailed vegetational history of the drainage basin is indispensable for the interpretation of changes in the developmental stratigraphy of the lake through its sediments.

Nearly all detailed paleolimnological analyses augment their interpretative power by means of pollen diagrams. Hence, the number of studies on pollen stratigraphy is very large. A few examples will demonstrate their usefulness.

In a classical study of the now meromictic Längsee, Austria, Frey (1955) demonstrated that permanent meromixis was well established and intensified at least 2000 years ago when humans moved into the area and began clearing forest vegetation from the drainage basin for agriculture. Pollen stratigraphy showed a marked decrease in the dominant forest species and a sharp increase in pollen of smaller species, two cultivated plants, and a number of agricultural weeds. Evidence also was found for markedly increased erosion of fine clay particles that probably were sufficient to increase further the density of lower water strata and subsequently maintain meromixis biogenically (cf. biogenic meromixis, Chap. 6). Subsequent detailed analyses of the complete chemical and fossil stratigraphy, with the loss of most benthic species, indicated that meromictic conditions began about 15,000 BP with a combination of postglacial climate changes, poor inflow system, and high carbonate content (Harmsworth, 1984; Löffler, 1997).

Numerous other examples exist in which the pollen stratigraphy reflects how sensitively lake metabolism responds to changes in the drainage basin. The response of the Italian Lago di Monterosi to construction of a Roman road, discussed earlier, also can be seen in the abrupt changes in pollen deposition from surrounding terrestrial vegetation. More recent changes in lake drainage basins resulting from agricultural clearing of land are seen in many parts of North America. As the land was denuded of trees, erosion and leaching of ions was increased markedly, usually resulting in accelerated nutrient loading and productivity. This sedimentary horizon is demonstrated by many chemical and biotic changes, the most conspicuous of which is the sudden rise in pollen of the agricultural weed *Ambrosia,* or common ragweed. The importance of the erosion rate in the drainage basin also was shown to be of major importance in the stratigraphy of lake sediments in the English Lake District (Tutin, 1969; Pennington, 1981). Pollen spectra throughout late and postglacial times correspond closely with the chemical history of the drainage basin. During the late glacial and early postglacial period, the erosion rates were controlled by low temperatures. In the midpostglacial period of deciduous forest, erosion was at a minimum. Within the last 5000 years, variation in or destruction of the deciduous forests surrounding many lakes in the English Lake District is evident from pollen stratigraphy and increased rates of erosional deposition.

C. Algal Remains

Several types of algae are well preserved in lake sediments. By far the most common algal microfossils are the siliceous frustules of diatoms (Round, 1964b; Juse, 1966; Korde, 1966; Bradbury, 1975). Diatoms are useful paleoecological indicators because their remains commonly occur in abundance, are often well preserved (see following discussion), and most can be identified to species from frustule morphology. Additionally, the physiological and ecological characteristics of many diatoms are distinct and well known, which permits reconstruction of probable past lake conditions from past diatom communities.

Diatom profiles in sediments are complicated by differential rates of dissolution of the frustules during and after sedimentation, which raises questions about how rigorously the remains found in sediments reflect the quantitative composition of producing populations. The few studies directed toward this question are conflicting, but it is apparent that dissolution rates vary among individual lake systems in relation to their chemical and morphometrically related history (cf. Chap. 14). For example, it has been found that frustules sedimented in the littoral and shallower profundal zones dissolved at higher rates than those sedimenting in the deep profundal zone (Tessenow, 1966). Under mildly acidic conditions, as in the hypolimnia of some meromictic lakes, dissolution of diatom frustules can be higher than in less acidic sediments (e.g., Meriläinen, 1969, 1971). Diffusive dissolved silica fluxes from sediments to the overlying water were proportional to the concentrations of biogenic silica in the sediments and increased with biogenic concentrations to ca. 100 mg g^{-1} of sediments, above which fluxes were limited by diffusive transfer rates (Conley and Schelske, 1989).

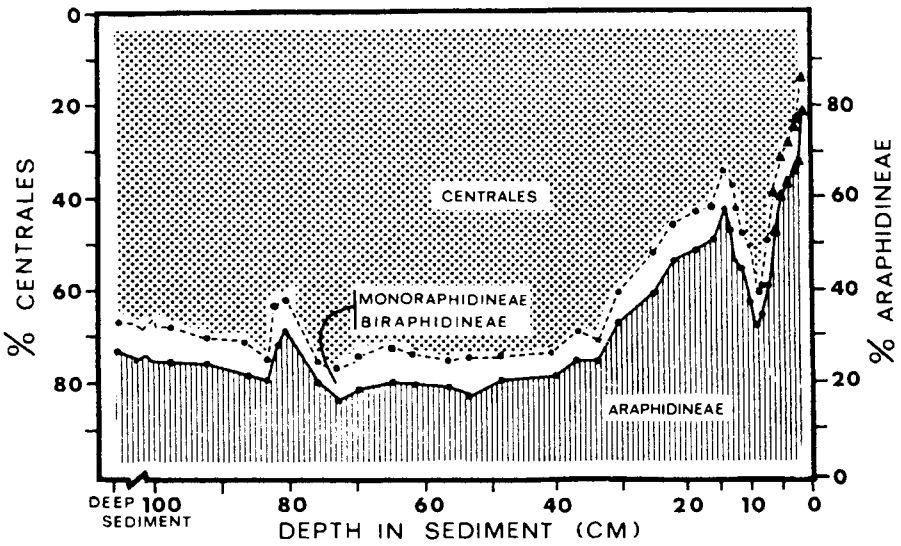

FIGURE 24-2 Changes in the percentage composition of the centric and araphid pennate diatoms in the surficial sediments of Lake Washington. The changes around 80 cm are associated with a clay turbidite layer peculiar to this core but not generally present throughout the lake. (Redrawn and modified from Stockner and Benson, 1967.)

Diatoms have been used extensively to assess environmental changes. Because much is known about how many diatom species respond quickly to changes in habitat characteristics, particularly their chemical environment, the diverse diatom communities contain much ecological information (e.g., Dixit *et al.*, 1992; Smol *et al.*, 1998; Stoermer and Smol, 1999). The identification of changes in species composition of diatom communities preserved in sediments can be used to infer long-trend ecological changes resulting from lake eutrophication, lake acidification, and climatic change.

In very general terms, centric diatoms are associated with more oligotrophic waters, while planktonic pennate diatoms tend to be more characteristic of eutrophic waters. The ratio of these two indicator groups of diatoms in the stratigraphic record can offer some help in interpreting the chronology of positive or negative changes in productivity. Around Lake Washington in Seattle, early development of the human population extended over the period from 1850 to the early 1900s (Edmondson, 1991a). From about 1910 to the mid-1920s, raw sewage entered the lake in increasing amounts. Between 1926 and 1941, much of the primary effluent was diverted away from the lake. In 1941, with progressively increasing regional human population expansion, large amounts of secondarily treated sewage entered the lake. These effluents of treated sewage continued to enter the lake until the mid-1960s, when all sewage was diverted to Puget Sound. Examination of the diatoms preserved in the recent sediments indicated detectable responses to the known sequence of enrichment, reduction, and renewed enrichment (Stockner and Benson, 1967). Major changes in the diatom community occurred (Figs. 24-2 and 24-3), related largely to reciprocal fluctuations in the abundance of the centric *Aulacoseira* (formerly *Melosira*) *italica* and the pennate *Fragilaria crotonensis*. The relative composition of the diatoms deposited, as well as species diversity redundancy values, was constant for the period prior to enrichment. Algal dom-

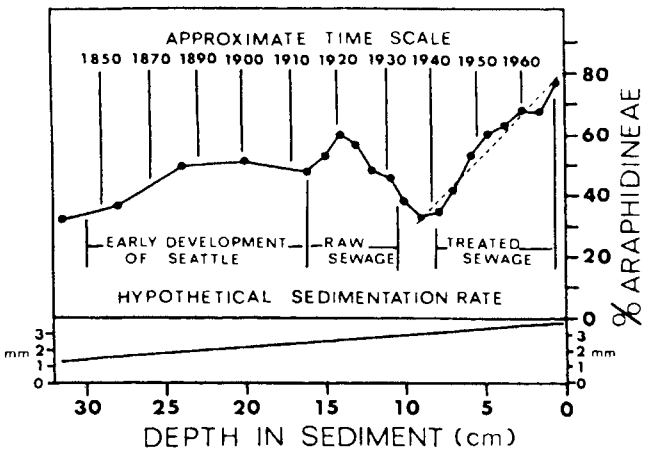

FIGURE 24-3 Changes in the relative abundance of araphid pennate diatoms in the recent sediments of Lake Washington in relation to the developmental history of the region surrounding the lake. The time scale is derived from an estimated average sedimentation rate of 2.5 mm per year over the upper 30 cm. (Redrawn and modified from Stockner and Benson, 1967.)

inance could be correlated with the pattern of sewage discharge into the lake. Many of the species changed in proportion in accordance with their generally known nutritional behavior as indicator species. It was concluded that the use of indicator groups (in this case, the ratio of centric to araphid pennate diatoms) was more reliable than the use of single indicator species.

The increased ratio of Araphidineae (e.g., *Fragilaria, Asterionella, and Synedra*) to centric diatoms (*A/C*) has been successfully applied to a number of other recent sediments as an indicator of eutrophication of lakes (e.g., Stockner, 1971, 1972, 1975; Bailey and Davis, 1978; Brugam, 1978; Culver *et al.*, 1981). It is clear, however, that high *A/C* indices of eutrophic conditions are not universal and are characteristic only in certain lakes of moderate total phosphorus concentrations and low alkalinities (Hall and Smol, 1999). High ratios of Araphidineae to centric diatoms are associated with low-alkalinity eutrophic lakes (Brugam and Patterson, 1983). In other lakes, even though araphidinate diatoms such as *Fragilaria* commonly increase in response to human settlement and increased nutrient loading, certain centric diatoms [particularly *Stephanodiscus* and *Aulacoseira* (*Melosira*)] increased even more vigorously (Bradbury and Megard, 1972; Haworth, 1972; Bradbury, 1975; Bradbury and Winter, 1976; Battarbee, 1978; Koivo and Ritchie, 1978; Brugam, 1979). Eutrophic lakes dominated by the centric diatom *Stephanodiscus* are nearly always of high alkalinity (> 1.5 meq liter^{-1}). Although the changes in species composition of diatom communities can provide some insights into changing trophic conditions, correlations of diatom abundances with phosphorus concentrations are poor, and as a result past diatom-inferred total phosphorus predictions are poor (e.g., Fritz *et al.*, 1993; Hall *et al.*, 1997). Caution is clearly warranted in any use of simple *A/C* ratios or of indicatory species as an index of trophic conditions.

Experimentally determined tolerances of diatoms to ranges of alkalinity and other chemical parameters have permitted reconstructions of past chemical conditions in lakes based on past diatom communities. For example, in certain shallow African lakes, wide fluctuations in total ion content, lake morphometry, and paleoclimate have been inferred from stratigraphic changes in diatom communities (Richardson *et al.*, 1978). A significant linear relationship was found between the biogenic silica concentration and diatom biovolume abundance in sediment cores, from which estimates of past changes in diatom abundance could be inferred (Conley, 1988). In several of the Laurentian Great Lakes, sedimentary stratigraphy of diatoms, silica, and phosphorus concentrations have provided evidence for water column reduction in silica as a response of increased diatom production to phosphorus enrichment and decreased diatom production resulting from silica reduction (Schelske *et al.*, 1986; Schelske, 1988, 1999). Rate constants of pelagic cycling of phosphorus are higher than those for silica recycling. As a consequence, relatively small levels of phosphorus enrichment can increase diatom production and sedimentation that eventually causes silica reduction and Si-limited diatom production in the water mass.

The predominant environmental habitats of many diatoms are well understood. Therefore, stratigraphic separation of diatom communities into littoral (epiphytic or benthic) versus planktonic-dwelling species can yield further insight into past conditions of lake morphometry, water-level fluctuations, and shifts between littoral versus planktonic dominance of primary productivity (e.g., Round, 1961c; Evans, 1970; Manny *et al.*, 1978; Wolin and Duthie, 1999).

Sedimentary diatoms have been used to evaluate rates of lake acidification, associated changes in water chemistry, and recovery. To reconstruct past estimates of lakewater pH, present-day pH optima of surface-sediment diatom communities are applied to down-core fossil diatom assemblages preserved in dated lake sediments (Battarbee *et al.*, 1999). These separations are based on known correlations of diatom species with different conditions of pH, acid-neutralizing capacities, monomeric aluminum concentrations, and dissolved organic carbon concentrations, in addition to the inferences about diatom assemblages in terms of nutrient (P and N) concentrations discussed earlier. For example, in analyses of 37 Adirondack lakes of New York, diatom stratigraphies indicated that many lakes have acidified considerably, some by over two pH units, since the 1850s (Kingston and Birks, 1990; Smol *et al.*, 1998). Many other examples exist of the reconstruction of historical lake pH from alkaliphilous to acidophilous sedimentary diatom remains (e.g., Del Prete and Schofield, 1981; Davis and Anderson, 1985; Birks *et al.*, 1990). Highly acidified lakes often have chronically toxic concentrations of solubilized monomeric aluminum. Changes in dissolved organic carbon from acidification were small and indicated no definite pattern. Acidification had occurred primarily because of atmospheric deposition of mineral acid pollution in liquid (rain or snow) and particulate (dust) precipitation (Battarbee and Charles, 1994). Weighted-averaging models have also been developed to infer lakewater total phosphorus in the low range (< 25 μg liter^{-1}) from diatom assemblages preserved in sediments (e.g., Hall and Smol, 1992). Using a number of assumptions, estimates of the onset, rate, and magnitude of lake eutrophication can be inferred in response to natural processes and human disturbances.

Other algae or parts of algae are preserved less completely than diatoms. Certain green algae (e.g., *Pediastrum*), scales and cysts of chrysophytes, cysts of dinoflagellates, and heterocysts of cyanobacteria are preserved in lake sediments (e.g., Leventhal, 1970; Brugam, 1978; Crisman, 1978a; Elner and Happey-Wood, 1978; Munch, 1980; Smol, 1980). The stratigraphy of these algae, and of diatoms as well, can be useful in interpreting past conditions when coupled with changes in other parameters recorded in the sedimentary record. However, less is known of the physiology and ecology of these other algae than is known of many diatoms, and as a result interpretation is often less rigorous than it is with changes in diatom stratigraphy.

The chrysophycean algae produce resting stages in the form of endogenously formed silicious cysts (statospores). The cysts are spherical or oval and often the walls are ornamented, which, along with other features, allows fairly specific taxonomic identification (Cronberg, 1986; Smol, 1988). The cells of chrysophytes of the family Mallomonadaceae are covered with loosely attached silica scales, some of which are also of taxonomic value. Upon death, scales and cysts are often deposited on sediments. Chrysophytes are primarily planktonic and have been used as indicators of water quality. Some six different assemblages of chrysophyte species, based largely on cysts, can be differentiated on the basis of water quality characteristics of pH, conductivity, and chemical constituents (Rybak, 1986; Siver, 1993; Duff *et al.*, 1997).

Mallomonadaceae species, identified from scales, have been used widely as indicators from which changes in lake development could be interpreted (e.g., Battarbee *et al.*, 1980; Munch, 1980; Smol, 1980). Changes in species composition of *Synura* and *Mallomonas* were seen in response to alterations of water quality, particularly changes in the drainage basin (e.g., road construction) and eutrophication. Differences in chrysophycean species were also shown in response to onset of meromixis (Smol *et al.*, 1983) and acidification (Smol *et al.*, 1984; Marchetto and Lami, 1994; Duff *et al.*, 1997) and recovery from acidification (Dixit *et al.*, 1989). Because chrysophytes tend to be associated with relatively oligotrophic lakes, declines are commonly associated with eutrophic phases of the development of a lake. As a result, a ratio of fossil eutrophic diatom frustules to chrysophycean cysts has been suggested as a potentially useful index of trophic status in temperate lakes (Smol, 1985).

D. Plant Macrofossils

Remnants of large plants are frequently preserved in lake sediments. Plant macrofossils usually consist of fruits, seeds, megaspores, and fragments of leaves, rhizomes, flowers, and woody tissue (see reviews of Dilcher, 1974; Birks, 1980; Birks and Birks, 1980; Collinson, 1988; Hannon and Gaillard, 1997). Seeds and other reproductive parts are often well preserved and identifiable to species. Such macrofossils supplement the pollen record. Many pollen grains cannot be identified to the species level, and some pollen types are poorly preserved. In addition, some common plants, particularly larger aquatic plants, produce so little pollen that they are not routinely represented in pollen counts. Because of their larger size, plant macrofossils are usually deposited close to their sites of origin; in contrast, pollen is easily and widely dispersed. The limited transport of plant macrofossils can result in heterogeneous distributions within sediments in different areas of a lake. Moreover, because the quantity of plant macrofossils per volume of sediment is usually very low, one must examine large quantities of sediment in order to acquire significant fossils.

Plant macrofossils preserve well in anaerobic sediments, although little is known of long-term diagenesis of vascular plant organic matter in lake sediments. Analyses of biogeochemical differences in contemporary tissues of white spruce (*Picea glauca*) with those preserved 10,000 years in lake sediments showed small changes (Meyers *et al.*, 1995). Hydrocarbon and total alcohol concentrations and distributions showed little diagenetic change. Cellulose components decreased relative to lignin, but C:N ratios were not significantly different.

Quantitative analyses of the stratigraphy of plant macrofossils assist in the reconstruction of past lake development and changes in primary productivity (see the Wintergreen Lake example discussed earlier). Changes in lake levels, water chemistry, and regional climate have been evaluated, in part, from plant remains and inferences from known physiological and ecological characteristics and tolerance ranges of the plants (e.g., Watts and Winter, 1966; Birks, 1980; Dearing, 1997; Hannon and Gaillard, 1997). The strongest lines of sedimentary evidence for lake-level change are the advance and retreat of littoral vegetation deduced from analyses of macrophyte fossils and coarse organic matter. Macrofossils can also provide insight into the rates and types of plant succession that have occurred in and surrounding lakes.

E. Animal Remains

Nearly all groups of animals leave at least some identifiable morphological remains in lake sediments. At the microscopic level, the most abundant animal

remains in sediments are those of ostracods, Cladocera, and midges, and under favorable circumstances, shells or cases of testaceous rhizopods, spicules of sponges, egg cocoons of neorhabdocoele Turbellaria, resting eggs of rotifers, bryozoan statoblasts, copepod spermatophores, and oribatid mites can also be found (Frey, 1964, 1969, 1976, 1988; Crisman, 1978b; Walker, 1993). At the macroscopic level, mollusk and beetle remains dominate. The remains of larger organisms (e.g., fish scales and bones) are generally less abundant and require larger volumes of sediments for the recovery of significant numbers. Therefore, their stratigraphy must be based on coarser intervals than that of microscopic fossils.

Numbers of species or groups are often expressed in relative percentages of the total assemblage or, preferably, are related to the weight of organic matter or some other volumetric mass parameter of sediment. Varying rates of sedimentation can be determined from radiocarbon dating and certain other stratigraphic criteria that permit expression as an absolute rate of accumulation, which can result in quite different interpretations than those based on percentage composition (cf. Davis and Deevey, 1964).

1. Midges

The nonbiting midges, or Chironomidae, are of particular interest in microfossil analyses of lake sediments because they provide insights into the ecological conditions of earlier periods of lake development (Walker, 1987; Hofmann, 1988). Some species of chironomids (*Chironomus*) are commonly distributed in the profundal zone of eutrophic lakes, which often experience low dissolved-oxygen concentrations at the end of the stratified period. Others (e.g., *Tanytarsus lugens*) are restricted to oligotrophic lakes, which commonly have high dissolved oxygen in the hypolimnion at the end of the stratified period. Therefore, if a lake becomes more eutrophic with decreasing oxygen content of the hypolimnion, one might expect, for example, a succession of profundal midge populations from those that require high oxygen to those that tolerate decreasing oxygen concentrations. It is important to note, however, that the profundal midges respond to the concentrations of dissolved oxygen, which may result from a combination of decreased volume of the hypolimnion through accumulation of sediments as well as increases in nutrient-controlled productivity.

In detailed studies of the stratigraphy of chironomid and *Chaoborus* midge faunas of several lakes in northern Indiana, Stahl (1959) demonstrated such a succession in midge populations and offered strong evidence for the transition from aerobic to anoxic hypolimnetic conditions among the more productive lakes. Additional evidence has been found for historical changes in eutrophication of lakes from marked changes in benthic invertebrate remains in sediments (e.g., Stahl, 1969; Carter, 1977; Hofman, 1978b; Wiederholm and Eriksson, 1979).

Changes in chironomid community stratigraphy have been used as an additional indicator of the effects of acidification of softwater lakes. For example, marked species alterations occurred as an oligotrophic lake shifted to a *Sphagnum*-dominated acidic, ombrotrophic lake (Walker and Paterson, 1983). Similar marked changes in profundal chironomid communities occur in lakes that have been acidified from acidic precipitation (Henrikson *et al.*, 1982; Uutala, 1990).

2. Cladocerans

Exoskeletons of cladoceran zooplankton preserve reasonably well in lake sediments. This group has been studied in the fossil record in great detail. Analyses of past populations also have been made in which information theory at the community level has been applied, thereby refining interpretations of responses to changing ecological conditions.

Species of chydorid Cladocera are largely littoral and occur on a variety of substrata. Considerable evidence exists, however, that the littoral faunal remains are redistributed by currents within lake basins, where they become integrated with remains of planktonic Cladocera (Mueller, 1964; DeCosta, 1968; Goulden, 1969a; Frey, 1988). The populations recorded in profundal sediments, therefore, offer a reasonable integration of community dynamics over habitats and seasons. Changes with time or among lakes can then reflect changes in the communities in response to such varying biotic conditions as shifts in food quantity and quality, competition, or predators (Frey, 1976, 1988; Hofmann, 1978a,b, 1986; Crisman and Whitehead, 1978).

There are many examples of the usefulness of cladoceran remains in interpreting past conditions (Frey, 1969, 1974; Birks and Birks, 1980; Hofmann, 1986). Changes in species diversity and equitability of chydorid communities, as pioneered by Goulden (1969b), have been used to assess the stability and responses of the communities to disturbances. Equilibria of the population associations have been shown to be disrupted by the establishment of competing species or by agricultural disturbances, climatic alterations, and shifts in the ratio of lake productivity contributed by littoral and phytoplanktonic sources (Whiteside, 1969). The ratio between planktonic and littoral cladoceran fossil remains also is useful in interpreting past changes in water level and the extent of littoral development. For example, in many glacial lakes of Europe and

North America, *Bosmina* is often the most abundant zooplankton group. *B. longispina* is often found early in the lake development and is a species unable to survive at high levels of phytoplankton productivity and conditions associated with that productivity. That *Bosmina* species is often replaced later in the development of the lake by *B. longirostris,* a species common to more eutrophic conditions (Boucherle and Züllig, 1983; Hofmann, 1986).

Changes in morphology of fossil cladocerans have been associated with known induction of such changes by invertebrate predators (Brugam and Speziale, 1983). Changes in piscivore fish that affect planktivore predatory efficiency on large cladocerans, such as *Daphnia,* appear in the fossil records with the increased abundance of *Bosmina* and decreased *Daphnia.* If fish community structure is altered by natural processes (e.g., winterkill) or pollution (e.g., lake acidification), the events can be reconstructed from the cladoceran fossil records (Nilssen and Sandøy, 1990). Fossil zooplankton are likely more sensitive indicators of predation than of lake trophic status.

3. Ostracods

Paleolimnological interpretation of fossil ostracod communities is poor because of limited modern ecological understanding at the species level. Although correlations have been made among ostracod distributions and limnological parameters (Delorme, 1971; Binford, 1982; Carbonel *et al.,* 1988), these data allow only limited estimates of past chemical conditions based on fossil ostracod stratigraphy. Ostracods are good indicators of differences in salinity and certain alkaline earth elements.

4. Molluscs

Fossil molluscs have been studied extensively and allow selective interpretations of past changes in water level, salinity, and trophic conditions (Frey, 1964). However, freshwater molluscs are relatively poor indicators of past paleoclimatic fluctuations and lake conditions because of their generally broad environmental tolerances (Ouellet, 1975). In some cases, however, temporal changes in the molluscan fauna provide useful interpretations of postglacial conditions of lakewater chemistry and water-level fluctuations (e.g., Covich, 1976; Ohlhorst *et al.,* 1977).

F. Pigments

Fossil pigments of biota have been investigated extensively as organic constituents of sedimentary stratigraphy (cf. Vallentyne, 1957b, 1960; Gorham, 1960; Brown, 1969; Sanger, 1988). Upon plant senescence and death, the photosynthetic pigments undergo molecular transformations in which ions (such as the coordinately bound magnesium atom of chlorophylls) and side groups (long-chain terpene alcohol, phytol) are lost progressively during physical or biological degradation. There is a tendency for the degradation products to increase in stability—that is, decrease in solubility and increase in relative resistance to further microbial and physical decomposition. Chlorophyll *a,* for example, degrades to pheophytin *a* with the loss of magnesium; pheophytin *a* then degrades to pheophorbide *a* with the loss of the phytyl group. The alternative sequence in which the phytyl group is lost first leads to the formation of the intermediate product, chlorophyllide *a.*

The number of pigments found in sediments is large. Nondegraded chlorophylls are rare, but pheophytins, chlorophyllides, pheophorbides, and bacteriochlorophyll degradation products have been identified and quantified. Additionally, a number of carotenoids have been found, some of which are highly specific to groups of organisms such as the cyanobacteria or certain families of organisms. Carotenoids commonly present in sediments are separated into (a) epiphasic (hydrocarbon carotenes), soluble in nonaqueous organic solvents (e.g., β-carotene); and (b) hypophasic, many oxygenated xanthophylls in hydroxy, keto, epoxy, or methoxy groups (e.g., lutein, violaxanthin, and zeaxanthin). As discussed earlier (Chap. 15), there is a general positive correlation between long-term growth and biomass of photosynthetic microbes and their community concentrations of pigments. Total carotenoid concentrations were found to be the most strongly correlated to other indices of lake trophic status (Sanger, 1988; Hilton *et al.,* 1991). If pigments are reasonably preserved by the time they are interred in sediments, the stratigraphic distribution of pigments would offer the possibility of identification and estimation of past plant populations as well as of environmental conditions of the water and sediment at the time of their deposition.

In the 1950s, Vallentyne and colleagues pioneered studies of fossil pigments in sediments of many different lake ecosystems. These data, when correlated with the stratigraphy of microfossils of organisms, allow interpretation of the ecological records of the various lakes. The potential information that pigments can provide, with critical interpretation, is exemplified in analyses of Bethany Bog, Connecticut (Vallentyne, 1956). Myxoxanthin, a carotenoid specific to the cyanobacteria, was present only in the sediments of the eutrophic phase of the lake and was not found in the more recent sediments of the lake as it entered its bog phase.

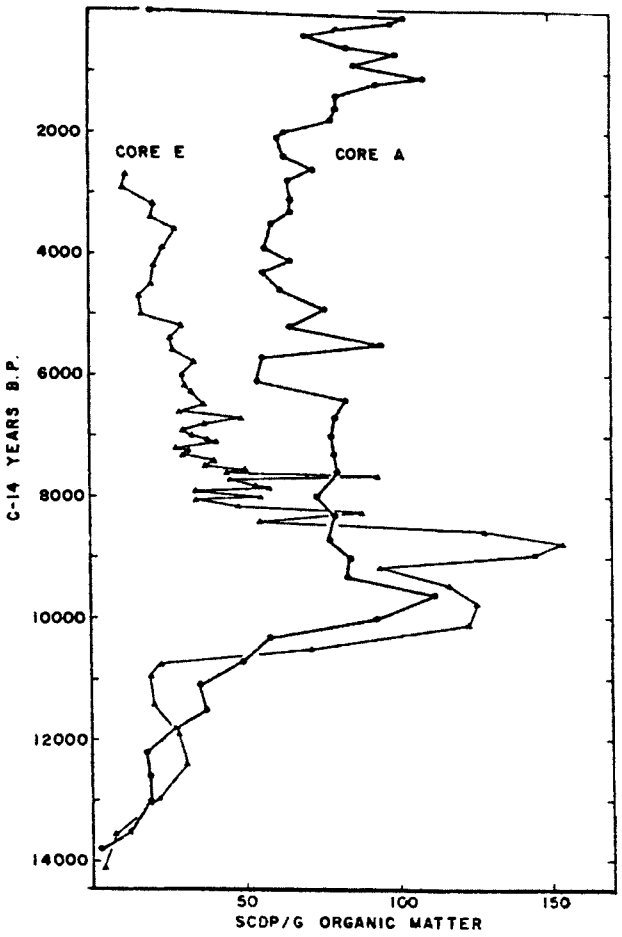

FIGURE 24-4 Sedimentary chlorophyll degradation products (SCDP) per gram organic matter in two cores from Pretty Lake, northeastern Indiana. Core A was from the deepwater central depression of the lake at a water depth of 25 m; Core E was from a shallow marl lakemount near shore that ceased accretion of sediment 2740 years BP because of water movements at a water depth of about 1 m below the surface. (From Wetzel, 1970, as modified by Frey, D. G.: Paleolimnology. *Mitteilungen Internat. Verein. Limnol.* 20:95–123, 1974.)

A number of analyses on several different types of lakes have indicated general correlations between sedimentary pigments and productivity. Most studies show maximum concentrations of pigments in early postglacial times after a period of tundra conditions associated with retreating glaciation (Fig. 24-4). The maximum concentrations are generally attributed to phytoplankton productivity stimulated by early leaching of nutrients from the drainage basin during the ameliorated thermal period following deglaciation, which is characterized by transitions from tundra to coniferous and then deciduous vegetation. This initial surge in pigment degradation products usually is followed by an intermediate period of relative stability or slowly declining rates of pigment deposition, with minor fluctuations associated with variations in climate, rainfall, and nutrient conditions. Subsequent pigment concentrations, assumed by inference to emanate from phytoplanktonic productivity, are variable but commonly have been lower until very recent times. This reduction has been associated with alterations within the drainage basin that increase the ratio of allochthonously derived organic matter (including pigment degradation products) to autochthonous organic matter sedimenting from production within the lake (Fogg and Belcher, 1961).

The rapid eutrophication of many lakes in recent times, often within the last century, generally is reflected in large increases in the pigment concentrations of recent sediments. This recent increase often coincides with renewed leaching of nutrients from the drainage basin as the land was deforested for agriculture. In highly calcareous drainage basins, deforestation can accelerate inputs of calcium and bicarbonate, which interact with numerous inorganic and organic factors to suppress productivity. The inverse relationship between $CaCO_3$ and pigment stratigraphy has been demonstrated in several hardwater lakes (Wetzel, 1970; Manny *et al.*, 1978; Wetzel and Manny, 1978). The abrupt decline in pigment concentrations and other measures of algal abundance and production within 200 years BP (Fig. 24-4, upper portion of Core A) coincided precisely with deforestation, massive increases in $CaCO_3$, and the initiation of *Ambrosia* (ragweed) pollen associated with agriculture.

As discussed above, morphologically recognizable parts of a number of algae (diatoms, certain desmids and green algae, and cysts of some dinoflagellates and chrysophytes) are well preserved in freshwater sediments. Parts of other algae are preserved less well or not at all. Therefore, if pigments that are preserved are restricted to specific taxonomic groups that are characteristic of relatively distinct ecological conditions, their stratigraphy can be most helpful in interpretation of past conditions in the ontogeny of a lake.

Chlorophyllous pigments are cosmopolitan in distribution among plants. Certain algal and bacterial carotenoids and bacteriochlorophyllous degradation products of purple photosynthetic and green sulfur bacteria have been found in sediment stratigraphy and associated with events that led to eutrophication and meromixis (e.g., Brown, 1968; Czeczuga and Czerpak, 1968; Züllig, 1982, 1989; Guilizzoni *et al.*, 1986; Sabater and Haworth, 1995; Hodgson *et al.*, 1998). Myxoxanthin, myxoxanthophyll, oscillaxanthin, and other carotenoids have been used in this manner to infer the time of invasion and development of algae and cyanobacteria (Züllig, 1961, 1981, 1982, 1989; Brown

and Coleman, 1963; Griffiths *et al.*, 1969; Griffiths, 1978). For example, quantitative measurements of myxoxanthophyll in sediment cores of many Swiss lakes provided a clear record of the first appearance of cyanobacteria, in the absence of morphological fossils, during the marked recent eutrophicational changes in some of these lakes (Züllig, 1961, 1982). The appearance of oscillaxanthin, which is specific to cyanobacteria of the family Oscillatoriaceae, in recent sediments of Lake Washington in Seattle was related directly to the development of dense populations of this microbial group as the lake became excessively eutrophic owing to enrichment with sewage (Griffiths *et al.*, 1969; Griffiths and Edmondson, 1975).

Interpretation of fossil pigments as a measure of qualitative and quantitative changes of former microbial populations must be done critically. Several assumptions are often made that are never completely valid and can vary with specific conditions of individual lake systems (cf. reviews of Moss, 1968; Brown, 1969; Wetzel, 1970; Swain, 1985; Hendry *et al.*, 1987; Sanger, 1988). A number of complex abiotic and biotic interactions alter the diagenesis of pigments before and after arriving to the sediments.

1. *Importation of Allochthonous and Littoral Pigments to Pelagic Sediments.* The extent to which pigment products of terrestrial and wetland origin dilute those formed within the lake is not always clear. Chlorophyllous pigments decompose readily to pheopigments in soils and in senescent leaves (Hoyt, 1966). The relative allochthonous input of inorganic and organic matter is largely a function of morphometry of the lake basin in relation to its drainage basin and the rate of erosion (cf. Mackereth, 1966). Although allochthonous and littoral inputs of *particulate* organic matter can be quite significant in small, shallow lakes, the distribution and decomposition rates of chlorophyll and carotenoid derivatives in woodland soils, swamps, ponds, and lakes indicate that *particulate* allochthonous contributions usually are small in relation to autochthonous sources (Gorham and Sanger, 1964, 1972, 1975, 1976; Sanger and Gorham, 1970, 1973).

Sanger and Gorham introduced a pigment diversity index, based on the enumeration of pigment spots on two-dimensional thin-layer chromatograms of acetone extracts, as a means of assessing the origins of sedimentary organic matter. Particulate detritus of terrestrial origin contains three dominant pigments—pheophytin *a*, β-carotene, and lutein—even though quantities of these pigments in leaves of various deciduous trees are very low at the time of abscission (Sanger, 1971). The carotenoids in aerobic soils are degraded more rapidly than pheophytins. Therefore, the terrestrial vegetation has a low pigment diversity, which decreases further on degradation in soils. Examinations of pigment diversities of upland vegetation, aquatic macrophytes, algae, and sediments showed a marked increase in diversity with the transition to lakes and autochthonous sources (Table 24-1). The pigment diversity in lake sediments was greater than that of other materials as a result of decomposition of the phytoplankton. Thus, the pigment diversity index can be viewed as primarily a measure of pigment diagenesis. The initially high pigment diversity of algae is further increased during decomposition (cf. Daley, 1973).

The ranges commonly observed were 7–8 for upland vegetation, 12–15 for aquatic macrophytes, 10–21 for algae, and 24–47 for lake sediments. The highest diversity was found under ideal conditions for preservation of pigments in sediments of a meromictic lake (Table 24-1). The results indicate that during oligotrophic conditions, much of the organic matter preserved in sediments is allochthonous in origin, while under eutrophic conditions pigments of autochthonous

TABLE 24-1 Pigment Maxima and Diversity Indices in Woodland Soil Detritus, Swamp Peats, and Sediments of a Series of Dimictic Lakes and a Meromictic Lake[a]

	Relative units per gram organic matter			
System	*Chlorophyll derivatives*	*Epiphasic (xanthophyll) carotenoids*	*Hypophasic (carotenes) carotenoids*	*Pigment diversity*
Woodland maximum	1.3	0.2	0.4	10
Swamp maximum	12.6	2.4	5.0	23
Dimictic lakes, minimum	1.1	0.4	0.8	24
Dimictic lakes, maximum	16.3	26.6	31.4	47
Meromictic lake, maximum	59.2	40.5	64.7	50

[a] Modified from Sanger and Gorham (1973) and Gorham and Sanger (1972).

origins can exceed those sedimented from external sources. Nonplanktonic inputs of pigments found in sediment traps, determined by the difference between the total trapped particulate pigments and that estimated in the phytoplankton, were found to be more than half of the total in midsummer in three northern Wisconsin lakes (Carpenter *et al.,* 1986). Sources of nonplanktonic inputs were unknown but believed to be largely from littoral periphyton and the resuspension and lateral transport of littoral sediments, where pigment concentrations can be very high (cf. Chap. 19 and Cyr, 1998).

2. *Proportionality between Planktonic Pigment Concentrations and Productivity.* Another assumption generally made is that the pigment concentrations of living algal populations represent a reasonable relative estimate of algal productivity, so that the sedimentary record reflects past levels of algal productivity. Although chlorophylls have been used widely as a measure of contemporary algal productivity (Chaps. 15 and 19), the pigment content of living populations is influenced by numerous environmental factors and can vary greatly under different conditions of growth. Over time, the succession of species and changes in nutrient status may result in changes in the ratio of pigment to organic matter in sedimenting materials. In a general and relative way, however, pigment concentrations do reflect contemporary microbial photosynthetic productivity. If nonplanktonic inputs of particulate pigments originate from littoral production, then that is part of the total lake productivity. However, it is probable that littoral inputs are highly variable under different environmental conditions affecting lateral displacement to the pelagic zone.

3. *Differential Degradation of Pigments.* Differential degradation of pigments during and after sedimentation is a more serious problem that is difficult to resolve. If pigment diagenesis is quite variable, it is difficult to distinguish between high productivity and rapid rates of degradation or low productivity and slow rates of diagenesis. Detailed experimental investigations of the destruction of chlorophyll and the formation of derivatives from lacustrine pigments demonstrated that several factors are involved (Daley, 1973; Daley and Brown, 1973). Photooxidative destruction of chlorophyll occurred in senescent phytoplanktonic cells and at an accelerated rate in cells lysed artificially, by bacteria or by a virus. Chlorophyll *a* was degraded faster than chlorophyll *b* (cf. Brown *et al.,* 1977). Enzyme-mediated chlorophyll degradation could not be detected. In prolonged darkness, reduced destruction was observed, but aphotic pigment degradation in the hypolimnion was still significant (Leavitt and Carpenter, 1990a). Decay of carotenoids ranged from 0 to an observed maximum of 8.7% day^{-1} and chlorophylls from 0 to 12% day^{-1}. Preservation varies greatly among different carotenoids, and preservation is relatively high for secondary carotenoids (e.g., β-carotene and diatoxanthin) (Hurley and Armstrong, 1991). From a comparison of available information, it was concluded that photooxidation is a principal cause of chlorophyll destruction *in situ.*

4. *Conditions for Preservation: Oxidation, Acidity, and Temperature.* The processes of destruction of pigments and derivative formation are unrelated. Pheophytins and pheophorbides accumulated only in lysed cells, and concentrations of these two derivatives increased in the presence of dilute acids and oxygen. Derivative formation is strictly chemical and governed by oxygen concentration and pH. The rate of derivative formation decreases precipitously at pH values above neutrality. Although most inland waters have a pH above neutrality, pH tends to decrease in the hypolimnion of stratified waters near the sediments where these materials are interred. As would be anticipated, preservation is increased and optimized in sediments of meromictic lakes that are anoxic, dark, cold, and not resuspended into the water column during mixing events.

The low temperatures found in hypolimnetic waters favor preservation of pigments. Thus one would anticipate that the best conditions for preservation occur in the anoxic, cold, and relatively dark monimolimnia of meromictic lakes (cf. Table 24-1). In more typical lakes, however, the effects of circulation should be kept in mind. Pigments deposited in organic matter of surficial sediments may be resuspended during circulation of the water column and thereby reexposed to oxygenated, lighted conditions. Temperatures are relatively low in hypolimnia during circulation periods in the temperate regions and during winter. Hence, the conditions for chemically mediated formation of pigment derivatives may be fairly similar over much of the history of the lake development. As the basin fills in and becomes too shallow to permit stratification or becomes meromictic, however, conditions for preservation and diagenesis can change markedly (Daley *et al.,* 1977).

5. *Ingestion by Zooplankton and Microherbivores.* Ingestion of algae by herbivores, such as *Daphnia* and the chrysophycean flagellate *Ochromonas,* resulted in the destruction of chlorophyll and the formation of pheophytins and pheophorbides (Daley, 1973; Daley and Brown, 1973; Carpenter *et al.,* 1986; Leavitt and Carpenter, 1990b). Pigment sedimentation increased significantly with the mean size of cladocerans and omnivorous copepods, presumably related to concentration of algal detrital particles in fecal pellets that sediment relatively rapidly into aphotic, cooler,

and potentially anoxic strata of the hypolimnion. Fecal pellets that are disrupted during sedimentation to a very small size (<30 μm) or released by microzooplankton and small (<20–35 μm) are likely to be degraded significantly by photooxidation (Soohoo and Keifer, 1982a,b).

Therefore, it must be recognized that use of concentrations of different pigment constituents as paleolimnological indices requires critical evaluation. The methods have merit in interpreting past lacustrine events but should complement morphological and other reconstructions (e.g., Manny *et al.*, 1978; Bradbury *et al.*, 1981; Schmidt *et al.*, 1998) rather than serve as a sole paleolimnological approach.

III. SEDIMENTARY RECORD AND LAKE ONTOGENY

As one examines the historical development of lake ecosystems, the chemical and biotic records within the sediments provide historical records of change. The cumulative organic matter retained in the sediments follows a general sigmoid increase, somewhat analogous to primary ecological succession on land (Fig. 24-5). The initial gradual eutrophication implies intensified recycling of nutrients as increasingly anoxic hypolimnetic conditions occur and are associated with increasing accumulation of organic matter. The following pseudoequilibrium in the trophic state is approximately set and maintained by the intensity of nutrient loading and internal recycling. Major disturbances, such as human-induced eutrophication, accelerate nutrient loading by disturbance of the drainage basins. Associated with that disturbance is a marked increase (1–5 orders of magnitude) in erosion and deposition of inorganic matter (Binford *et al.*, 1983). Accelerated nutrient and nonnutrient inputs into lakes tend to have opposing effects on the pelagic productivity. In the next Chapter 25, we will see how sedimentation and paludification, terminal organic production processes that overwhelm pelagic production, can result from a shift to predominant accumulation of organic sediments associated with higher plants that are more resistant to rapid decomposition. Assuming that diagenesis within anoxic organic sediments is relatively constant over millennial time periods, the rates of pelagic organic accumulation respond to disturbances. The ecosystem exhibits appreciable resilience to minor disturbances that are relatively unsustained, from which recovery can be relatively complete (Fig. 24-5). Major disturbances, however, such as those associated with many cases of human eutrophication, result in major accelerations in organic accumulations and reductions in pelagic biotic diversity.

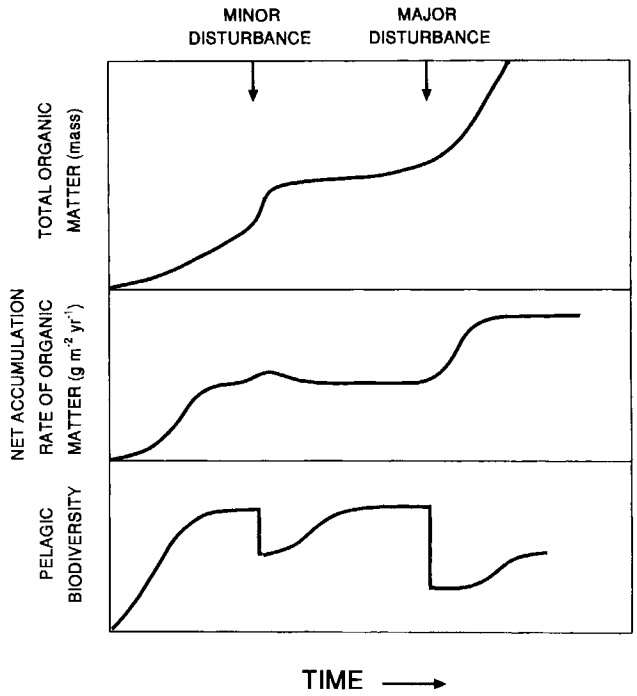

FIGURE 24-5 Trajectories inferred from sedimentary profiles for the cumulative total organic matter in lake sediments, net rate of accumulation of organic sediment, and biotic diversity within the pelagic zone. A major disturbance, as indicated by cultural eutrophication, that can result from major alteration of the drainage basin with accelerated inputs of nutrients is depicted as a continuation of earlier Holocene eutrophication. (Modified extensively from Binford *et al.*, 1983.)

IV. SUMMARY

1. Paleolimnology allows reconstruction of past lake communities, lake biogeochemistry, and lake development (ontogeny).
   a. Disturbance to a lake ecosystem often is derived from changes in the drainage basin. Materials within sediments include both remains of production from the drainage basin (erosional inputs, pollen, and other organic matter from vegetation), the atmosphere (metals, nutrients, organic compounds, and particles), and the biota within the lake.
   b. Changes in preserved lake biota (algae, zooplankton, certain benthic invertebrates, and macrophytes) can then be correlated with changes in external inputs and geochemical remnants.

c. Changes recorded in lake sediments prior to human interference and alterations to the drainage basins and compared to contemporary records allow interpretation of the responses of the lake communities to natural and human-induced environmental changes (e.g., eutrophication, acidification, and climate change).

2. As in all paleontological records, gaps occur and the record is incomplete. Variable inputs from the drainage basin, redistribution of sediments within the lake basin, and differential preservation of interred remains demand critical interpretation of the record. Nonetheless, the amount of information in the sediments is large. Accurate interpretation of the historical records depends, however, upon a good understanding of the biology and regulatory physicochemical processes of contemporary ecosystems.
3. Evaluations of past events in the historical development of a lake require accurate determinations of the rates of sedimentation over time. Several methods have been used to determine the age of sedimented materials.
   a. Radioactive carbon-14 is being continuously generated from atmospheric nitrogen by cosmic radiation. This ^{14}C is also in equilibrium with CO_2 in the water. During photosynthesis, a small amount of the radioactive ^{14}C is incorporated proportionally into new organic matter. When organic matter is interred in the sediments, the ^{14}C decays back to ^{14}N at a constant, known rate. Accurate radioassay of the amount of ^{14}C remaining in old organic matter thereby provides an estimate of its age. Numerous variables in the synthesis of ^{14}C and its incorporation into organic matter require careful time corrections in order to provide accurate dates. The ^{14}C dating technique permits age estimates over the past 40,000 years or somewhat longer.
   b. The age of recent sediments (to 150 years) can be estimated by the content of more short-lived isotopes (e.g., lead-210).
   c. As sediments are deposited in a lake, they retain remnant properties of magnetic declination and intensity in minerals such as hematite (F_2O_3). The remnant magnetism is caused by Earth's magnetic field, which oscillates about a mean direction with a constant frequency at a given location (approximately 2700 years).
   d. Some lake deposits are laid down in distinct laminae. When annual laminations are distinguishable, they are called *varves*. Under ideal depositional circumstances, as is found in certain meromictic lakes and in lakes where annually pulsed loading (e.g., glacially fed streams) occurs during thermal stratification, varves permit direct age determinations.
4. Paleolimnological analyses of many chemical and biological remains in sediments indicate that the old concept that most temperate lakes progress from oligotrophy to eutrophy is not universal, or is applicable only to very recent times.
   a. In glaciated regions, nutrient loading and productivity were commonly very low for long periods following the inception of lakes under the cold boreal conditions after glaciation. But the transition period from tundra to coniferous to deciduous forested conditions, with its ameliorated temperatures, is characterized by high lake productivity. Productivity often declined and stabilized as land surrounding lakes became impoverished of nutrients by leaching of the soils and as nutrients were retained by forested vegetation surrounding lakes.
   b. As the vegetation of the drainage basin was disturbed by human activities for agriculture and other purposes, nutrient loading commonly increased, resulting in enhanced productivity.
   c. In calcareous regions, drainage basin disturbances increased cation and carbonate loading to recipient lakes, which counteracted the effects of simultaneous loading of important nutrients (e.g., phosphorus) and thereby reduced productivity.
5. Sediments of lakes contain numerous organic compounds of biological origins produced either autochthonously or within the drainage basin and transported to the lake.
   a. Some compounds (e.g., lipid derivatives) are specifically characteristic not only of terrestrial plants but also of algae and bacteria. Analyses of the proportions of these compounds in sediments provide insight into the differences in the proportion of allochthonous versus autochthonous sources of the organic matter found in sediments.
   b. Degradation products of plant pigments are relatively stable after the death of the organisms that synthesized these compounds. Certain pigment degradation products preserve well in sediments, and their composition and remnant concentrations in sediments have been used to interpret past changes in algal and bacterial communities and productivity.
      i. Certain carotenoids are synthesized only by specific algal or bacterial groups. The stratigraphy and quantities of these compounds have permitted inference about the time of

invasion and development of certain algae, cyanobacteria, and other photosynthetic bacteria that do not leave morphologically recognizable fossils in the sediments.

ii. In conjunction with other chemical and biological characteristics, the quantitative stratigraphy of chlorophyllous and carotenoid degradation products in sediments has been used in a number of paleolimnological studies to corroborate past general productivity. Critical chromatographic discrimination of the many pigment degradation products is necessary for the accurate evaluation of those compounds that originated from autochthonous primary productivity. In many large lakes, evidence indicates that much of the remnant pigment products originated from autochthonous primary producers (pelagic and littoral).

6. Morphological remains of many plants and animals are fossilized in lake sediments. Because most lakes are young (<20,000 years since inception), if the contemporary physiology and ecology of the organisms are known, inferences can be made about past ecological conditions.
   a. Plant pollen and spores are commonly deposited into lakes in proportion to changes in the composition and quantity of parent plants in or surrounding lakes. Most pollen grains preserve well once they have settled into anoxic reducing sediments, and they can be identified, sometimes to species. Absolute pollen accumulation rates provide independent measures of each species in proportion to its density and past population dynamics.
      i. The stratigraphy of pollen and spores provides presumptive evidence of the chronology for vegetational changes in the drainage basin related to changes in temperature, rainfall, soil development, and disturbances caused by the activities of humans.
      ii. Pollen stratigraphy is used in all comprehensive studies to augment other paleolimnological analyses. Changes in the plant communities of the drainage basin markedly influence the nutrient loading characteristics and are reflected in subsequent chemical and biological indicators of lake productivity.
   b. Although the siliceous frustules of diatoms are the most common algal microfossils preserved in lake sediments, some other algae or algal parts (e.g., cysts or scales of chrysophytes or dinoflagellates) are also found. Because diatoms generally preserve well, can be identified to species from the frustules, and much is known of their physiological ecology, their stratigraphy has been studied extensively in conjunction with other paleolimnological parameters.
      i. Changes in diatom communities through the history of lake development have been related particularly to probable past changes in nutrient chemistry and salinity, and by inference to alterations in lake level and climate.
      ii. Changes in ratios of littoral-dwelling to planktonic diatoms have also been used to evaluate past changes in water levels and littoral development.
   c. Plant macrofossils (fruits, seeds, megaspores, and tissue fragments) are frequently found in sediments but are less abundant than are microfossils. Plant macrofossils assist in reconstruction of past changes in plant succession, water levels, water chemistry, and regional climate from known physiological and ecological characteristics of the plants.
   d. Nearly all animals of inland waters leave some identifiable remains fossilized in lake sediments. The most widely studied and abundant fossils are remains of Cladocera, ostracods, and midges, many of which can be identified to species from exoskeleton and mouth-part remnants.
      i. Study of past midge community structure has proven particularly useful in the reconstruction of the historical transitions of increased productivity and resulting depletion of oxygen from the hypolimnia of lakes in more productive stages.
      ii. Based upon known population dynamics and factors controlling community composition and species diversity, past cladoceran communities provide presumptive evidence for past environmental conditions, including food quantity and quality, competition, and selective predation. Ratios of past littoral versus planktonic cladocera can be useful in interpreting previous changes in lakewater levels and littoral development.

III. Summary

The successional development or ontogeny of inland aquatic ecosystems is governed by many interacting causal mechanisms that affect the rates of autotrophic productivity and utilization of that organic matter. Nearly all of the preceding discussion of this book has been directed to these regulating mechanisms and their integration. As we have seen, a number of complex factors influence productivity at all levels within inland waters. Those mechanisms control from the base by limitations of resources needed for production and from predation that limits growth and reproductive capacities.

Among the multitude of dynamic factors that regulate the productivity of individual ecosystems at any given time, a fundamental property prevails: The ecosystems are constantly changing, succeeding, and evolving, largely as a result of sedimentation. For example, lakes are formed, usually by catastrophic geological events, and proceed through a series of stages to eventual filling. Often lakes are obliterated as lakes per se and are incorporated into the terrestrial landscape. As we have seen, particularly in Chapter 24, the rate at which lakes fill varies greatly. Filling by inorganic materials is governed to a great extent by the basin morphometry, characteristics of the drainage basin, and climatic factors. Organic loading is influenced to a greater extent by factors regulating autotrophic productivity and the decomposition rates of the organic matter produced. Rivers also are influenced by sedimentation and are constantly maturing as the channels are eroded and aggraded, with appreciable migration and filling of the channels within flood plains.

Although the general ontogeny of lakes is from low to higher productivity, we have seen many cases (Chap. 24) in which past productivity was higher in the earlier developmental history of lakes than in subsequent periods. In very recent times, however, many lakes are experiencing accelerated productivity or *eutrophication*, often as a direct result of increased loading of nutrients (see particularly Chap. 13). The enhanced productivity is desired and is encouraged by certain human cultures to increase, despite very low conversion rates of energy, production of protein for consumption. In Western cultures, eutrophication is held less desirable, at least at the present time, because lakes are used primarily for water supply and recreational purposes, and these uses are more compatible with oligotrophic or mesotrophic characteristics.

Throughout the previous discussions, I have attempted to integrate the drainage basin, river metabolism, and littoral and wetland productivity into the

overall functions of aquatic ecosystem functions. In the late stages of lake ecosystem ontogeny, autochthonous productivity shifts from phytoplanktonic prevalence to total dominance by littoral components. In shallow lake basins, which predominate the Earth, and in lake systems in which sedimentation has reduced water depth sufficiently for littoral dominance, rates of lake ontogeny accelerate greatly. The ensuing brief discussion attempts to summarize and integrate the earlier treatments.

I. SUCCESSIONAL DEVELOPMENT OF AQUATIC ECOSYSTEMS

Succession is a concept developed over a century ago largely from phytosociology and plant ecology, including some plant communities of ponds. However, lakes have not been merged well into conceptual successional theory but have been organized under the concept of eutrophication (Rodhe, 1969; Likens, 1970).

A. River Ecosystems

Successional theory has been applied only moderately well to stream ecosystems (Fisher, 1990). ***Succession*** can be defined simply as changes that occur on a site or in a community after a disturbance. Usually the disturbance induces habitat change or causes substantial mortality. Primary succession occurs after a disturbance that is so intense that no trace of the previous community remains. Secondary succession from disturbances that are not as severe as to remove the entire habitat and organisms is more common.

Successional theory is difficult to apply in spatially heterogeneous, hierarchically organized ecosystems like streams. Although succession in streams has been studied at many scales from microdistributions to drainage basin levels, much attention has been directed to longitudinal patterns of functional succession under the river continuum concept discussed earlier (see Chaps. 8 and 22), which is likely a product of disturbance. Succession occurs almost totally as secondary succession in many streams. Streams are spatially heterogeneous. After a disturbance, rates of succession are modified by the extent of spatial heterogeneity, and as a result successional theory is difficult to apply. Succession is really a part of ecosystem stability (see Chap. 23, pp. 775–778), and there is not great support for its separate application to streams.

B. Lake Ecosystems

The biogeochemical context, with its quantitative flux approach, provides insight into the mechanisms controlling contemporary productivity. Aquatic ecosystems usually are not in steady state, except in a restricted, short-term sense. The differences among aquatic ecosystems, as is evident from comparative studies, are obviously related to an array of dynamic factors that change over time. Short-term changes, keyed to diurnal and seasonal fluctuations, are reasonably repetitious and can be accommodated within a longer-term steady state. The preceding summary of paleolimnology (Chap. 24), however, should make it clear that the long-term progression cannot be adequately viewed as a steady-state process.

Aquatic ecosystems change. Erosion is a dominant geomorphological feature in running water systems. Lotic metabolism changes with progressive physical and chemical changes that occur in the headwater regions. Geomorphology also is critical to the ontogeny of lake ecosystems. Geochemical inputs to lake basins, coupled with morphometric characteristics of the lake basin depression in the landscape and changes in both the morphology and drainage patterns, influence lake productivity.

A primary characteristic of this ontogeny is the process of sedimentation, which gradually alters river valleys and fills lake basins. Inorganic inputs to the sediments vary greatly with the parent materials of the surrounding catchment area. Sedimentation is generally quite slow, and most organic inputs are mineralized prior to and soon after initial sedimentation. The ratio of organic to inorganic deposition can shift markedly in response to changes in the nutrient incomes, drainage basin characteristics, and basin morphometry. A time is reached at which the rate of organic deposition exceeds the capacity for its decomposition. Sedimentation rates can increase very rapidly once such a combination of characteristics is reached and can result in an accelerated conversion of the lake basin toward a terrestrial or bog landscape. Although the precise mechanisms involved in this ontogeny are highly individualistic, certain similarities among lakes emerge.

Inputs of organic matter are crucial in determining ecosystem metabolism and ontogeny. The organic productivity of rivers and lakes is fundamentally heterotrophic and is based on utilization of both autotrophic productivity and imported organic matter. Both production and utilization of the organic matter are controlled to a great extent by regulating factors of inorganic and organic biogeochemical cycling.

The boundary of the lake per se can usually be delineated relatively easily by the shore line and the supralittoral area, but in many cases, it is much more diffuse. From a functional standpoint, both in terms of the pelagic region and of the entire lake, saturated

wetland and littoral areas that surround many lakes constitute a major source of inorganic and organic inputs that usually radically alter metabolic processes within the lake or stream and its ontogeny. Separation of these massive sources of organic matter from consideration of the metabolic processes that occur in the open-water "lake" is functionally incorrect. Similarly, one cannot ignore the sensitivity of the lake per se to differences in the types, quantities, and timing of allochthonous inputs of nutrients and organic materials.

Rivers and especially lakes cannot be treated as separate microcosms. While the importance of allochthonous inputs has long been known, especially from British work, there remains an erroneous, persistent tendency to treat the pelagic community as an isolated, nonintegrated component of the lake ecosystem. Dissolved organic matter is important in changing the trophic states of lakes by accelerating the cyclic regeneration of nutrients through bacterial metabolism, which both accelerates the decomposition of organic matter and increases the recycling and availability of inorganic nutrients required for photosynthesis.

Major causal pathways governing the eutrophicational ontogeny of lakes are based on interacting mechanisms, mainly nutrients and their availability, that regulate autotrophic metabolism. In many cases, the following discussion is applicable to certain lakes since their inception. In other cases, the pathways described are applicable only to recent times, such as since the recent disturbances by humans or those changes that could be anticipated with changes induced by human activities that affect the loading rates of nutrients and organic matter.

C. Increasing Eutrophication

Low rates of productivity of oligotrophic lakes are frequently determined by low inputs of inorganic nutrients from external sources. Morphometric characteristics of relatively large size and depth that yield high ratios of hypolimnion to epilimnion volume are commonly characteristic of oligotrophic lakes and affect nutrient cycling. The low production of organic matter, resultant low rates of decomposition, and oxidizing hypolimnetic conditions result in relatively low rates of nutrient release from the sediments in a cyclical causal system (Fig. 25-1). The importance of phosphorus and nitrogen limitations to maintenance of low productivity in a large percentage of lakes of the world was discussed in detail earlier (see particularly Chap. 13, pp. 279–286).

Oligotrophic conditions can be maintained by a combination of properties, including:

1. Low external loading of nutrients, particularly phosphorus and nitrogen
2. Geomorphic conditions of many oligotrophic lakes that often preclude the extensive

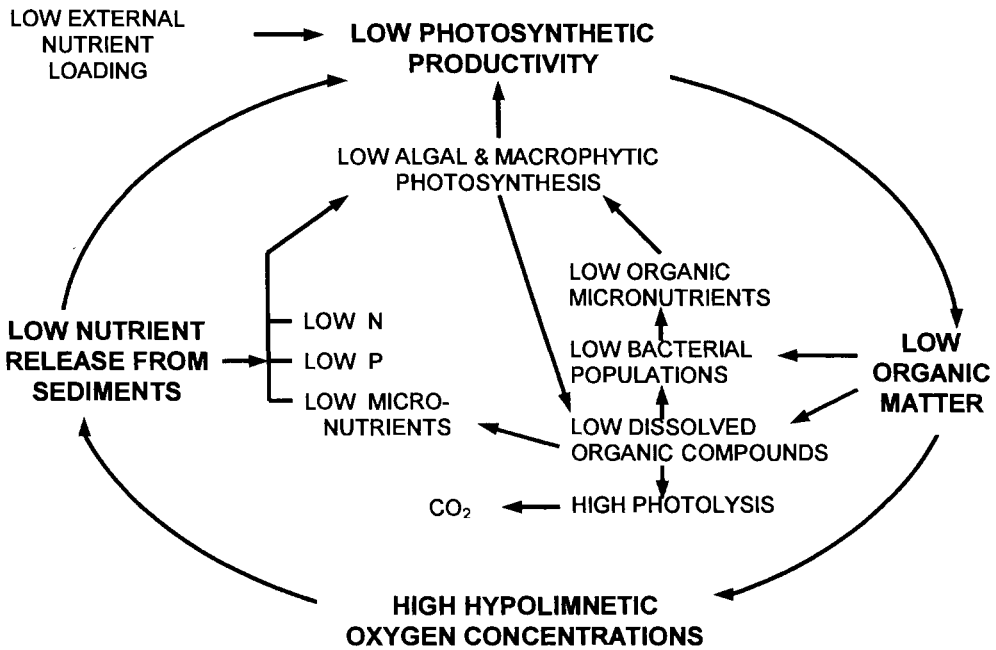

FIGURE 25-1 Major inorganic and organic interactions influencing the metabolism of phytoplankton of oligotrophic lakes. (Extensively modified from Wetzel and Allen, 1970.)

development of the highly productive wetland and littoral communities of higher plants and attached microflora.

3. The low production of phytoplankton, resulting from many interacting factors:
   a. Low loading of nutrients from external sources
   b. The larger size and depth of oligotrophic lakes and their deep mixed layers
   c. Carbon to phosphorus (C:P) ratios that tend to rise when more light is available, which encourages development of more efficient phytoplankton species; in turn, higher C:P ratios increase zooplankton grazing efficiencies and growth rates (Sterner *et al.*, 1998)
4. The decomposition of much of the organic matter production of the lake under oxic conditions and long sedimentation pathways; and the low organic loading to the sediments in both the littoral and pelagic regions
5. Low dissolved organic matter because of low autotrophic production, and the high transparency of the water, which increases the rates and depths of photolytic degradation of humic substances imported from the drainage basin
6. Low bacterial and protistan degradation of algae and other particulate organic matter because of limitations of nutrients and dissolved organic matter
7. Correspondingly limited synthesis of organic micronutrients, which are essential to most planktonic algae. Complexing of essential inorganic micronutrients, particularly iron, by dissolved organic compounds, by which solubility and physiological availability could be partially maintained under oxidizing conditions, would be less effective under oligotrophic conditions of low organic matter and high rates of degradation of available substrates.

The circumstances of the oligotrophic lakes of the Precambrian Shield region of Ontario, Canada, are ideal for demonstrating the importance of phosphorus limitation and rapid recovery from eutrophic conditions once the inputs are controlled. The Lake Washington and Swiss lake examples, discussed earlier (Chap. 24), are analogous examples of the success in the abatement of phytoplanktonic eutrophication that is possible once control by phosphorus-loading measures are instituted. In spite of the obvious caution that must be exercised in making generalizations about such complex and varied systems as lakes, it is important to emphasize once more that phosphorus abatement will not return all lakes to preenrichment conditions. As discussed in Chapter 13, recycling of phosphorus from internal stores in the sediments can sustain high rates of production for many years after influent loading has been reduced. The importance of phosphorus demand and supply for plant growth is such that its reduction in inputs to fresh waters is the first place to begin and likely to succeed in most cases.

Further, if phosphorus inputs to surface water are to be reduced most effectively, point sources should be eliminated as rapidly as possible. For example, the millions of tons of phosphate still being introduced into surface waters by synthetic detergents can be eliminated relatively easily by means of phosphate-free substitutes of equal cleaning efficacy. In addition, technologically available methods exist for nearly complete phosphate removal during wastewater treatment. The scientific basis for the importance of phosphate and nitrogen in eutrophication is so overwhelming that an international resolution was ratified at the 19th International Congress of Theoretical and Applied Limnology in 1974 (Wetzel, 1975a). This resolution emphasized the critical role of phosphorus in the rapid eutrophication of inland waters and the need to control the addition of this element to any inland water by any means available. In addition to full secondary, and in many cases tertiary, treatment of sewage, methods of control include (a) restrictions on the use of cleaning products that contain phosphates or other ecologically harmful substances, (b) removal of phosphate at sewage treatment facilities discharging effluents into such water, and (c) control of drainage from feedlots, agricultural areas, septic tanks, and other diffuse sources of nutrients. Control measures for nitrogen should also be considered in basins in which there is evidence that such controls are appropriate. Implementation of such control measures is socially complex, politically controversial, but technologically attainable and economically prudent.

Under eutrophic conditions, the loading rates of phosphorus and nitrogen, as well as of other nutrients of less acute demand, are relatively high (Fig. 25-2). As the rates of photosynthetic productivity increase during eutrophication, the cyclic interactions involving regeneration of inorganic nutrients and organic compounds increase in intensity. Planktonic productivity increases markedly per unit volume of water and results in increasing light-limited compression of the trophogenic zone. Reduction in depth of the trophogenic zone continues with intensification of eutrophication, largely as a result of biogenic turbidity of the phytoplankton. Eventually, planktonic populations impose self-shading to such an extent that further increases are not possible under natural conditions of

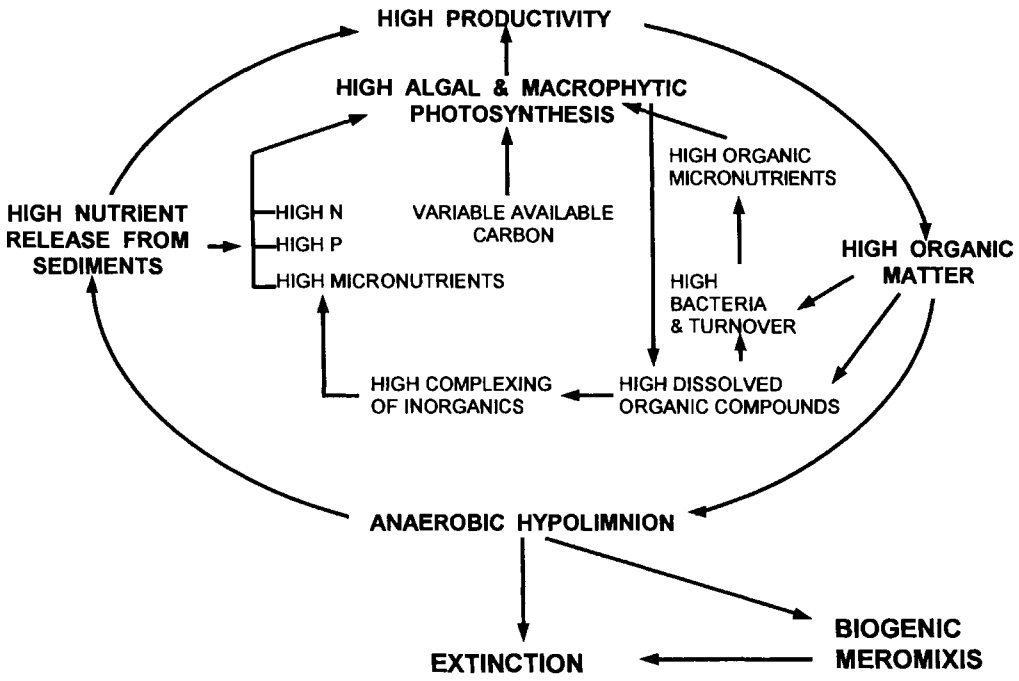

FIGURE 25-2 Major inorganic and organic interactions influencing the metabolism of phytoplankton of eutrophic lakes. (Extensively modified from Wetzel and Allen, 1970.)

incident solar irradiance (Fig. 25-3). The rate of planktonic production then reaches a plateau, with a gradual progression toward eventual extinction through sedimentation of organic matter that accrues faster than decomposition can remove it. Under certain conditions of lake basin morphometry, meteorology, and productivity, it is not rare for mesotrophic to eutrophic lakes of small surface area and moderate depth to undergo biogenically induced meromixis (Chap. 6). A reduction, usually temporary, in productivity can

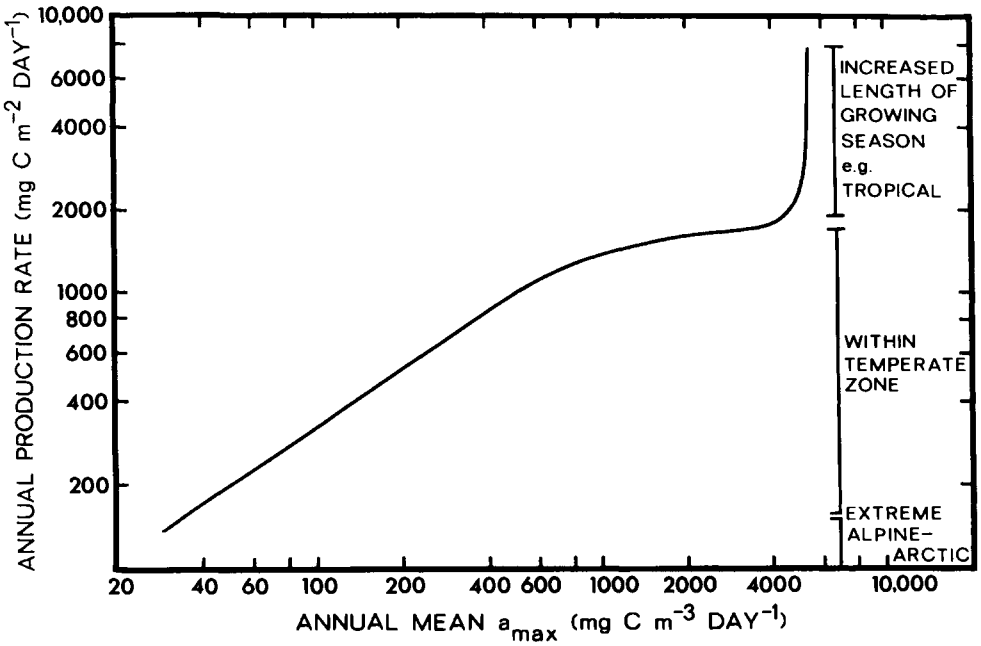

FIGURE 25-3 General relationship between the annual mean volumetric production rate at the depth of optimal growth and the annual mean areal production rates of phytoplankton. (After Wetzel, 1966a, and others.)

occur when redistribution of nutrient-rich hypolimnetic waters is prevented.

D. Food-Chain Length in Relation to Changing Ecosystem Productivity

A community food web or chain includes the feeding relations among the organisms found in a defined habitat. Organisms with similar groups of prey and similar predators have been combined into aggregated trophic species or levels. As indicated earlier (Chap. 8), the "top" species is a predator that has no higher predator, intermediate trophic species are those organisms that are both a predator and a prey, and a basal trophic species is a prey that has no prey (Cohen and Briand, 1984; Cohen and Luczak, 1992). A trophic link is any feeding relation between two trophic species in a community web. The mean number of trophic links between any two categories of trophic species (basal, intermediate, and top) is proportional to the geometric mean number of species in the categories joined.

The food chain is a sequence of trophic links in which energy starts at a species that eats no other species in the web and ends at a species that is eaten by no other species in the web (Briand and Cohen, 1987). The length of a food chain is the number of trophic links it comprises. The mean chain length of a food web is the arithmetic average of the lengths of all chains in the web. Many studies have correlated food-chain length of pelagic organisms to various environmental parameters. For example, based on energetic relationships, the food-chain length was hypothesized to be limited by inefficiencies of energy transmission by predation in relation to the minimal energy requirements of predators (Hutchinson, 1959). This hypothesis predicted that food-chain length should be longer in ecosystems with higher primary productivity of phytoplankton. Some support for this direct relationship has emerged (cf. Pimm, 1982; Jenkins *et al.*, 1992; Persson *et al.*, 1992; Vander Zanden *et al.*, 1999). However, examination of many community food webs of lakes indicated that the average and maximal lengths of food chains of higher organisms (phytoplankton to fish) are independent of primary productivity (Briand and Cohen, 1987; Hairston and Hairston, 1993; Post *et al.*, 2000). Food-chain length was found to be directly correlated with "ecosystem size" (lake volume) among many lakes, but not with resource (phytoplankton) availability.

As Hutchinson (1959) so effectively noted, ecosystem productivity certainly constrains food-chain length. It must be recalled, however, that higher trophic levels consume heterotrophically a very small percentage of the productivity, particularly in more productive pelagic waters (Wetzel, 1995; Chaps. 16 and 23 of this work). The microbial communities metabolize heterotrophically most of the organic matter in lake ecosystems. Hence, it is not surprising to find in the microbial loop with protists that resource availability and basal productivity was directly correlated with population-level responses and food-chain length (Kaunzinger and Morin, 1998). Except under conditions of very low productivity or in small, shallow lakes where the habitats are much more heterogeneous and varied than in the pelagic of large lakes, one would anticipate that productivity is quite adequate to support higher trophic levels and that other factors dominate in regulation of food-chain length. Greater volume among natural lakes, particularly in regions analyzed by Post *et al.* (2000), is often inversely correlated with primary productivity but can obviously be limited by many other factors quite unrelated to basin morphometry (cf. Chaps. 3 and 15).

The common separation and emphasis of the higher trophic of the pelagic of lakes from the rest of the lake ecosystem provides for interesting theoretical analyses. However, these studies are frequently naive because of their decoupling and false assumptions of relative independence from the energetic fluxes of the entire lake as an integrated ecosystem. It also should be recalled once again that many of these studies are based on feeding relationships during summer periods of maximum growth and productivity of higher trophic levels. These trophic relationships are totally different and many feeding couplings are completely absent during large portions of the annual cycle.

E. Differences among Hardwater Calcareous Lakes

The ontogeny of an oligotrophic lake toward eutrophic conditions can be altered markedly by natural inputs of carbonates and associated cations from surrounding sedimentary bedrock and glacial till. Calcareous hardwater lakes are common to large regions of the world, and in many regions of the temperate zone a quarter of the lakes contain very hard water with large amounts of precipitated $CaCO_3$. In such lakes, oligotrophic states are often maintained by high calcareous inputs sustained over long periods of time. In these waters, reduced productivity is maintained by decreased nutrient availability rather than the type of oligotrophy persistent in softwater lakes of low productivity, in which nutrient inputs to the systems are deficient and limiting at times.

Among both calcareous and noncalcareous lakes, early postglacial eutrophication generally proceeded rapidly as the regional climate ameliorated. Initial high rates of eutrophication were favored by inputs of

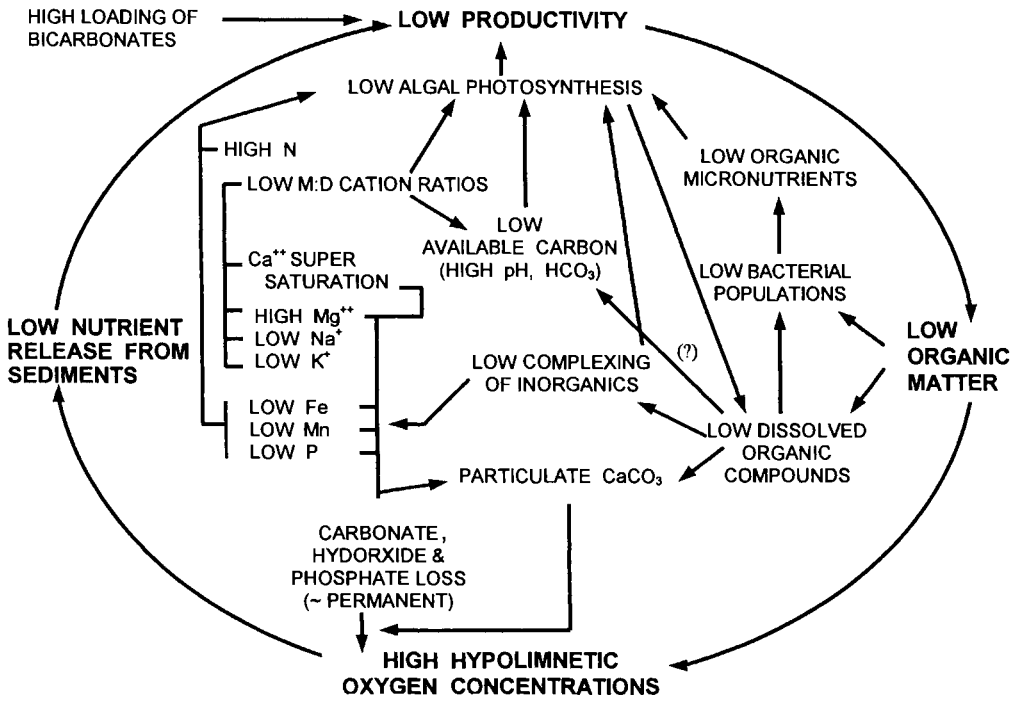

FIGURE 25-4 Major inorganic and organic interactions influencing the metabolism of producers in hardwater calcareous lakes. (Extensively modified from Wetzel, 1972.)

readily leached nutrients that entered lakes postglacially from adjacent terrestrial areas. In calcareous regions, however, high inputs of carbonates can be maintained over long periods of time (millennia). Under excessively buffered bicarbonate conditions, productivity is suppressed by an array of inorganic-organic interactions affecting the metabolism of the micro- and macroflora (Fig. 25-4). Major interactions have been discussed in earlier chapters and need be mentioned only briefly here for continuity.

Phosphate and essential inorganic micronutrients, particularly iron and manganese, form highly insoluble compounds and precipitate from the trophogenic zone of hardwater lakes (Wetzel, 1972). Combined nitrogen compounds tend to occur in high concentrations as a result of the relatively high inputs common in calcareous regions and the low rates of biotic utilization within the lake. In extremely calcareous lakes, it is not rare to find inorganic nitrogen concentrations that approach levels considered toxic (>10 mg NO_3 liter^{-1}) for human consumption. Calcium and magnesium concentrations can be exceedingly high; calcium is often in apparent supersaturation and approaches or exceeds 100 mg Ca^{++} liter^{-1}. Intensive biogenically induced decalcification is characteristic of these hard waters, during which massive amounts of particulate carbonate precipitate from the trophogenic zone. The sedimenting particulate and colloidal $CaCO_3$ adsorbs inorganic nutrients and certain labile and recalcitrant dissolved organic materials and effectively removes them from the trophogenic zone. The major monovalent cations, sodium and potassium, commonly occur at low concentrations. Low levels of sodium, an essential element of certain cyanobacteria, have been implicated as a contributory factor in reducing the growth of heterocystous cyanobacteria in calcareous lakes (Ward and Wetzel, 1975).

Although inorganic carbon concentrations occur at very high levels, the low availability of free CO_2 can reduce photosynthesis of certain plants under stagnated conditions when the pH is excessively high (see Chap. 11). Certain species of natural phytoplanktonic algae of calcareous lakes are capable of significantly (<10%) augmenting photosynthesis by photoheterotrophy of simple organic substrates and compounds produced extracellularly by aquatic macrophytes (Chap. 15).

The low photosynthetic productivity of calcareous lakes contributes to reduced inputs of dissolved organic compounds, such as lytic and extracellular losses from phytoplankton and macrovegetation. This situation is compounded by effective adsorptive losses of dissolved organic matter to monocarbonates as they precipitate. Bacterial rates of metabolism are low because of the low concentrations and turnover of easily decomposable organic compounds, which can lead further to

concomitant reduced synthesis of organic micronutrients. Reduced concentrations of certain organic micronutrients such as vitamin B_{12} have been shown to be contributory to reduced phytoplanktonic productivity in calcareous lakes; a portion can be metabolically inactivated by adsorption to $CaCO_3$. The more reactive organic substrates are either utilized rapidly by bacteria or are inactivated by adsorption to sedimenting $CaCO_3$. The loss of organic compounds reduces the complexation capacity of the water, so that certain inorganic nutrients cannot be maintained in solution. In addition, the selective removal of the more labile organic constituents leads to a relative accumulation of more recalcitrant dissolved organic matter. It is common to find very hard lakes with a stained coloration (brown) and high concentrations of dissolved humic materials; these compounds degrade slowly and may inhibit additional epilimnetic decalcification by interfering with the formation of $CaCO_3$ particles, thereby sustaining an oligotrophic condition. A portion of the dissolved organic matter is degraded to CO_2 by solar photolysis.

Factors that reduce the buffering capacity and carbonate reservoirs of calcareous lakes promote eutrophication in these ecosystems. Two obvious means of altering the major controlling aspects of calcareous inputs are reductions in or depletion of bicarbonate and cation sources in the drainage basin or increases in the loading of dissolved organic matter. At some point in this transition, the inhibitory effects of the calcareous state on nutrient availability are reduced and the stimulatory effects (both direct and indirect) of dissolved organic matter increase. At that point, eutrophication can proceed relatively rapidly. Morphometric changes that accompany eutrophication-induced increases in sedimentation rates and infilling also have significant effects on stratification patterns, hypolimnetic capacity of maintaining oxidizing conditions, and nutrient recycling. These changes accelerate as productivity increases and operate to further enhance eutrophication.

Where large areas of sedimentary rock have been glaciated, it is common to find former very calcareous lakes underlying bog lakes[1] or bogs (discussed in some detail further on). It is apparent that numerous marl lakes have shifted relatively rapidly, in the range of a millennium, from highly calcareous, alkaline conditions to a very acidic, organic-rich state, markedly depleted in divalent cations and bicarbonate. In partially closed basins of moderate to small size that have shifed to dominance of water inputs from precipitation rather than surface flows, the ontogeny of initially calcareous lakes can be altered at a rapid rate by the development of specialized littoral flora, particularly the mosses such as *Sphagnum*. These plants and associated encroaching vegetation function as particularly effective cationic sieves (Clymo, 1963, 1964). It is not uncommon to find small pioneering hummocks of *Sphagnum* growing in the wetland and back-littoral reaches of calcareous lakes directly on a thin organic deposit overlying sediments containing >50% of $CaCO_3$ (see, e.g., Glime *et al.*, 1982). The eulittoral of highly stained alkaline hardwater lakes is often interspersed with stretches of *Sphagnum* in dense mats. These alkaline bog lakes represent a transitional stage between certain calcareous lakes and true acidic *Sphagnum* bogs. The ionic exchange mechanisms of these mosses, accompanied by the simultaneous release of organic acids (e.g., polyuronic acids), are effective in reducing the cation influxes from surface sources. As the littoral sieving vegetation circumscribes the basin, the buffering capacity of the calcareous lake system is progressively reduced. The subsequent vegetative development then can proceed relatively rapidly, in a classical pattern of bog succession (discussed further next) via accelerated accumulation of organic matter under acidic, reducing conditions that does not favor rapid decomposition.

II. DYSTROPHY AND BOG ECOSYSTEMS

Early workers formulating relationships in studies of comparative regional limnology were acutely aware of the important differences among lakes in regard to the proportion of allochthonous and autochthonous organic matter.[2] ***Trophy*** of a lake refers to the rate at which organic matter is supplied by or to the lake per unit time.[3] Trophy, then, is an expression of the combined effects of organic matter supplied to the lake.

As has already been indicated (Chap. 23), under natural conditions, the relatively resistant humic substances of largely terrestrial plant origin represent the most common component of allochthonous organic

[1] Bog lakes have been variously described; they commonly refer to strongly basic alkaline lakes surrounded by an extensive acid-forming bog mat (see Welch, 1936).

[2] Birge and Juday (1927), for example, in their extensive studies on the origin and supplies of dissolved organic matter, differentiated between autotrophic lakes dominated by autotrophic inputs and allotrophic lakes that received a majority of their soluble organic matter from the drainage basin.

[3] A concise review of the development of the trophic concept is given by Rodhe (1969). A number of other terms have been used to indicate the direction of the state of trophy, for example, *eutrophication* in the broad sense of an increase in productivity (also *auxotrophication*; Thunmark, 1948; Lillieroth, 1950), which refers to an increase in trophic standard. The contradictory term *oligotrophication* (also *meiotrophication*; Quennerstedt, 1955) refers to a decrease in trophic standard.

matter. Lakes that receive large amounts of their organic matter supply from allochthonous sources commonly are heavily stained and have been referred to as "brown-water lakes." These lakes were termed ***dystrophic***, in reference to their high content of humic organic matter.

The productivity of most dystrophic lakes classically has been described as low. However, more detailed examinations indicate the contrary. Phytoplankton biomass (chlorophyll concentrations) is significantly higher in colored ("brown-water") lakes than in clear lakes. Phytoplanktonic primary productivity was higher in dystrophic lakes when expressed per volume of epilimnion (Jasser, 1997; Nürnberg and Shaw, 1998). Annual integral primary productivity expressed on an areal basis was somewhat smaller in colored lakes, probably as a result of shallower phototrophic depths in these lakes, than in clear lakes.[4] It must be emphasized further, however, that this moderate productivity criterion refers to the planktonic productivity and, as it was developed, ignored the littoral plant components of the lake system. As we shall see, in dystrophic lakes that develop bog flora, the littoral plants completely dominate the metabolism of these lake ecosystems as sources of dissolved and particulate organic matter and energy.

Annual integral productivity of the epilimnetic bacterioplankton was also found to be much higher (four times) in dystrophic lakes than in clear lakes (Nürnberg and Shaw, 1998; see also Satoh and Abe, 1987). Also in the hypolimnia of organically stained dystrophic lakes, hypolimnetic bacterial production is commonly higher than epilimnetic production, particularly in anoxic hypolimnia that are frequent in dystrophic lakes. Even though these DOC compounds are relatively recalcitrant, photolytic degradation certainly assists in enhanced availability for bacteria (see Chap. 23).

As a consequence of uncritical use of the terms associated with dystrophy, bogs, bog lakes, and dystrophic lakes have been loosely, and incorrectly, equated. Much of the unfortunate confusion emanates from inappropriate generalizations about ontogeny of lake systems from specific lake investigations. For example, the famous successional scheme put forth by Lindeman for Cedar Bog Lake, Minnesota, has been more than once uncritically proposed in general ecology texts as the universal situation. In this way, the erroneous concept that all lakes become bogs and then land may become widely accepted. Although some lakes do progress through this sequence, it is far from the rule. A large, heavily stained Finnish lake on a primary bedrock basin with no characteristic bog vegetation can be correctly termed dystrophic just as effectively as the *open pelagic water* of a quaking *Sphagnum* bog. *Trophy* refers to the rate of supply of organic matter, and *dystrophy* denotes a high loading of allochthonous organic matter (Fig. 24-5). Dystrophy is a subset of trophy (oligotrophy to eutrophy), rather than a parallel concept.

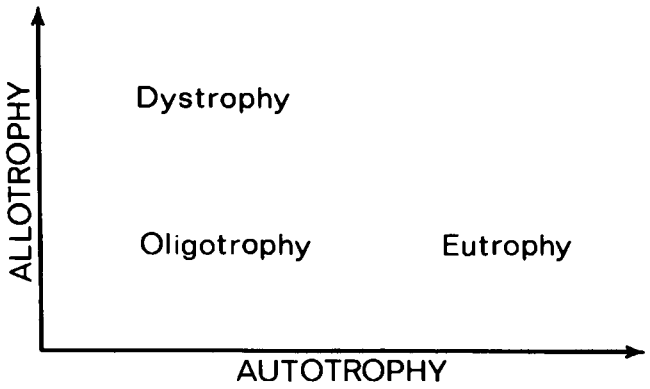

FIGURE 25-5 Classical trophic types of lakes based on the rate of supply of organic matter from autotrophic and allochthonous sources. In the original development of these concepts, only phytoplanktonic productivity was considered. (Modified from Rodhe, 1969.)

These examples emphasize an important point. As developed originally and as largely used today, the trophic concept refers to the pelagic-zone-planktonic portion of the lake ecosystem. The differentiation was between the rate of organic matter input to the system from autotrophic phytoplanktonic sources and from allochthonous sources of the catchment basin (allotrophy) (Fig. 25-5). The littoral flora and its often dominating supply of autochthonous organic matter to the system, was, and usually still is, ignored. Although conceptually it is easy to place the wetland and littoral productivity within such trophic schemes, there are few quantitative evaluations of its contribution. Sufficient information is available, however, to indicate that it cannot be ignored in most cases.

The photosynthetic rates of phytoplankton are moderate to high on a volumetric basis in highly stained open basins that receive copious quantities of dissolved organic matter from allochthonous, wetland, and littoral vegetation sources (Fig. 25-6). The abundance of dissolved humic materials in these systems is conducive to high bacterial metabolism, in part certainly stimulated by solar photolysis of the complex humic macromolecules (cf. Chap. 23). Nutrient regeneration rates are generally high under such conditions. Additionally, monovalent-to-divalent cation ratios tend

[4] High productivity of phytoplankton in heavily stained dystrophic lakes is known, especially in lowland areas of Scandinavia. Järnefelt (1925) called these lakes *mixotrophic*, but introduction of another term in this conceptual discussion is unnecessary and confusing.

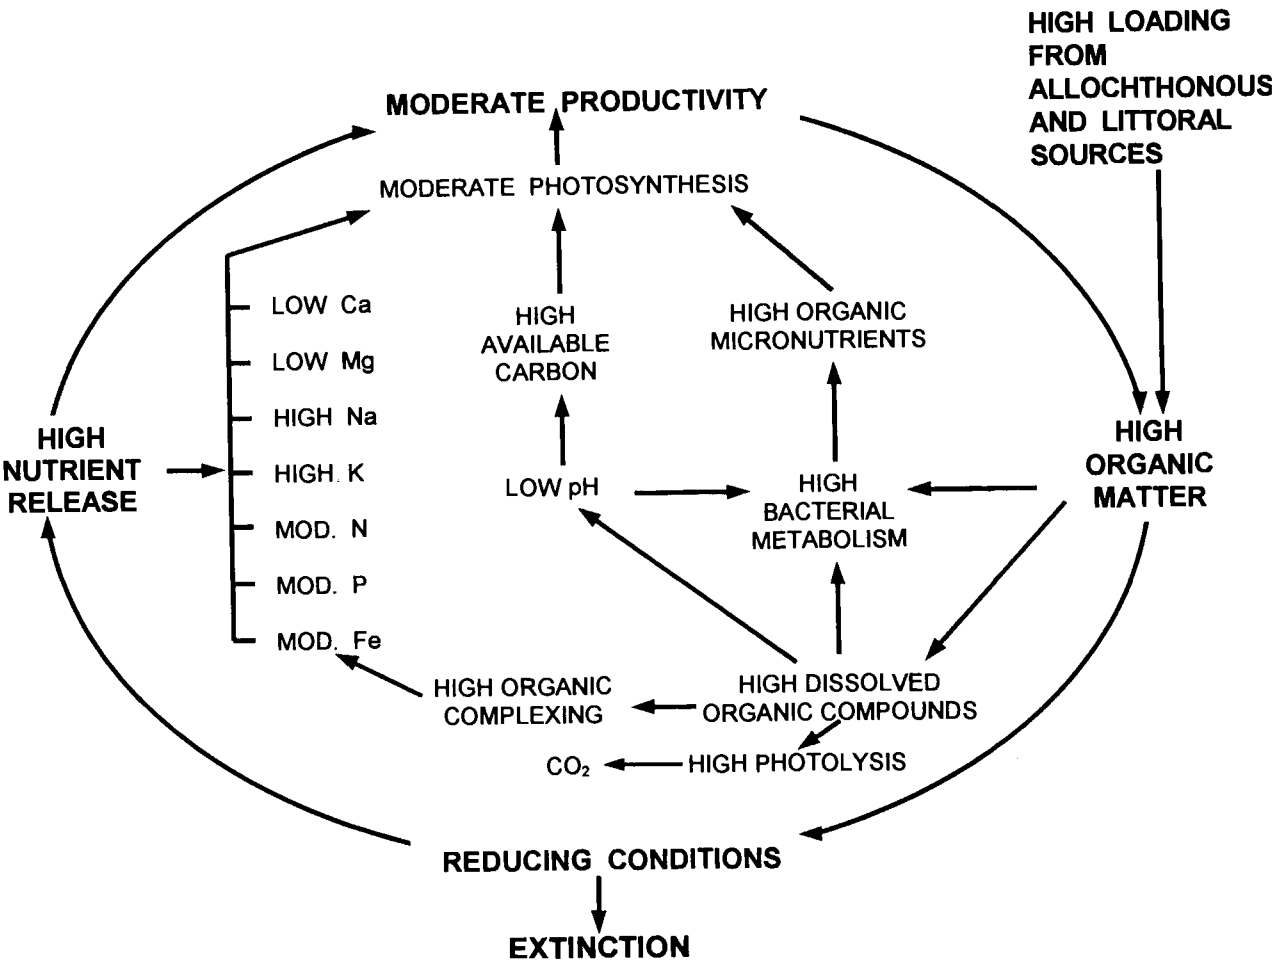

FIGURE 25-6 Dominant inorganic and organic interactions influencing the metabolism of phytoplankton in the pelagic waters of dystrophic and bog lakes. (Extensively modified from Wetzel and Allen, 1970.)

to be high because of low inputs from the drainage basin or because of effective cation exchange mechanisms of the littoral flora, particularly if dominated by bryophytes.

The relationships among the major causal mechanisms regulating the phytoplanktonic trophic states in the four main types of lakes may be further connected in an overall sequence of development (Fig. 25-7). This scheme of lake ontogeny emphasizes the importance of changes in functional relationships and environmental parameters that regulate algal, and to some extent, macrophytic productivity. The designated pathways of ontogeny (Fig. 25-7) can obviously vary greatly, depending upon the geomorphology of the specific ecosystem and the macroclimate of the area. The rate at which a lake proceeds to extinction via sedimentation is determined both by interactions that occur within the pelagic zone and by certain aspects of geomorphology of the drainage basin. Finally, as has been stressed repeatedly throughout this text, one must have an appreciation for the importance of littoral macrovegetation in the culmination of this sequence.

A. Littoral Development

Shallow water bodies, correctly termed *lakes* but often referred to in older literature as *ponds*, are usually characterized by an abundance of aquatic macrovegetation and associated microflora attached to all surfaces (see Chap. 20). It is not unusual for the vegetation to extend over the entire basin, provided the depth does not exceed plant tolerances, primarily for adequate light (cf. Chaps. 18 and 20). Shallow lakes include basins that were never preceded by a larger, deeper lake, as well as those basins that represent a terminal stage in the extinction of deeper lakes. From a hydrological viewpoint, the shallow water bodies can be separated into those that are permanent, containing

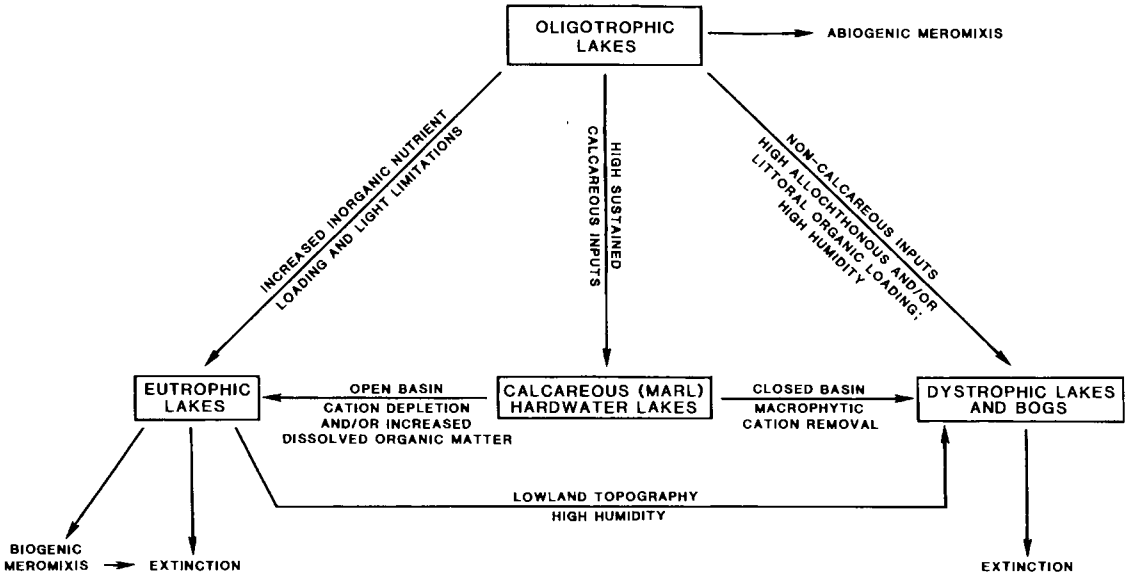

FIGURE 25-7 Potential ontogeny of the four main types of lakes. See text for discussion.

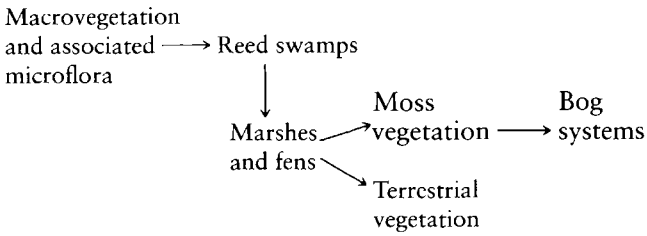

some water at all times of the year, and those that are temporary, in which the basin periodically becomes dry (Chap. 20). It is apparent that a nearly infinite variety of conditions lead to the development and persistence of small, shallow lakes in relation to seasonal and long-term climatic changes in the water budget. Outflow (surface and subsurface), evaporation, and retention, including water retained by large accumulations of organic matter of plant origin, counterbalance inflow and precipitation.

Excellent reviews and interpretation of the widely dispersed literature on peat-producing ecosystems or ***mires*** are given by Gorham (1957) and in the books by Kulczynski (1949), Moore and Bellamy (1974), Kivinen *et al.* (1979), Crum (1988), Gottlich (1990), and Feehan and O'Donovan (1996). The terminology and synonymy of this area of study are complex; only a brief résumé of major features of the systems is given here. It should be noted that *mire* is a collective term which includes both ***bog*** ("moss" in British literature) and ***fen***, differentiated according to water and nutrient sources, as well as by rather subtle floristic variations. "Mire" is equivalent to the Swedish ***myr*** and the German ***Moor***. All mires are in areas where the groundwater table is permanently at or near the surface of the ground. Mires are commonly separated into ***minerotrophic mires*** (fens) in which water and nutrients are supplied from ground water, surface sources, and atmospheric precipitation. The water of fens tends to be base-rich (pH > 5.5) and commonly supports herbaceous vegetation. In ***ombrotrophic mires*** (bogs), water-table recharge and nutrient inputs originate mainly from atmospheric precipitation. Water is of very low salinity and tends to be acidic (pH < 5.5). A ***carr*** refers to a mire or portion of a mire that is dominated by woody shrubs or trees among the herbaceous vegetation on a relatively stable peat mass (e.g., a fen carr could be dominated by trees, such as species of *Alnus*, *Fraxinus*, and *Betula*, with a dense understory of fen herbaceous plants). The terminology and characteristics of these gradients in peatlands and associated waters are discussed more extensively in Damman (1986), Bridgham *et al.* (1996), and particularly Wheeler and Proctor (2000).

The terminal stages of the transition from lake to terrestrial ecosystems are characterized by an accumulation of organic matter in excess of degradation. Partially decayed organic matter, mainly of plant origin and termed ***peat***, accumulates in aquatic ecosystems under a wide variety of conditions in all except the driest macroclimatic regions of the world. Mire ecosystems form (1) in basins or depressions (primary mire systems); (2) beyond the physical confines of the basin or depression (secondary), the peat itself acting as a reservoir and increasing the surface retention of water; and (3) above the physical limits of the ground water (tertiary), the peat functioning as a reservoir holding a volume of water by capillarity above the level of the main groundwater mass of the region (Moore and Bellamy, 1974). In addition, large quantities of trapped gases, particularly methane, occur in the deeper deposits of peat (Brown *et al.*, 1989). Entrapped gases could reduce the hydraulic conductivity in the lower layers of the peat by blocking the soil pore spaces, preventing fluid movement, and generating an elevated water table. This last mire system obtains much of its

water directly from precipitation and forms a slightly raised (perched) water table.

Although dense stands of small mosses and herbs are the dominant components of contemporary active peat formations over immense areas of subarctic and temperate regions, shallow depressions of lake systems commonly gain excessive organic matter deposits through submersed, floating-leaved, and emergent macrophytes. The successional sequence may or may not terminate in moss and associated bog vegetation. Many highly fertile eutrophic lakes develop increasing amounts of emergent littoral vegetation (Fig. 19-21), to the point at which organic matter accumulation increases the level of flora and sediments above the water table, which allows terrestrial vegetation to encroach. A common successional pattern associated with the ontogeny of shallow basins follows along the pathway of excessive macrophytic and sessile algal production:

Reed swamps are characterized by closing vegetation of the littoral, often polycorm, tall graminoid emergent plants—for example, *Phragmites, Cyperus papyrus, Scirpus*, and tall *Carex* species—with only

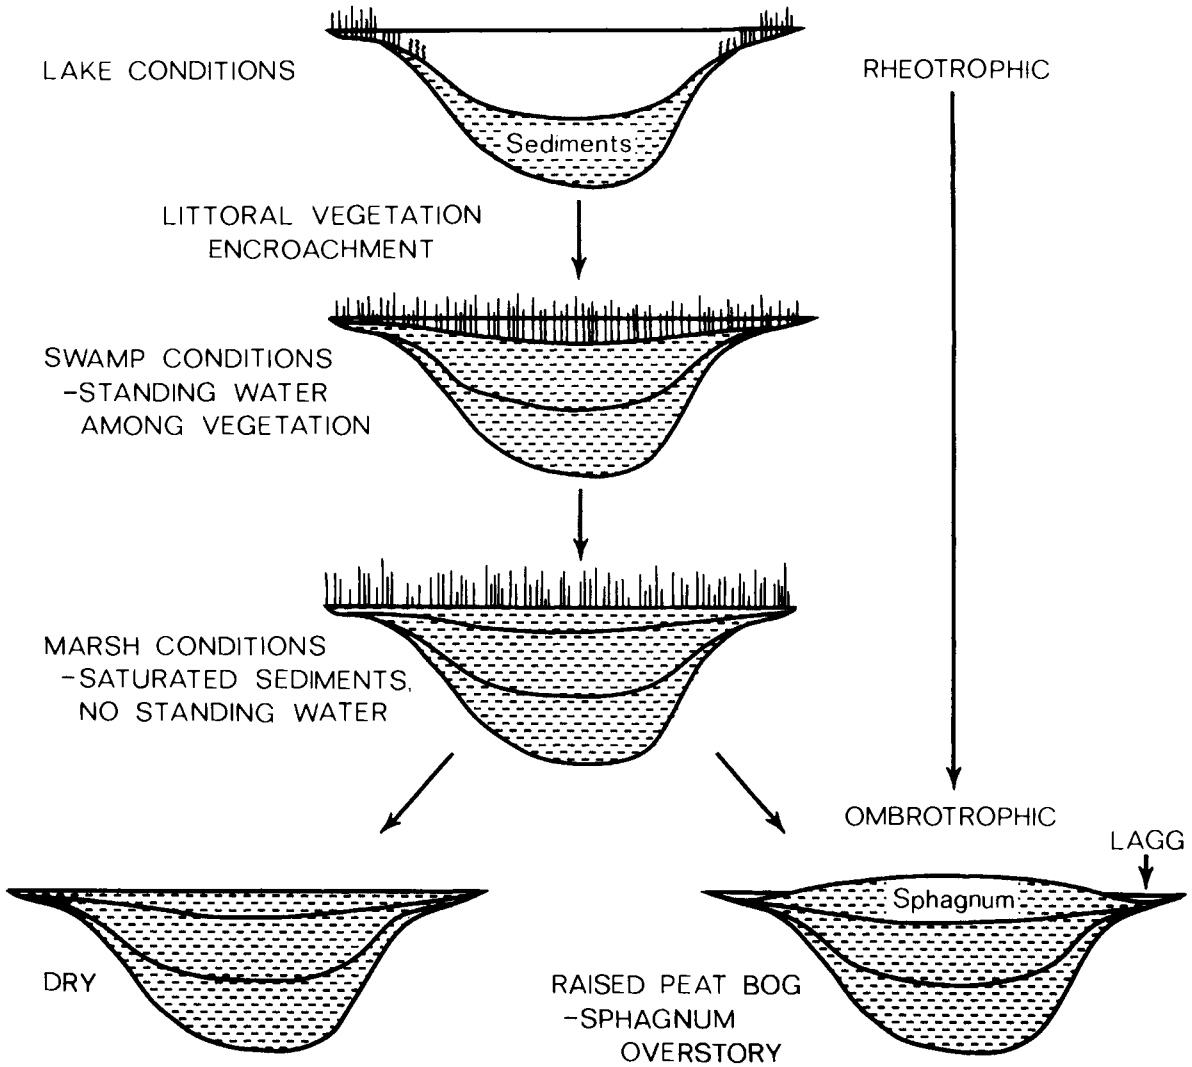

FIGURE 25-8 Frequently observed ontogeny of shallow lake systems through swamp and marsh stages to terrestrial conditions or to raised peat bogs. See text for discussion.

occasional mixtures of submersed and floating-leaved macrophytes. Usually macrophyte species diversity is low, and two herbaceous layers commonly dominate within the main vegetative structure. The understory can contain main species of bryophytes and algae. As organic accumulations increase with gradual displacement of the standing water, the water-logged peat habitat often is characterized by moderate-sized graminoid vegetation and small herbs in two or three layers. This vegetation is referred to as *marsh* or *fen* in areas of slightly flowing surficial water, or *bogs* in areas of subsurface seepage drainage. The distinction between the terms *marsh* and *fen* is largely made on the basis of phytosociological differences in floristic associations. As marshes and fens "dry" and depositions of organic matter exceed the mean water table, very tall terrestrial dicotyledonous vegetation increasingly colonizes and develops over the basin and displaces the emergent aquatic macrophytes. In nutrient-poor areas that are humid and receive abundant rainfall, marshes and fens may possess well-developed bryophyte floras. In many instances, mosses (especially species of *Sphagnum*) dominate the system and can lead to the formation of bogs (e.g., Glime *et al.*, 1982).

Early distinctions of various bog systems and types were made mostly on the basis of the primary, secondary, and tertiary stages of mire development just discussed in relation to water sources and floristic differences. Classical hydrosere succession hypothesized that infilling of a shallow lake by organic sediments produces a sequence of vegetation communities beginning with a marsh community of aquatic plants such as sedges, often followed by a fen or bog community composed mainly of *Sphagnum* mosses, sedges, and ericaceous shrubs, and culminating in a mature upland or mesic "climax" forest (Fig. 25-8) (reviewed in Klinger, 1996). Succession to fens and terrestrialization can proceed as set forth in this model. The ontogeny of mire systems is generally interpreted with respect to a combination of hydrological, phytosociological, and chemical processes.

A sequence under ideal geomorphological and hydrological conditions illustrating common stages in the succession of mire systems in shallow surface depressions is portrayed in Figure 25-9 (Moore and Bellamy, 1974, after Kulczynski). Water supply to the model lake system of Figure 25-9 consists of direct rainfall, runoff, and seepage from the immediate catchment of the lake basin, and a continuous flow of ground water that enters by an inflow stream of sufficient volume to affect the whole lake. The depth of the open water decreases continually because of the sedimentation of organic matter. As the basin progressively fills, the littoral vegetation simultaneously advances toward the center of the

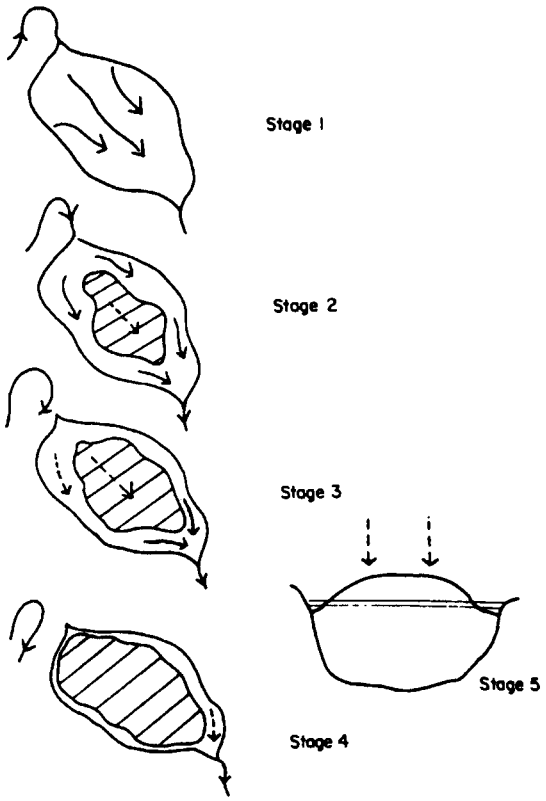

FIGURE 25-9 Idealized successional stages in mire systems from a small, shallow drainage lake (1), through a seepage system (2, 3), to a raised bog deriving most of its water supply from precipitation directly on its surface (4, 5). Hatched area = peat accumulation. (From Moore, P. D., and Bellamy, D. J.: *Peatlands*. London, Paul Elek Scientific Books Ltd., 1974.)

lake basin. Eventually, the entire area is covered with what is loosely referred to as ***swamp*** conditions, with standing water occurring among the vegetation. Production of littoral vegetation increases because of the high productivity of emergent macrophytes, and sediments eventually reach the surface of the original lake. This stage can be referred to as a ***marsh***, for the sediments are continually saturated but there is little, if any, standing water among the vegetation. Under these conditions, decomposition proceeds rapidly. However, for a number of reasons (discussed in detail in Chap. 21 and summarized in Fig. 25-10), inputs of relatively recalcitrant organic matter from the emergent macrophytes occur even more rapidly. The mean pH decreases substantially, and concentrations of dissolved humic materials in the water increase. Changes in the dominant vegetation also occur, and acidophilic flora (especially sedges and grasses) becomes more abundant.

When these mire systems initially develop in a shallow drainage lake (Fig. 25-9), the system is under the influence of continuously or intermittently flowing

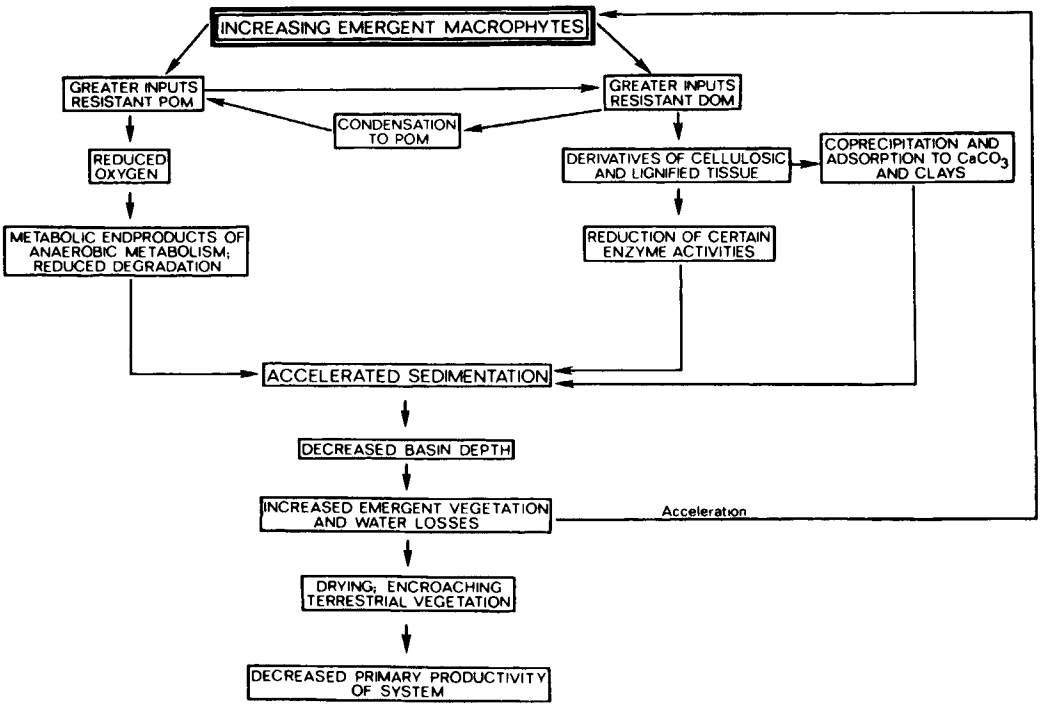

FIGURE 25-10 Relationships of increased loading of relatively resistant organic matter from dominating emergent littoral and wetland flora to controls of decomposition rates, acceleration of emergent macrophyte development, and the ontogeny of lake systems. POM and DOM = particulate and dissolved organic matter, respectively. (From Wetzel, 1979.)

ground water. The ionic composition of the water of these "rheophilous mires"[5] is dominated by calcium and bicarbonate. Allochthonous organic matter inputs are high and result in accrual of peat within the central portion of the basin (Stage 2). In some cases, this peat is sufficiently buoyant to float as a mat. The main flow of water tends to be channelized to peripheral areas. In the third transitional stage of mire development,[6] continued accrual of peat deposits diverts inflow from the basin. Water supply is derived largely from the immediate catchment of the mire and from direct precipitation on the surface. Ionic composition usually is dominated by calcium and sulphate. Further accrual of peat results in large areas of the mire surface that are not affected directly by moving water (Stage 4), but are inundated periodically when the water level rises during heavy rainfall.

Ombrogenous or ombrophilous (ombro = rain) mires[7] (Stage 5) are no longer subject to the influence of flowing ground water. Nearly all of the water, which is dominated by sulphate and hydrogen ions, is received from direct rainfall. The surface of the mire system is too high to be materially influenced by fluctuations in the level of ground water. The change in ionic composition of water from dominance by calcium and bicarbonate to that of sulphate and hydrogen ions is a conspicuous feature characterizing these mire systems (Fig. 25-11). The loss of ions from surface water supplies results in very low salinities and greatly reduced buffering capacity. Under these conditions, relatively small additions of acids can result in a considerable reduction in pH.

The origin of acidity and control of cation exchanges of mire systems result from a combination of factors. The increase in acidity and reduction of cations is particularly marked in communities dominated by the mosses of the genus *Sphagnum*. Water surrounding *Sphagnum*, a dominant genus of mosses over immense areas of the temperate, boreal, and subarctic regions of the world (see e.g., Sjörs, 1961), has a pH usually below 4.5 and sometimes below 3.0. Much of the acidity of the aquatic environment surrounding *Sphagnum* can be attributed to cation exchange (Anschütz and Gessner, 1954; Clymo, 1963, 1967; Brehm, 1970; Glime *et al.*, 1982; and others). *Sphagnum* and other mosses behave as cation exchangers even when dead because of their high concentrations (up to 30% of the plant's dry weight) of polymerized unesterified

[5] Synonymous with terms "low moor" and *Niedermoore*.
[6] *Ubergangsmoore* of older German literature.
[7] Termed "high moors" or *Hochmoore* in early works.

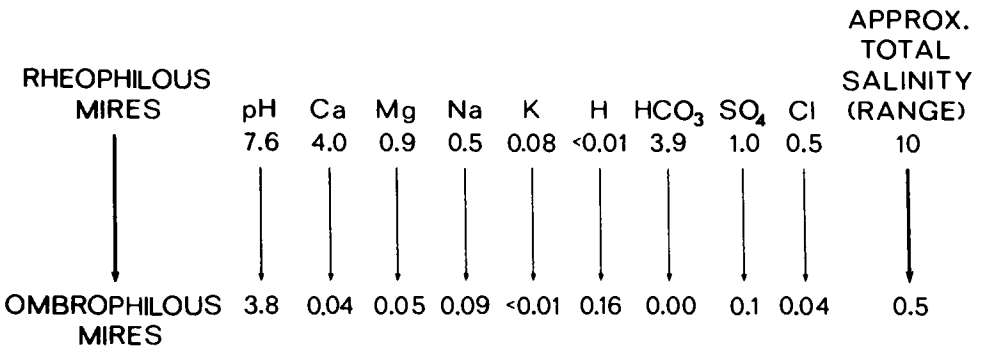

FIGURE 25-11 General shifts in ionic composition (milliequivalents liter^{-1}) of the water in the transition from rheophilous to ombrophilous mire systems of Western European mires. (From average values of Bellamy and of Sjörs given in Moore and Bellamy, 1974.)

uronic acids.[8] Although small amounts of free organic acids are released from *Sphagnum*, evidence indicates that most of the acidity of *Sphagnum*-dominated mire systems originates from the release of carboxyl-associated H^+ ions by freshly produced plant growth. The hydrogen ions are exchanged for nutritionally important cations that occur in rain or ground water. Some of the acidity of bog pools may be derived from H^+ ions released during the metabolic activities of anaerobic sulfur-metabolizing bacteria (Clymo, 1965, Gorham, 1966), but this source of acidity is clearly minor.

B. Bogs and Quaking Bogs

Littoral vegetation as the dominant source of organic matter produced in excess of decomposition is clearly critical in the senescence of a lake. Bogs are acidic, dystrophic aquatic ecosystems that possess an exceptionally characteristic littoral flora. Bogs do not represent an ontogenetic stage through which all lakes must pass in their route to extinction. The development of a bog system requires climatic conditions of abundant precipitation and relatively high humidity over much of the annual cycle. The littoral vegetation of bogs completely dominates key characteristics of the system: acidic pH, heavy staining resulting from the presence of large amounts of dissolved and colloidal humic materials, and low concentrations of nutritionally important cations.

Commonly, the transition of a small lake to a bog and a terrestrial ecosystem occurs sequentially, as depicted in Figure 25-12. A *Sphagnum* bog climax model of hydrosere succession proceeds from two directions from the margin of a lake or a pond: (a) inward toward the lake or pond center following the classical hydrosere succession (i.e., terrestrialization), and (b) in the other direction outward from the margin into the surrounding forests involving the successional conversion of upland forest to bog (i.e., paludification—swamping or inundation that results in saturated hydrosoils, which retards the decomposition of organic matter) (Godwin, 1956; Klinger, 1996). Water levels of the original water body increase in height because of impeded drainage from peat accumulation (Heinselman, 1963) and the capillarity of the moss vegetation. In advanced stages of succession, the ombrotrophic bogs develop perched water tables that are decoupled from the groundwater table.

The formation of a bog depends greatly on the prevailing climate. In moderately dry regions, the transition is from marsh conditions to terrestrial vegetation, without the characteristic development of mosses. Over much of the temperate zone, however, conditions are sufficiently moist to encourage the colonization and eventual dominance of *Sphagnum* and other mosses among the often predominantly sedge flora. Through a succession of mosses, especially *Sphagnum* species, cations decrease and acidity increases, which effectively decreases rates of decomposition (Chap. 21) and accelerates net accumulation of organic matter. The accumulation of particulate organic matter in the understory, continued growth of plants at the surface, and excellent capillarity of the dead and living mass of mosses raise the water level within the mat above the original level of the lake. In this way, the vegetative mat can develop slightly (usually <50 cm) above the water table; hence, the term *raised bog*.[9]

[8] Similar to sugars, but the sixth carbon is part of a carboxyl group. These long-chain molecules may be mixed polymers containing both sugars and uronic acids.

[9] Raised bogs occur in depressions, often in former lake basins, where losses of water from runoff are not as great as in more upland areas. In areas of high rainfall (>130 cm yr^{-1}) and low evaporation, bog vegetation can extend onto low-lying landscapes that have slopes of >15°, forming ***blanket bogs***. Blanket bogs cover large regions, notably in northern Great Britain, western Norway, and boreal continental areas in general (Sjörs, 1961).

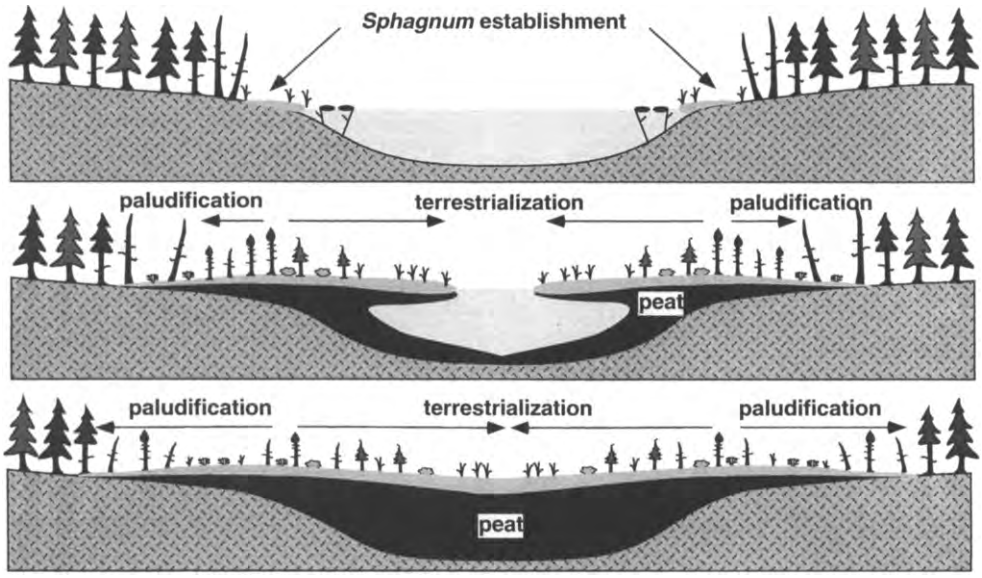

FIGURE 25-12 Bog climax model of succession whereby development of climax bog communities occurs via both terrestrialization and paludification beginning at the margins of a water body. Key stages in the succession involve (*upper*) establishment of peat-forming (e.g., *Sphagnum*) mosses along shore lines; (*middle*) peat accumulation via both terrestrialization and paludification, resulting in slight impoundment and a rise in water levels; and (*lower*) continued terrestrialization and paludification, resulting in the formation of an ombrotrophic bog. (From Klinger, L. F. 1996, reproduced by permission of the Regents of the University of Colorado. The myth of the classic hydosere model of bog succession. Arctic Alpine Res, 28:1–9.)

Moatlike areas of shallow water characteristically surround the central mat of peat; these areas, which are called *lagg zones*, are the remnants of flowing ground water whose path has been diverted around the central peat mat (cf. Fig. 25-13). Organic matter accumulates more slowly in the lagg zones than it does in the raised portions of the bog because of greater movements of water and better oxidizing conditions. Vegetation of the lagg zone is commonly dominated by small graminoid species, bryophytes, and foliaceous liverworts.

A dominant feature during the succession of lakes to bogs is a shift in the origin of nutrients. Initially, most of the nutrients are derived from soil in the drainage basin; in later successional stages, most of the nutrients enter the bog ecosystem via atmospheric precipitation and particulate fallout. In mire systems in general, the terms ***rheotrophic*** and ***ombrotrophic*** have been introduced[10] to designate systems whose nutrients are derived predominantly from surface water/ground water or from atmospheric sources, respectively. These two terms emphasize the interplay of geomorphological, chemical, climatic, and biotic factors that are involved in the succession of wetlands and of bogs. In regions where the ionic composition of rainfall is strongly influenced by oceanic contributions (cf. Chap. 10), such as in western Britain and much of Ireland, ombrotrophic nutrition is only slightly less effective than weak rheotrophic nutrition, and little difference in vegetation results.

Ombrotrophic bogs occur in cool temperate regions (45–65° lat.) with annual precipitation exceeding evaporation and a summer precipitation deficit <100–150 mm (Proctor, 1995). Raised bogs occupy flat sites (filled lake basins, flood plains, and coastal flats), whereas ombrotrophic bogs growing on sloped land (*blanket bogs*) occur only where the summer precipitation deficit is ca. <25 mm. Strong-acid anions in equivalents are less than the total cations, and this "anion deficit" is made up by organic anions of the dissolved organic compounds. Bog plants typically grow slowly and are adapted to low nutrient supply.

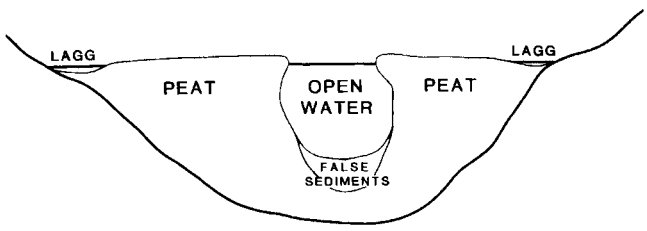

FIGURE 25-13 An idealized quaking *Sphagnum* bog in which the mat encroachment toward the center of the basin overlies littoral peat accumulations and much of the open water.

[10] Originally proposed as "minerotrophic" and "ombrotrophic" by DuRietz (Sjörs, 1961). A detailed discussion of the interrelationships and terminology is given by Moore and Bellamy (1974).

Nitrogen is commonly limiting in unpolluted areas, and phosphorus is limiting in regions of high atmospheric nitrogen deposition.

Quaking bogs represent a particular development of bogs within a relatively deep lake basin of small surface area. The development of *Sphagnum* mosses occurs early in the succession of littoral flora and in geological context leads to a very rapid accumulation of organic matter in the littoral areas (Figs. 25-12 and 25-13). In more advanced conditions, the littoral vegetation encroaches more rapidly on the open water than deposition of peat deposits occurs beneath it. This growth results in a thick mat (several meters) that floats above the open water and sediments consisting of loosely aggregated, flocculant organic matter. Growth proceeds all along the periphery toward the lake center, and eventually covers the entire surface.

A marked feature of quaking bogs is the concentric zonation of plant communities. *Sphagnum* is most often one of several pioneering mosses and dominates the floating mat formation closest to the center of the lake. Within the open water of the bog, certain submersed angiosperms (e.g., *Potamogeton* and *Utricularia* spp.) and floating-leaved macrophytes (e.g., *Nuphar* and *Nymphaea*) may be abundant. Lakeward portions of the mat may contain sedges (especially *Carex* spp.) and low shrubs such as leather leaf (*Chamaedaphne*) and blueberry (*Vaccinium*). Farther landward, tall shrubs and, finally, bog trees, such as black spruce and tamarack (*Larex*), are common (Gates, 1942).

The older portions of the mat are grounded firmly in the basin by underlying deposits of peat. The floating mat, growing considerably above the level of water-saturated flocculent organic matter, often is attached only by the vegetative mass and can be displaced by the added weight of a person and "quake." The sensation is that of walking on an immense floating, saturated sponge. The sedimentation of much particulate, littorally derived organic matter in the open water areas, results in loosely aggregated, flocculent sediment that is not compacted sufficiently to support small weights (e.g., an anchor), often for many meters; hence, the term *false bottom* or *false sediments* (Fig. 25-13).

Quantitative information on the productivity and population dynamics of biota of the pelagic and profundal regions of bog lakes and quaking bogs is extremely sparse. Much more knowledge exists on qualitative aspects simply because of the extremely diverse and interesting biota that are adapted to the extreme conditions of bogs. The microflora of the plankton and of small pools among hummocks of *Sphagnum* and larger plants are characterized by a great diversity of algal species, although few are ubiquitous. Most abundant are desmids, often represented by several hundred species. Species of cyanobacteria, chrysomonads, dinophyceans, and diatoms are adapted to bog conditions but seldom are found in abundance. The microfauna is dominated by testaceous rhizopod protozoans and other protists and rotifers; very few cladoceran and copepod zooplankters are tolerant of the bog milieu.

Larger animals have not adapted well to the extreme acidity and low salinity of bog waters. Species diversity of larger animals is low and entire groups are lacking or poorly represented. For example, in acidic, quaking *Sphagnum* bogs, sponges, coelenterates, ostracods, hydracarnid mites, oligochaetes, Ephemeroptera, Malacostraca, mollusks, nematodes, flatworms, and fish are completely absent or very poorly represented.

The genesis and ontogeny of bog systems can be viewed as a transitional succession of lake basins of greatly differing geomorphology to wetlands in which organic matter of macrophytic vegetation accumulates in excess of complete degradation. The causal processes regulating productivity can be effectively viewed from a short-term biogeochemical standpoint as operating in a reasonably steady-state system. However, the very nature of excessive accumulation of organic matter, the successional pathways of which are profoundly influenced by climatic and hydrological factors, indicates that the systems are not balanced even over very brief geological time periods.

III. SUMMARY

1. The interacting mechanisms regulating autotrophic productivity follow several pathways of development (ontogeny) as lake basins undergo succession and are ultimately obliterated as aquatic ecosystems and transformed into terrestrial ecosystems. Many rate-regulating mechanisms are influenced by the general transition from a dominance of allochthonous loading of nutrients and organic matter to accelerated loading of organic matter from littoral and wetland productivity.
   a. In the early stages of lake ontogeny, particularly among lakes formed by glaciation, autochthonous and allochthonous productivity is severely limited by climatic conditions, especially cold temperatures.
   b. In the intermediate stages of ontogeny, autochthonous autotrophy by phytoplanktonic production is supplemented with some contributions by littoral production.
   c. In the later and terminal stages, however, a rapidly accelerating shift occurs to a total dominance of productivity by littoral and wetland components.

   d. The planktonic-dominated stages of lake development are relatively lengthy; during these stages, organic sedimentation and deposition are nearly balanced by decomposition.
   e. In shallow basins and in lakes in which gradual sedimentation has reduced the depth sufficiently, massive production by littoral plants and wetland *emergent* macrophytes dominates inputs of photosynthetically accrued organic matter.
      i. The increasing contribution of derivatives of lignified and cellulosic tissues results in reduced rates of, and less complete, decomposition, and
      ii. Leads to accelerated rates of sedimentation and favors conditions conducive to enhanced emergent macrophyte development in a cyclically reinforcing process (cf. Fig. 25-10).
2. Increased inorganic nutrient loading, particularly of phosphorus and combined nitrogen, is fundamental to initial eutrophication and to maintenance of high sustained productivity by the phytoplankton community.
   a. Low rates of productivity in oligotrophic lakes are maintained to a large extent by low inputs of inorganic nutrients from external sources. Low production of organic matter, concomitant low rates of decomposition, and oxidizing hypolimnetic conditions result in low rates of nutrient release from the sediments in a cyclical causal system (Fig. 25-1). Dissolved organic compounds from both internal and external sources are usually low, in part as a result of solar photolysis, which results in limited availability of organic micronutrients and reduced complexing capability for essential inorganic micronutrients.
   b. Under eutrophic conditions, the loading rates of inorganic nutrients, especially of phosphorus and combined nitrogen, are relatively high (Fig. 25-2). As rates of photosynthetic productivity and organic loading to lower strata increase, nutrients are released from sediments into anoxic hypolimnia, increasing recycling rates.
   c. Phytoplanktonic productivity of eutrophic lakes increases markedly. In increasingly eutrophic lakes, dense algal communities reduce light penetration and thereby compress the depth of the trophogenic zone. Light limitations caused by self-shading set an upper boundary to the phytoplanktonic photosynthetic productivity, beyond which further increases are not possible, regardless of increased nutrient availability (Fig. 25-3). Further increases in photosynthetic productivity are possible only by extending the length of the growing season (e.g., in the tropics) or by increasing turbulence and frequency of exposure to available light (as in artificially mixed sewage lagoons).
   d. In calcareous hardwater lakes, the availability of certain organic micronutrients (such as vitamins) and inorganic nutrients (particularly phosphorus and inorganic micronutrients) can be suppressed by inactivation, that is, chemical competition or sedimentation with inorganic particulate materials (e.g., coprecipitation with $CaCO_3$) (Fig. 25-4). Maintenance of reduced productivity in calcareous lakes by lowered nutrient availability depends upon high carbonate loading from the drainage basin. Calcareous loading may be reduced through long-term leaching or overcome by increased loading of dissolved organic matter. The result is a relatively rapid transition to eutrophic conditions. Under certain conditions, high cationic (e.g., Ca or Mg) loading also can be counterbalanced and reduced by cationic exchange mechanisms of littoral-wetland plants (e.g., bryophytes), which may result in the transition of calcareous lakes to acidic bogs.
3. Many lakes receive large amounts of dissolved and particulate organic matter from allochthonous and surrounding wetland-littoral sources. These lakes are commonly heavily stained as a result of the abundance of dissolved humic compounds of plant origin; such lakes are termed *dystrophic*.
   a. Phytoplanktonic productivity is usually moderately high in dystrophic lakes (Fig. 25-6), and productivity of the surrounding littoral vegetation is moderate to very high.
   b. The surrounding macrovegetation can function as effective nutrient scavengers and frequently reduces the nutrient loading that reaches the open water. In some cases, particularly in bogs, the vegetation can effectively shift the lake per se from an open to a closed basin, so that nutrient inputs to the lake are mainly from atmospheric precipitation.
4. Terminal stages in the successional sequence of lake ontogeny are dependent upon the types of macrovegetation in the littoral zone and wetland areas surrounding the basin. The development of the vegetation is, in turn, strongly influenced by prevailing climatic conditions (rainfall and humidity) and the geomorphology of the region.
   a. Many fertile eutrophic lakes develop ever-increasing amounts of emergent littoral vegetation until littoral vegetation encroaches over the entire lake basin (Fig. 25-8). The resultant ***swamp*** conditions, with standing water among the emergent vegetation, gradually succeed to ***marsh*** conditions, with little or no standing

water over the water-saturated sediments. Evapotranspiration from the vegetation can gradually exceed water income, permitting invasion of a terrestrial flora. Ecosystem productivity decreases in the transition to terrestrial conditions.

b. Under climatic conditions of high rainfall and humidity, various types of mire ecosystems develop; in these systems, partially decayed plant organic matter (peat) accumulates in abundance.
   i. *Rheophilous mires* can develop from shallow drainage lake basins in which large amounts of organic matter accumulate in the depression.
   ii. The development of climax bog communities occurs via both terrestrialization and by paludification (inundation), beginning at the margins of a water body. Key stages of the succession involve establishment of peat-forming mosses, peat accumulation, and progressive terrestrialization and paludification (Fig. 25-12).
   iii. Eventually, the mire is no longer under the influence of flowing ground water. In these *ombrophilous mires*, water and nutrients are received primarily from rainfall. The salinity, buffering capacity, and pH of the water are low.
   iv. The acidity of the water often increases during mire development. Mosses, particularly *Sphagnum*, often develop in profusion in *bog* mires. Mosses have effective cation-exchange mechanisms, in which divalent cations are retained with a commensurate release of H^+ ions and organic acids. *Sphagnum* and other acidophilic plants can develop above the mean water table (raised bog) yet still acquire sufficient water by capillarity.
   v. Bog mats and underlying peat accumulations can gradually encroach upon, and eventually eliminate, the open water of the lake remnant within the bog.
   vi. Individual bog succession proceeds at rates and along developmental pathways that are controlled by a complex interplay of geomorphological, chemical, climatic, and biotic factors.

VI. Summary

I. WATER QUALITY IS ESSENTIAL; WATER QUALITY IS BIOLOGICAL

Water is an essential physiological requirement of humans for survival and for provision of food and basic living needs. Even with the catastrophic dangers that are upon human society because of excessive population growth, availability of fresh water could be reasonably satisfactory for modest standards of living if essential characteristics of water quality, allocation, and prudent use were instituted and practiced.

Water problems are not only of hydrological availability. We have great quantities of water in the oceans and it is close to human concentrations, as about 50% of humans are aggregated in coastal regions. It requires large amounts of energy to desalinate and clean marine water to a quality acceptable for human use. That energy requirement is too great at the present time simply because water is used and misused on such a massive scale without regard for its true economic value to societies. Moreover, much water is needed inland for agriculture and industry, and distribution costs are simply too great at present rates of water use and waste.

A false idea has emerged in modern society that water is a basic human right. Humans do not have a right to water but rather have a responsibility for wise and optimal use of available water. Responsibility is an obligation for human survival and realization of a reasonable standard of living. If that responsibility is given to society and its leaders, then it is essential that humans understand the fundamentals of water science for its responsible use and the effective management of water resources for both hydrological availability and acceptable water quality.

Contemporary management of freshwater resources is often performed in erratic and irrational ways. The rationale behind many practices is commonly purely hydrological, without the slightest interest in or appreciation of the biotic interactions of the water bodies themselves or the long-term related effects

on the climate of large regional areas and, in the end, on the biosphere. Water quality is biologically mediated. Aquatic ecosystems have changed slowly over time. Adjustments have occurred internally as organisms adapted to these changes. The result is a complex integration of the biological components within environmental variability. Certainly one can poison a water body to such an extreme extent that biotic metabolism is eliminated, but that is not usually the situation. Inland aquatic ecosystems are biological systems. Understanding biogeochemical cycling and metabolic regulation of productivity is essential for effective management and use of fresh waters. The biological metabolism of aquatic ecosystems *does* matter and must be considered and understood in all the manipulative measures taken in management.

A. "End of Science" Nonsense and Effects on the Discipline

A strange theme that irrupts periodically and is especially prevalent at the present time is that "all major functions of the natural world are known" and that we "know enough science to understand and manage our world." That is to say that we understand the mechanisms controlling the chemical and biological processes of freshwater ecosystems so that we can manage, use, and restore damaged ecosystems effectively. Such statements are irrevocably and absolutely nonsense. Limnology has just recently emerged from descriptive stages and is just beginning to evaluate controlling mechanisms that regulate and produce the observed biological and chemical results. Statements to the effect that we know enough to manage lakes and rivers are tantamount to saying that we know enough at present to control and manage human cancer and enough to restore health—again a nonsense statement. Excising an organ or irradiating cells to delay the spread of cancer are not solutions to cancer. Causality must be delineated and understood.

Only feeble insights exist regarding control mechanisms in lake, reservoir, and river ecosystems. Fortunately, improved or completely changed insights of previous conceptions of how these ecosystems work are being gained. For example, less than a decade ago we were aware of the abundance of humic substances dissolved in lake and river waters, but prevailing dogma assumed that most dissolved organic matter was recalcitrant to enzymatic hydrolysis and relatively unavailable for use by bacteria and other organisms. It is now known from extensive recent experimental work that both natural ultraviolet light as well as visible light induce major photolytic changes in the complex organic molecules and generate large quantities of readily utilizable substrates for microbial metabolism (cf. Chap. 23). This important process makes available a huge reservoir of organic carbon and energy that was largely ignored previously. Moreover, much of that source of organic matter and energy is derived from structural tissues of higher plants of external and littoral sources that were previously treated as unimportant. These data also explain in part why good, quantitative budgets of organic carbon fluxes would not balance without including this massive external subsidy of energy. The entire picture of how lakes and rivers operate is undergoing changes, and there will be many analogous important discoveries in the future. These changes in understanding must modify how we manage lakes and rivers.

II. BIODIVERSITY OF INLAND WATERS

The biodiversity of most microbial, plant, and animal groups of stream, lake, and wetland ecosystems is very poorly known. Moreover, it is likely erroneous to believe that the biodiversity of many taxa in temperate ecosystems is appreciably less than in tropical inland aquatic ecosystems. For example, the rivers and streams of Alabama, a "hot spot" within the United States, contain 43% of all gill-breathing snails, 52% of freshwater aquatic or semiaquatic turtles, 60% of mussels, and 38% of freshwater fishes of North America (Lydeard and Mayden, 1995). Over half of the species in some of the groups mentioned are either threatened or endangered under the U.S. Endangered Species Act of 1973.

Over a decade has passed since the perceptive insights and concerns of E. O. Wilson (1985, 1988, 1992) brought the problems of diminishing global biodiversity into overdue prominence. Rates of loss of biodiversity vary both because of differences in intensities of disturbances to the habitats as well as the number of species inhabiting particular areas. Because of the extremely high biodiversity in many tropical forested areas that are very vulnerable to catastrophic alterations by human activities, great attention has been given to these critical ecosystems or "hot spots" (Myers 1988; Wilson, 1992). Essentially, all of the emphasized biodiversity crises have focused on terrestrial ecosystems, particularly in tropical rainforests, which are under intensive siege.

A. Water Quality Alterations as Disturbances to Biodiversity

The fresh waters of the world are collectively experiencing markedly accelerating rates of degradation.

These major sources of disturbance impact the biodiversity of fresh waters in many ways. Direct chemical toxicants released into surface and ground waters are common. Many forms of heavy metals, inorganic reducing agents, and organic compounds enter the environment and eventually fresh waters. Although some are inactivated, such as by chemical precipitation, or oxidized, many have long residue resident times (see, e.g., Francko and Wetzel, 1983). Despite dispersion and dilution in the aquatic environment, bioconcentration of both metals and organic compounds is common, by which toxicity can be increased exponentially. The biological effects of many of these compounds are unknown. Elemental and compound toxicity is increased markedly when the pollutant substances are radioactive or acidic. Increased acidity in poorly buffered fresh waters can increase the bioavailability and potential toxicity of metals, such as aluminum, that are not normally abundant in soluble, reactive states (e.g., Hall *et al.*, 1985; Havas and Likens, 1985; Cronan and Schofield, 1990).

Plant nutrients, particularly phosphorus and nitrogen, can lead to well-understood enrichments of plant and other organic productivity in fresh waters (cf. Chaps. 13, 15, and 25). This eutrophication process often results in enhanced rates of decomposition and in chemical conditions that greatly reduce or eliminate suitable habitat for many species of plants and animals. Similar excessive loading of organic matter and enhanced rates of degradation result from organic sewage from human populations, industry, and agriculture. A further common pollutant that reduces habitat availability markedly is the suspension of finely divided organic and inert inorganic matter. Erosion and transport of such suspensions are increasing as large areas of forest and interface buffer zones of former wetlands between land and water are eliminated, primarily for agricultural expansions. As a result, flow patterns of surface waters are often altered and benthic habitats of surface waters can be obliterated by sedimentation.

Changes in biodiversity in freshwater ecosystems can arise from many disturbances. The introduction of certain competitively superior species can result in marked losses of biodiversity. The infamous example of the introduction of the Nile perch into Lake Victoria of eastern Africa resulted in the extinction of over 200 species of its cichlid fish taxa in two decades (Kaufman, 1992; Lowe-McConnell, 1994, 1996; Goldschmidt, 1996). Many other examples exist of introductions of exotic plant and animal species that resulted either in direct destruction of prey species or indirect alteration of habitats required by many species. Dense floating macrophyte communities and other eutrophication-associated excessive plant productivity often result in deoxygenation and reduction in habitat and elimination of many plant and animal species.

Technological and social responses to degradation of water, and the rates at which changes can be implemented, vary under different societal structures (Francko and Wetzel, 1983; Wetzel, 1992a). Effective utilization of extant freshwater resources is complicated by distributions of humans and their exploitations in regions low in water availability. Accelerating anthropogenically induced changes in hydrological patterns associated with flood controls and water supply reservoirs and with ongoing and impending climatic changes further obfuscate efficient utilization practices. Certain societies can cope with pollution and water availability constraints and even reduce freshwater degradation with habitat restoration. In most of the world, however, human population growth continues without any significant reduction of rates. Until human growth is stabilized, either by intelligence or catastrophes, further losses and degradation of fresh waters can be controlled only partially on a global basis (Wetzel, 1992a). It is sadly remarkable that organisms as intelligent as humans can be so stupid in unrestrained population growth and unsustainably exploiting and destroying the environment essential for survival. Other animals of far less advanced intelligence have evolved the recognition that it is essential not to foul their living quarters. Control and reversal of degradation requires a proper economic valuation of fresh waters for efficient, conserved utilization of water supplies for agricultural, industrial, and residential purposes.

B. Shifting Resilience, Stability, and Biodiversity of Freshwater Ecosystems

Many definitions of stability exist. A central feature of stability is the ability of a property (nutrient concentration, population, and community) of an ecosystem to return toward a steady-state equilibrium following a disturbance. Resilience, or relative stability, is a measure of the rate at which the property or system approaches steady state following the disturbance. The return time (T_R) to equilibrium can be formalized mathematically by integration of the asymptotic curve of return to equilibrium (e.g., DeAngelis, 1980, 1992). Resilience is approximately the inverse of the return time ($1/T_R$). As a rate of recovery, resilience is a function of the turnover time of limiting resources, such as a limiting nutrient, and thus approximately the inverse of turnover time ($1/T_{res}$) (DeAngelis, 1992). A faster rate of nutrient input per unit biomass, for example, will generally decrease the nutrient turnover time and thus increase the rate at which a system can recover from a disturbance. Therefore, any mechanism by

which the rates of nutrient turnover and recycling are increased should generally result in a reduction in resilience to disturbances.

Many theoretical ecologists have evaluated resilience and its couplings to the structure of ecological food webs. Contemporary views of ecosystem stability focus on the rates of recovery (i.e., resiliency) after perturbations (Pimm, 1984; DeAngelis, 1992) or the strengths of trophic interactions in community food webs (de Ruiter *et al.*, 1995). Largely based on terrestrial studies, the Eltonian diversity–stability hypothesis suggested that, because of the many different traits of multiple species, more diverse ecosystems will likely have species that will survive and expand during and following an environmental disturbance and compensate for those species that are reduced by the perturbation (supporting evidence reviewed by Tilman, 1996). Thus, a more species-diverse ecosystem should be able to be more resilient to disturbances than a less biodiverse system.

Because physiological differences and tolerances among species can be small, the individual interactive strengths among some species in an ecosystem can become saturating at high biodiversity. As a result, a point is reached where increasing species may be functionally redundant and have reduced individual impact on ecosystem processes (e.g., Vitousek and Hooper, 1993). On the basis of both theoretical and experimental grounds, only a small fraction of species manipulations have strong influences on food-web structure (de Ruiter *et al.*, 1995). This species-redundancy hypothesis implies an appreciable functional resiliency in which the ecosystem can compensate in collective metabolism and biogeochemical cycling when disturbed. Thus, although population dynamics become progressively less stable as the biodiversity and number of competing species increases (May, 1973; Tilman, 1996), biodiversity can enhance the resiliency of many community and ecosystem processes in terms of the rate at which the system metabolism returns to equilibrium states following a perturbation.

Dead organic matter or detritus clearly functions in the regulation of nutrient dynamics of ecosystems and, as a result, has manifold implications for ecosystem stability (Wetzel, 1983, 1984, 1995; DeAngelis 1992). Nine essential points impact biodiversity and ecosystem stability. Some of these points are well supported by empirical data; some are hypothetical but probable in most freshwater aquatic ecosystems.

1. Most organic matter of aquatic ecosystems is dead (detritus) and most is in dissolved or in colloidal form. Dissolved organic matter is energetically and functionally detritus (Chap. 23). This source of organic matter is physically unavailable to the metazoan food web and can enter the metazoan food web primarily only through bacteria.
2. Most of the instantaneous mass of dissolved organic matter (soluble detritus) present in lake, pond, and river ecosystems originates from the structural tissues of higher plants. These higher plants occur in the littoral, adjacent wetland and floodplain regions, and upland terrestrial areas. Upon partial decomposition of these plants, the relatively recalcitrant macromolecules from structural tissues are imported in soluble or colloidal form to the aquatic systems.
3. Once within the aquatic ecosystem, the recalcitrant DOC is metabolized, although slowly (ca. 0.5–2% per day) as mediated by a combination of hydrolytic enzymatic and physical (e.g., photolysis, Wetzel *et al.*, 1995) processes.
4. Bacterial, viral, and much of protistan heterotrophic metabolism (respiration) represents a major output of carbon, largely as CO_2, from the aquatic ecosystem. Although this output is a loss of carbon from the ecosystem, it is not an energetic loss from the ecosystem. Nonpredatory metabolism and death (biochemical senescence, or lysis) of prokaryotic and protistan heterotrophs dominate. Although the organic carbon packaged in these microbial heterotrophs is largely not available or little used for ingestion by higher trophic levels, this nonmetazoan pathway is a dominant energetic and carbon flow within the entire ecosystem (pelagic, benthic, and littoral) and dominates nutrient regeneration from organic carbon substrates. Even ignoring the benthic portions of lakes where most of organic carbon metabolism occurs, and considering only the pelagic metabolism of lakes, for example, most of the organic carbon entering the system does not reach higher trophic levels (Wetzel *et al.*, 1972; Wetzel, 1983a, 1984, 1995; Gaedke and Straile, 1994; Gaedke *et al.*, 1996).
5. There is very little storage capacity for organic carbon within the higher trophic levels, and low system residence times results in rapid cycling of carbon and nutrients within the higher food-web components. Such rapid cycling and recycling results in a reduction in the resilience of the higher trophic levels of the ecosystem.
6. Most of the storage of organic carbon occurs in the dissolved organic carbon (DOC) compartment in the open water and in the particulate organic carbon (POC) and DOC compartments of the sediments. In both of these compart-

ments, the soluble organic carbon of the pelagic of lakes or running water of streams and the DOC and POC of the sediments, the cycling of carbon is slowed. That rate of cycling is slowed in the pelagic by the recalcitrant chemical composition of the dissolved organic carbon emanating largely from higher plants and in the sediments additionally by the anoxic conditions that prevail almost universally among aquatic sediments. The reduced rates of cycling and recycling result in an inherent increase in the resilience stability of the ecosystem.

7. Any process that changes the sources and hence chemical composition of soluble organic matter and their rates of loading to or within aquatic ecosystems will affect the rates of nutrient recycling. Reduced percentage composition of recalcitrant dissolved organic matter will increase the rates of nutrient recycling and decrease the resilience of the system to return to an equilibrium state following a disturbance.
8. Pivotal to these arguments is the coupling of the chemical type of organic matter loaded to the aquatic ecosystems. Shifts from organic matter inputs dominated by in-lake (autochthonous) algal production to organic matter loadings dominated by littoral/wetland and external (allochthonous) organic matter, largely in the form of imported dissolved organic macromolecules, could result in decreased rates of degradation of total organic matter. As a result, the shift would be toward decreased rates of nutrient and carbon recycling and increased resilience to disturbance.
9. These arguments address total energetic fluxes of the aquatic ecosystem, of which only a small portion consists of the metazoan higher food web. Much, and often most, of the energetic and material (carbon and nutrients) fluxes never enter the metazoan food web, as was long ago demonstrated quantitatively (Chap. 23) and theoretically (Patten, 1985, 1995). These arguments, however, do not imply in any way that the microbial metabolism pathways are not coupled with higher freshwater food webs:
   a. Rates of nutrient cycling and recycling *in the entire aquatic ecosystem* are governed largely by bacterial, fungal, and protistan metabolism either (i) directly by hydrolytic degradation of *dissolved* organic substrates or (ii) indirectly by modifying the retention (e.g., adsorption to particles) and movements of nutrients as a consequence of the release of metabolic products into, and alteration of the redox of, the environment. Higher trophic levels, in particular herbivorous zooplankton, can have a significant effect on nutrient recycling by partial heterotrophic decomposition of particulate organic matter, which can decrease nutrient turnover time in the food web by creating short circuits in nutrients directly back to the nutrient pool without delays of storage in particulate detritus (DeAngelis, 1992). An important distinction made in the present text (Wetzel, 1984, 1995) is that most of the organic detritus is in dissolved form and includes major loading sources from allochthonous and littoral sources. This point differs from that of others, such as DeAngelis's (1992) excellent synthesis, which largely restricts the detrital compartment in aquatic ecosystems to that particulate detritus emanating from the metazoan food web.
   b. Any factor that influences the rates of nutrient and carbon cycling will influence the resilience of the ecosystem to disturbances. Changing sources of organic matter, as discussed later, and hence bacterial metabolism and nutrient cycling thus change resilience and biotic stability.
   c. A wealth of limnological data from a spectrum of hundreds of lake ecosystems suggests that with a shift in nutrient loadings, concomitant shifts in the development of photosynthetic producers and loadings of organic matter occur. During the common sequential development of lake ecosystems over time (reviewed in Chaps. 23 and 25), shifts in the ratios of higher vegetation versus algal dominance can occur. Increased relative organic loadings from higher vegetation result in proportionally greater loadings of recalcitrant DOC, which can suppress nutrient cycling and increase resilience of the ecosystem.
   d. In addition, the development of higher vegetation in littoral and wetland combinations increases enormously the habitat heterogeneity, commonly by a factor of 10, 100, or more. Species diversity nearly always increases under these circumstances by at least an order of magnitude among nearly all major groups of organisms, particularly among the lower phyla.

Resilience or relative stability in an aquatic ecosystem is governed by *process rates,* that is, the rates at which energy and materials are transferred among

biotic components (Wetzel, 1999b). Because so much of the organic matter of aquatic ecosystems is detrital, most of the assimilation and decomposition metabolism is microbial (bacterial, fungal, or protistan). Each of the species constituting the biotic groups has a physiological range for growth, competition, and reproduction within the environmental constraints. Some of these ranges differ with developmental or temporal changes in life histories of the different species, which can affect species responses to disturbances. Resilience occurs at the community level, however, from an ecosystem perspective within the medley of combined species process-response capabilities.

Physical and chemical environmental conditions, mediated by a host of biogeochemical and climatic/meteorological factors, regulate the bounds of these material and energy flux rates. The average range of these environmental conditions is reasonably finite for different ecosystems and habitats within the ecosystems. Major deviations of natural ranges of these environmental conditions from the average can arise from human or abnormal natural disturbances. The collective, integrated ecosystem responds to major disturbances by shifting dominant metabolism from one species to alternative species as the physiological tolerances of certain species are exceeded and they succumb. In ecosystems with greater species diversity, physiological and behavioral differences among many species may be small. Within limits, productivity and energy flux rates may increase with mild disturbances that remove certain species, because greater species biodiversity can result in increased interspecific competition and cause a reduction of community productivity and biomass. Given sufficient information, one can model the differences in physiological ranges and abilities of the individual species to tolerate change and still maintain stable productivity and reproductive capacity.

Greater biodiversity may have a greater collective effect by improving the ability for ecosystems to recover from large disturbances. Reduced biodiversity increases vulnerability by reducing the total collective physiological tolerances of the community to large habitat changes/disturbances. Recovery after a major or catastrophic disturbance would be slower, with a reduced aggregation of residual physiological ranges within the remaining species. Recovery then must depend to a greater extent on slower fortuitous methods, such as importation of species rather than generation from residual surviving species or slow recolonization processes such as from remnants in resting stages or seed banks. In some cases, such as in many ponds, streams, and reservoirs in clay-rich regions where high turbidity often occurs with successive rain events, total submersed photosynthetic productivity is intermittently but repeatedly suppressed; biodiversity is likely also suppressed and restricted to *r*-strategist species with high reproductive potential to utilize periods between turbidity disturbance events.

C. Extent and Timing of Disturbances and Shifting Stability

As implied in the earlier introductory comments, disturbance to freshwater ecosystems can occur in many forms and to different extents. Certain perturbations can be catastrophic, such as overwhelming a lake or stream with an organic or inorganic poison in which most of the biota are eliminated (e.g., Hanazato, 1994; or copper poisoning of an entire lake, Corbella *et al.*, 1958; Bonacina *et al.*, 1973). However, many disturbances are more gradual over long periods of time (months or years), such as nutrient enrichment, or irregularly episodic and often of short duration (days or weeks), such as severe flooding and scouring of a section of a river. Several examples are worthy of brief discussion to point out couplings of biodiversity to ecosystem stability (resilience) and the type and extent of disturbances.

The ensuing hypothetical model of the responses of the photosynthetic productivity of lake ecosystems to changes in nutrient loadings from the drainage basins (Fig. 26-1, *upper panel*), originally set forth by Wetzel and Hough (1973) and variously improved (Wetzel, 1983a; Carpenter *et al.*, 1998), has been abundantly verified by nutrient and comparative primary productivity data of phytoplankton, attached algae, and macrophytes from dozens of lakes in different stages of successional development. The differences in plant productivity result in very different types of chemical composition of organic matter loaded to lakes, especially that associated with the structural tissues of higher plants. Because of the large amounts and relative chemical recalcitrance of dissolved and particulate organic detrital sources from higher plants, heterotrophic utilization of this pool is slowed (Chap. 23). The resulting large but slow metabolism of organic detritus provides an inherent ecosystem stability that energetically buffers the reserves from rapid exploitation and nutrient recycling. Alterations to the quality and quantities of dissolved organic matter entering the aquatic ecosystem from the drainage basins will influence this inherent chemically mediated metabolic stability. In this context, forested watersheds, undisturbed riparian flood plains, and wetland/littoral zones are important to the metabolic stability within the lake and stream ecosystems. Alterations to these organic loading sources will be translated into altered stability within the lakes and streams. Stated another way, the organic carbon cou-

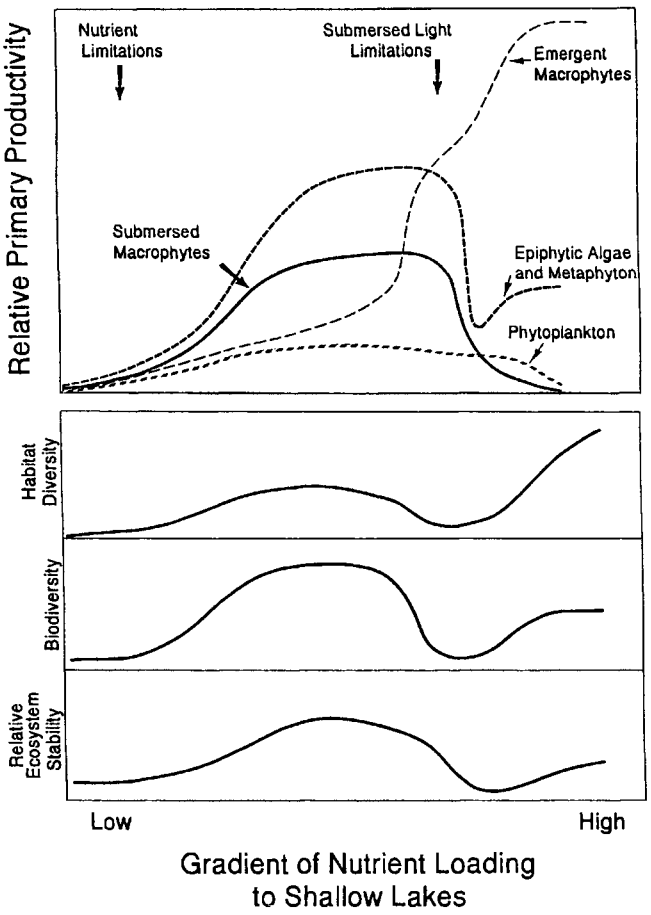

FIGURE 26-1 Relative changes in primary productivity of phytoplankton, macrophytes, and attached microflora and habitat diversity, species diversity, and ecosystem stability along a gradient of nutrient loading to lake ecosystems (see text for discussion). (From Wetzel, 1999b.)

plings between the drainage basin and land–water interface zones are metabolically as important to lake and stream energy and carbon flux stability as are the traditionally studied nutrient (N, P, Si) loading relationships to food-web productivity. Indeed, the predominating recalcitrant chemical quality of the organic reserves retards the rates of utilization and related nutrient recycling within the lakes and streams. As the sources of the organic matter change, the chemical recalcitrance to degradation can change. Alterations of *rates* of utilization, nutrient recycling, and energetic resilience can ensue as a result.

These quantitative differences in photosynthetic organic matter sources in relation to nutrient loadings from the drainage basin can be integrated with hypothetical differences in biodiversity. These relationships can be coupled to lakes of different developmental stages among a series of, for example, a hundred lakes along the trophic gradient.

A common disturbance to lake and reservoir ecosystems involves progressive increases in loading of nutrients. These loadings, in excess of losses to sites of temporary or permanent inactivation, such as to the sediments, result in enhanced nutrient availability for phytoplankton and other autotrophs and increased rates of growth and productivity. If nutrient loadings increase to an oligotrophic lake, increased productivity is rapid. Similarly, if the disturbance is brief (i.e., the duration of increased nutrient loading is relatively short), nutrient cycling is rapid, the ecosystem will recover rapidly, and productivity would be reduced proportionally to the load reduction. The return time of such an oligotrophic ecosystem is high, but the resiliency is low. Species diversity of the plankton tends to be high in oligotrophic lakes, but because of limited habitats, particularly associated with littoral areas and surfaces, composite biodiversity of the lake ecosystem would be low (Fig. 26-1).

As nutrient loading increases, particularly among shallow lakes that predominate globally (Wetzel, 1990a), a marked shift in productivity occurs from the pelagic to the attached surfaces associated with living aquatic plants and the particulate detritus of senescing macrophyte biomass (Fig. 26-1). Under these conditions, primary productivity and biomass increase greatly. Habitat diversity among the massively dissected surfaces of submersed aquatic plants increases exponentially, and biodiversity among attached biota and associated metaphyton would increase by at least an order of magnitude. It is likely that among all autotrophic and heterotrophic microbial groups, as well as most of the smaller metazoans, >90% of the species are sessile in association with surfaces.

As nutrient loading increases further, phytoplanktonic productivity per unit volume increases, but self-shading by the algae restricts the depth of the photogenic zone. Phytoplanktonic productivity per unit area declines precipitously under these eutrophic conditions and is usually accompanied by a marked decrease in planktonic biodiversity as well (Fig. 26-1). Submersed light limitations also reduce or eliminate submersed macrophyte growth and attendant surfaces for microbial growth. The elimination of photosynthesis of attached microbiota decouples the metabolic mutualism to the attached heterotrophs and decreases collective productivity markedly (Wetzel, 1993a; Neely and Wetzel, 1995). Biodiversity of the attached biota would decline precipitously. The losses of attached microbial communities and their coupled metabolism cause a massive reduction in the capacities of the lake ecosystems to retain loaded nutrients and dissolved organic compounds. Because of the great accumulation of nutrients in the sediments from a largely planktonic

eutrophic system, the time for recovery from a reduction of the loading (reduced disturbance) would be long and not proportional to nutrient load reductions. Under these conditions, after the loading perturbations end, the internal nutrient loading and recycling could be greater than external nutrient loading. With increased nutrient recycling, resiliency (relative stability) would be reduced.

Continual high nutrient loadings and hypereutrophic phytoplanktonic conditions generate large areas of anaerobic reducing conditions and lower rates of decomposition of organic matter. Production exceeding decomposition leads to rapid sedimentation and generation of increased shallow habitat conducive to colonization by emergent macrophytes. The high productivity of emergent macrophytes increases the proportion of lignocellulose supporting tissues that are relatively recalcitrant to rapid decomposition, particularly under reducing conditions. The collective result is markedly increased productivity and habitat diversity (Wetzel, 1979, 1990a). However, although habitat diversity is high among very shallow wetland-dominated waters, environmental fluctuations are also more extreme than in continually submersed habitats. Quite different community structures occur and biodiversity is likely tempered as a result, though comparative data to support this statement are few.

D. Biodiversity and Nutrient Recycling (Turnover Rates)

Fragments of data from many descriptive and experimental studies suggest that *greater biodiversity results in a greater efficiency of utilization of nutrients.* Stated quite simply, greater biodiversity likely results in a greater physiological diversity to cope with natural vagaries in environmental parameters. Competition for resources—nutrients in this specific case—is intensified. The efficiency of nutrient retention in an ecosystem would be maximized under conditions of greatest *microbial* community diversity. That microbial diversity (bacterial, algae, fungi, and protists) is maximized in the attached communities where habitat diversity and microenvironmental differences are the greatest. The physical constraints of boundary layers and mucopolysaccharide matrices in which the microbiota live mandate ionic and gaseous movements predominately by diffusion to organisms living within the attached communities (Riber and Wetzel, 1987; Losee and Wetzel, 1993). Nutrients, once acquired, are intensively recycled among the attached biota and conserved. Resources from external sources can then be utilized largely for new growth and reproduction (Wetzel, 1993a, 1996). Nutrient retention is very high within the microcommunities and, collectively, the attached habitats. As dependence on more labile organic substrates from algae increases, reduced resilience to disturbances results. That reduction in resilience accelerates when external nutrient loadings to the ecosystems push the productivity to hypereutrophic phytoplanktonic densities that shade out submersed macrophytes and, by elimination of substrata, the attached microflora.

E. Predation-Induced Shifts in Energy Fluxes and Biodiversity

As we have seen (Chaps. 16 and 20), in certain moderately productive lakes, piscivore consumption of planktivorous fishes can lead to sporadically enhanced development of cladoceran zooplankton. The high grazing rates of the cladocerans can result in selective reduction of larger algae for brief-to-moderate intervals of time. The effects of these changes among the larger forms are, however, poorly translated to smaller microbiota, and only minor changes are seen at the microalgal and bacterial levels (e.g., Pace, 1993). For example, removal of portions of the larger algae can decrease competition for nutrient and light resources. Often, the smaller forms with shorter generation times increase in productivity. Nutrient recycling likely also increases, particularly as decomposition of these algae and metabolically coupled bacteria is accelerated by protistian microconsumers (heteroflagellates, ciliates, and related organisms) and tightly retained among the microbiota. Little is known concerning changes in biodiversity under these conditions, but it appears that biodiversity among the microbiota would increase and likely more than compensate for the losses of larger forms by the crustacean grazing. Once again, a shift in energy fluxes occurs, here from larger planktonic forms to smaller forms with much higher turnover rates and increased rates of resource turnover. Compensatory mechanisms likely also appear in composite biodiversity. Resiliency within the pelagic food web likely declines as a result.

III. RIVER REGULATION

A. Riparian-Littoral-River Interface

Flooding adds dissolved and particulate organic matter and mineral nutrients to both the aquatic and terrestrial portions of the river ecosystems. The river ecosystem includes both the channel and the flood plain, both of which are dependent on erosion and sedimentation associated with lateral migration. Inundation results in silts and nutrients that replenish the floodplain pools and flooding of terrestrial mineral and organic

matter releases nutrients to the water. Primary production increases markedly, usually far in excess of losses by decomposition. After the flood maximum is reached, decomposition processes usually exceed production.

Many of the organisms, particularly plants, are highly adapted to such inundation gradients and flooding disturbances with rapid growth and reproduction (*r*-strategy traits). Some species, such as the red gum and cypress trees, are totally dependent upon fluvial flooding. Many animals (invertebrates, fish, birds, and mammals) are adapted to the flood cycle and the high plant and microbial productivity associated with it.

Migrations of the river channel occur across the flood plain as alluvial rivers erode and deposit sediment along and above their banks. During more active flows, meandering can lead to rapid avulsions of parts of the flood plain. Spatial and temporal variations in lateral migrations vary greatly (0–800 m yr^{-1}, Hooke, 1980). Periodic disturbances by riverine erosion and deposition are essential to the successional processes in floodplain forests and their associated high habitat and biological diversity (Johnson, 1992; Marston *et al.*, 1995). In addition, the timing and duration of flooding as an agent of erosion and deposition are important in the regulation of riparian plant communities, particularly the forests (Scott *et al.*, 1997; Auble and Scott, 1998; Johnson, 1998). The natural periodic movement of sediment and redeposition within the flood plain are essential to the biota at all levels—primary production, secondary (animal) production, and critical decomposition cycles for nutrient regeneration. The floodplain habitats must constantly be reset by natural disturbances mediated by variations in river discharge.

Fluvial processes create a pattern of physical features that balance successional processes of sedimentation and terrestrialization with scour and channel migration. Periodic rejuvenation of the flood plain by erosion and deposition is essential to sustain the health of the ecosystem (Bayley, 1995). Floodplain patches or habitats are defined both by type (e.g., sand bars, levees, cutoff channels, and backswamps) as well as by age, frequency, and duration of connectivity by flooding and channel migration. Different habitat types and their changing arrangements relate to the channel pattern (meandering, braided, or anastomosed) and mobility over time scales of many years. The diversity of vegetation development of flood plains is directly related to the rejuvenation and succession generated by channel erosion (Petts, 1996).

A complex of flowing channels, backwater areas, lakes, springs, wetlands, and terrestrial patches characterizes floodplain rivers. These diverse patch and habitat areas exhibit a high degree of connectivity, particularly during flooding conditions. Primary process variables, such as diurnal and annual temperature ranges, channel stability, and flood régime and predictability, tend to increase downstream among large rivers (Fig. 26-2). Coarse particulate matter (CPOM) and the importance of the floodplain biotic communities also increase in large floodplain rivers. The interactions of these factors contribute to the high biodiversity found among large floodplain rivers (Fig. 26-2).

Most river flood plains function as storage reservoirs for flows at or below the 40-yr return-period events (Bhowmik and Demissee, 1982). At higher flows, the storage advantage is reduced, as the river and flood plain function more as a conveyance channel. Flooding disturbances, however, function positively because floods can "reset" floodplain patches, destroy floodplain forest, flush pools, and rejuvenate successions.

In large floodplain rivers, the ecological integrity of the river is dependent upon the predictable connection to a diverse range of floodplain habitats. Most (to 90%) of animal biomass in large rivers derives directly or indirectly from production within the flood plain and not from downstream transport of organic matter (Junk *et al.*, 1989; Junk, 1997a,b). Most of that production of organic matter and energy is derived from plant and microbial production within the flood plain, including herbaceous vegetation that shows high productivity during the dry season and abundant aquatic plant growth during the wet season. The high range of habitats created and rejuvenated by channel instability and flooding in a highly predictable manner results in an extremely high productivity and biodiversity of the flood plain. Any reduction in the floodplain habitats and inundation periodicities results in a precipitous decrease in the biodiversity of these ecosystems.

B. Dam Impoundments and Channelization

About two-thirds of the fresh water flowing to the oceans is obstructed by approximately 40,000 large dams (>15 m in height) and more than 800,000 smaller dams (McCully, 1996). In addition, many more rivers are constrained by levees or dikes. Such hydrological alterations are undertaken to hold water for agricultural, industrial, and domestic purposes, for hydroelectricity generation, and for flood protection (Nilsson and Berggren, 2000). Regulation of river flows by dams and the controlled release of water downstream and by channelization reduce or eliminate the linkage between the river and its floodplain margins. The fluvial processes of flooding, erosion, and deposition determine land areas within these lateral habitats adjacent to the river channel. These abiotic variables tend to be relatively regular and predictable on an annual basis. Water quality is governed by

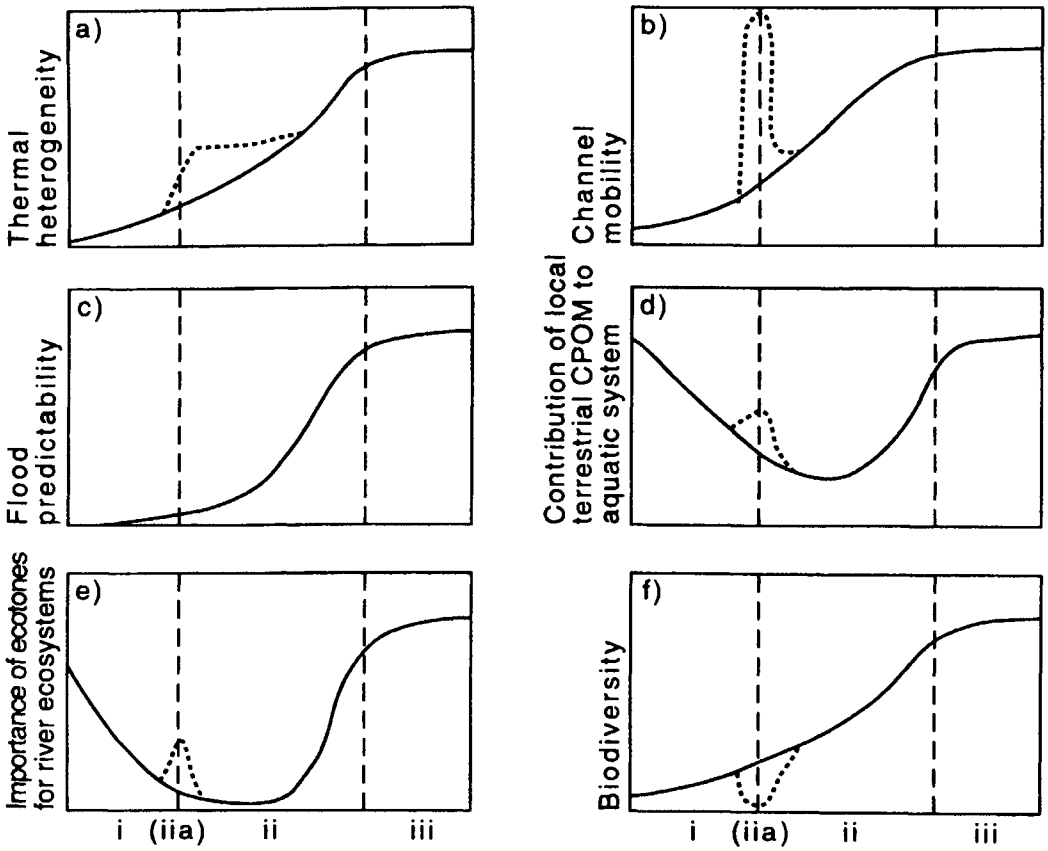

FIGURE 26-2 Downstream patterns (low to high) along an idealized river contrasting the large floodplain river (iii) with the middle river (ii) including braided sections (iia) and headwater streams (i). (From Petts, G. E. 1996, Sustaining the ecological integrity of large floodplain rivers. In M. G. Anderson, D. E. Walling, and P. D. Bates, eds. Floodplain Processes. John Wiley & Sons, Limited, Chichester. Pp. 535–551. Reproduced with permission.)

biologically mediated processes of uptake, retention, transformation, and regulation of physical retentive processes on particles. The biotic communities are governed by dynamic interactions of fluvial and terrestrial processes (current, nutrient loading, physiological adaptations to flooding and desiccation, et cetera).

In regulated rivers, floods are controlled and channel morphology is stabilized (Shields *et al.*, 2000). Reservoirs that reduce the frequency and duration of high flows typically reduce later migration rates by factors of 3–6. Following flow regulation of the Missouri River downstream from Fort Peck Dam in Montana for flood control and hydropower production, for example, lateral migration of the river channel was severely attenuated. The mean rate of channel centerline migration declined from 6.6 to 1.8 m yr^{-1} after impoundment. The primary effects of the isolation of natural flood plains and channelization effectively remove the resetting function. Secondary succession then ensues, with a cascade of responses as terrestrialization progresses closer to the river per se. Production in the controlled flood plain and particularly the entire river ecosystem declines precipitously (Table 26-1). The biodiversity of the river ecosystem also declines markedly, often in the range of <10% of the preregulation conditions. The great biodiversity of floodplain river ecosystems is a direct result of the high spatial and temporal heterogeneity (Ward *et al.*, 1999). That heterogeneity is a direct result of the patterns of disturbance created by flooding and channel migration.

Without question, large dams and river diversions destroy aquatic habitat, contribute substantially to the destruction of fisheries, the extinction of species, and overall loss of ecosystem services on which the human economy depends (McCully, 1996; Postel, 1998; Pringle *et al.*, 2000; Rosenberg *et al.*, 2000). Hydrological alterations induce habitat fragmentation, deterioration of irrigated terrestrial environments and associated surface waters, and dewatering of the rivers from diversions. Hydrological modifications have resulted in regional bi-

TABLE 26-1 Contrasts between Natural and Regulated (Canalized and Embanked) Large Floodplain Rivers Having Late Spring/Early Summer Flood in Temperate Regions[a]

	Natural	*Regulated*
Productive processes	High P/R ratio due to high *in situ* production on the inundated flood plain	Low P/R ratio due to processing of material from upstream and low *in situ* production
	High CPOM/FPOM ratio—floodplain contributes wood, bark, leaves, fruit, flowers, and terrestrial arthropods. High productivity of herbaceous vegetation during dry phase and hydrophytes during wet phase	Low CPOM/FPOM ratio—dependent upon downstream flux of organic matter from head waters
Dominant role of floods	Resource: life cycles of many aquatic and terrestrial organisms are adapted to the flood régime	Disturbance: *frequent* flushing "resets" physical and biological environments and limits successions
Dominant role of main channel	Routeway for gaining access to adult feeding areas, nurseries, spawning grounds, and refuges	Supports whole life cycle
Bulk of riverine animal biomass derives from:	Production within flood plain	Downstream transport of organic matter from head waters
Biodiversity	Very high	Limited by homogeneous substratum (bed and banks), turbidity, and oxygen deficits
Sensitivity of biota to headwater catchment "events" (major floods or pollution incidents)	Low	High

[a] After Petts (1996). P = production; R = respiration; CPOM = coarse particulate organic matter; FPOM = fine particulate organic matter.

otic impoverishment, ranging from reduced population abundance and biodiversity to range fragmentation and increases in exotic and lake-adapted taxa.

C. Climate Changes: Effects on Rivers

Global warming is clearly occurring and is directly coincident with increases in the CO_2 concentration in the atmosphere. CO_2 concentrations are clearly increasing (Fig. 23-31), largely from combustion of fossil fuels, and will more than double in the present century. Global warming is also clearly occurring in part related to the "greenhouse effect" of reduced radiative thermal loss of heat. The combined effects, based on several climatic models (Cushing, 1997; Lettenmaier *et al.*, 1999; Magnuson *et al.*, 2000), are predicted to result in an increase in temperature between 1–3°C in the present century, with perhaps a greater warming in the central parts of continents. Summer precipitation is anticipated to decrease appreciably, with marked increases in evapotranspiration, in some continental regions and increase in others. Downstream flows are anticipated to fluctuate to a much greater extent relative to base flow on an annual basis than was the case previously.

Snowmelt is a dominant climate-controlled factor regulating the hydrology of many large river ecosystems. Increasing temperatures and early seasonal melting result in rapid alterations of the rates of snowmelt, discharge, and seasonality of streamflow hydrographs (Murdoch *et al.*, 2000). Spring snowmelt maxima are reduced and average winter flows increase. Of greater importance than the seasonal shape of the hydrographs, however, are changes in precipitation that are directly coupled to annual total runoff volumes. In general, climatic change models predict that the increased warming will result in decreased precipitation and additionally a decrease in frequency but with more intense precipitation events.

Climate warming effects that generate reduced river flows may be favorable for urban and agricultural flood control but would be detrimental for all other ecosystem use objectives (water supply, navigation, hydropower, recreation, and most importantly biodiversity). In particular, major declines in habitat quality of semipermanent wetlands of the flood plains will occur as the differences between flooding and drying events increase (Poiani and Johnson, 1991; Grimm, 1993; Poiani *et al.*, 1996). Nearly balanced cover:water ratios will shift to closed basins with no open-water areas, with elimination of many fish and wildfowl populations. Clearly, human-induced changes in discharge patterns will be exacerbated by additional progressive climatic changes.

IV. RESTORATION OF AQUATIC ECOSYSTEMS

Aquatic ecosystems are damaged in a number of ways. Alterations of water quality by pollution can occur in many different forms; all decrease how effectively the aquatic ecosystems can be used for human activities. The most common type of degradation is contamination of the water and biota by inorganic and organic pollutants. In the case of toxic substances, remedial measures are difficult or impractical once the substances are dispersed (Wetzel, 1992a). Indeed, dispersion and dilution are unfortunately relied upon as a common corrective, remedial measure. Once the loading of the pollutant to the aquatic ecosystem has ceased or been reduced appreciably, natural water renewal rates are relied upon to dilute the contaminants to acceptable levels. Lakes are more susceptible to function as sinks for pollutants than are rivers, which means that pollutants tend to accumulate and potentially increase in toxicity with time.

The need for management of lakes and rivers reflects an inability of the ecosystems to operate in self-sustaining ways because of interference or damage that exceed the capacities of the ecosystem for self-repair (Moss, 1999). Most demands for management are a result of disturbances by human activities. Impediments to successful management include (a) the basic complexity and stochasticity of natural ecosystems, which may change or be altered faster than they can be understood and managed; (b) an ecosystem scale required in evaluation of appropriate methods for effective management, a scale that does not lend itself readily to rigorous scientific evaluation methods and experimentation of potential effects; and (c) political impediments, often large, such that if a portion of a society should choose to exploit a resource in an unsustainable way, scientific understanding is of little assistance.

Four major types of degradation of surface waters have occurred in recent times. Nutrient loadings, particularly of phosphorus and nitrogen, have resulted in nutrient enrichments and excessive growth of algae and macrophytic plants. This accelerated ***eutrophication*** process has led to a concert of remedial techniques to mitigate the problems and return the lake or reservoir to some state of improved, lower productivity. A second major degradation involves soil erosion, primarily from agriculture, leading to ***siltation,*** loss of volume in the aquatic habitat, and pesticide contamination. A third major type of degradation results from excessive loading of hydrogen ions associated largely with strong acids. These acids result from gases (e.g., SO_2, and NO_x) from fossil fuel combustion products that are dissolved in precipitation or adsorbed to particles that are deposited from the atmosphere onto surface waters or the land (see Chaps. 12 and 14; also Schindler, 1988b). The resulting ***acidification*** of poorly buffered waters not only increases acidity and alters osmoregulatory capacities of organisms but alters the solubility and bioavailability of many metals and other ions of variable toxicity. A fourth type of degradation includes the introduction of ***toxic materials*** such as heavy metals, chlorinated hydrocarbons, and radioactive materials. The sources of all of these pollutants are often diffuse (nonpoint), which makes their control very difficult.

When one attempts to restore a disturbed aquatic ecosystem to some former state or condition, the question arises as to what are the objectives of such recovery. The objective may be the complex task of restoring specific habitats for important native species or, more commonly, to restore community functions such as trophic structure (Palmer *et al.,* 1997). On the basis of much study of community development in streams and rivers, there is reasonable probability that natural succession processes can be exploited to accelerate restoration of disturbed ecosystems.

A. Lake Management and Restoration

Lake management and restoration have focused upon problems particularly associated with excessive nutrient loading and poor land management. The subject has been treated in detail in several recent monographs (Ryding and Rast, 1989; Klapper, 1991; Cairns *et al.,* 1992; Welch, 1992; Cooke *et al.,* 1993; Eiseltová, 1994; Kortmann and Rich, 1994; Geller *et al.,* 1998). Restoration of acidified surface waters involves complex socioeconomic issues to reduce atmospheric pollution. Temporary mitigation of surface water acidity can be accomplished by chemical treatment (Olem, 1991). Only a brief summary of management and restoration is presented here.

1. Eutrophication

Eutrophication is a process leading to increased biological productivity and decreased basin volume from the excessive addition of dissolved and particulate inorganic and organic materials to lakes and reservoirs (Cooke *et al.,* 1993). Although much of the earlier emphasis on eutrophication was on the basis of increased growth of phytoplanktonic algae (e.g., Likens, 1972), a broader context in which rapid alterations of the basin morphometry occurs by siltation is more realistic. The increased littoral areas lead to rapid increases in the development of aquatic macrophytes of high productivity and accelerated internal loadings of organic matter (Wetzel, 1979). In addition, this increased proximity of the sediments with the productive trophogenic zone as lakes become shallower can result

in enhanced exchange of nutrients that are remineralized in the sediments.

The cause of the enhanced productivity in lakes and reservoirs is clearly most frequently enhanced phosphorus availability (cf. Chap.13). Although other elements, particularly nitrogen (e.g., Suttle and Harrison, 1988; Dodds *et al.,* 1989) can become the dominant limiting nutrient for phytoplanktonic growth in certain alpine waters when phosphorus supplies are sufficient. On a global basis, phosphorus is the foremost nutrient limitation to autochthonous photosynthesis on a sustained long-term basis. Lake restoration efforts have, as a result, been directed largely toward reducing the loading of phosphorus, and to a lesser extent nitrogen, to the surface waters by advanced wastewater treatment, diversion, land management, or reducing the phosphorus load in wastewater by restricting the phosphorus content of detergents. If releases of sediment phosphorus stores become significant, in part stimulated by low redox potentials that have resulted from organic matter loading, production, and deposition (cf. Chap. 13), attempts are often made to control the availability or recycling of nutrients by physical or chemical methods within the lake or reservoir.

Prevention of nutrient pollution and eutrophication is clearly the most prudent long-term solution. Often, reductions in nutrient loadings require evaluation of diffuse and point sources within the drainage basin and a systematic multifaceted program of reduction and control (Cooke *et al.,* 1993). Once the loadings of nutrients and water are known, a nutrient budget can be used to evaluate the dynamics of annual inputs and outputs of substances. The budget permits the estimation of changes in algal biomass that could result from increases or decreases of nutrient loadings, water residence time, or increased mean depth as may occur from sediment removal. Various phosphorus and water input–output models have been developed that rather accurately predict what loading rates are and what effects reductions would have on phytoplankton biomass (see Chap. 13 and Dillon and Rigler, 1974; Vollenweider, 1975, 1976; Uttormark and Hutchins, 1980; Reckhow and Chapra, 1983; Cooke *et al.,* 1993). Phosphorus release from sediments can be very high in lakes with anoxic hypolimnia, which can delay the predicted reduction in phytoplankton biomass following reductions in external nutrient loading (Marsden, 1989). Internal loading can be estimated and incorporated into nutrient budget data and models (e.g., Nurnberg, 1984; Chapra and Canale, 1991; Rossi and Premazzi, 1991). Restoration of lakes from excessive productivity from eutrophication is accomplished by (a) nutrient loading reduction and (b) control or removal of plant biomass.

2. Nutrient Control

Eight common methods are used, singly or in combination, to reduce nutrient availability or suitable habitat for photosynthesis (Klapper, 1991; Cooke *et al.,* 1993).

1. *Nutrient Removal by Advanced Treatment and Land Management.* Regulation and reduction in external loadings of nutrients to eutrophic lakes is the best of long-term corrective measures, without which treatments within the lakes will have minimal lasting results. Advanced wastewater treatment is only practical where used water is collected in a wastewater system where phosphorus of the water can then be removed to quantities that will not appreciably alter lake productivity when the treated water is returned to the stream, reservoir, or lake. Lake quality, as measured by biomass of phytoplankton or transparency, is often a function of the absolute equilibrium concentration of lake phosphorus, not the proportional change in concentration. Agricultural land-management practices, including manure storage and changes in tillage, can also reduce nutrient loading.

2. *Nutrient Diversion.* Occasionally diversion of major external nutrient loadings has been adequate to restore a eutrophic lake—Lake Washington in Seattle is a well-documented example (Edmondson, 1991a). In situations where the primary source or sources of nutrient loadings are defined, the waste water or storm water may be diverted without appreciable alteration of lake or reservoir hydrology. Diversion is most likely to be successful in rapidly flushed lakes (low retention time) and where internal nutrient loading from sediments is small.

3. *Hypolimnetic Withdrawal* Nutrient-enriched hypolimnetic water is removed by large-scale siphoning, pumping, or deepwater discharge at the dam. Nutrient-rich water, rather than nutrient-poor epilimnetic water, is discharged. Residence time of hypolimnetic water is reduced and the oxygen content of water overlying sediments may be increased with a concomitant decrease in internal loading of phosphorus from the sediments. If designed and regulated carefully, it is possible to have hypolimnetic removal without thermal destratification.

4. *Dilution and Flushing.* If a major source of nutrient-poor water is available, addition of such water to an enriched lake or reservoir may be adequate to dilute nutrient levels adequately to suppress algal productivity. If sufficiently large quantities can be added, the water alone can be adequate to flush out algal cells and maintain lower productivity by dilution. Lower algal biomass can be maintained even with nutrient-rich water if flow is adequate to wash out the algae faster than

algal growth rates. Both methods require the availability of a suitable water supply, particularly during seasons of high productivity. These methods are sometimes used in coordinated management with induced lake circulation, chemical precipitation, and biological manipulations.

5. *Phosphorus Precipitation and Inactivation.* Recovery from eutrophication (oligotrophication), in which essential nutrients are reduced to growth-limiting concentrations, can be a slow process if lake water renewal times are long and if nutrient releases from sediments and entrainments of nutrient-rich hypolimnetic water into the epilimnion are large. Phosphorus is adsorbed to and/or coprecipitated with clay and carbonate particles (cf. Chap. 13). A similar process can be induced by adding aluminum compounds to the water and the sediments. Aluminum sulfate (alum) or sodium aluminate or both form a precipitate of aluminum phosphate or a colloid of aluminum hydroxide, depending upon the alkalinity and pH conditions. In both cases, phosphorus is bound and scavenged to the sediments without aluminum toxicity if circumneutral pH is maintained. Further additions of these aluminum compounds to the sediments inactivate and retard phosphorus migration into the overlying water.

6. *Sediment Oxidation.* High bacterial respiration of organic matter in sediments results in anaerobic conditions in nearly all sediments. These reducing conditions lead to reduced iron and the release of associated phosphate into interstitial sediments and overlying waters (see Chap. 13). Additions of nitrate as an alternative electron acceptor for oxygen delays the reduction of iron and release of phosphate. Artificial addition of nitrate to stimulate denitrification and oxidation of organic matter, ferric chloride to remove hydrogen sulfide and precipitate phosphorus, and lime to raise the somewhat pH of the hypolimnetic water and/or of sediments can result in inactivation of phosphorus release from sediments.

7. *Aeration.* Two methods have been employed to aerate water of stratified lakes and reservoirs—artificial circulation (destratification) and hypolimnetic aeration. Oxygenation can induce precipitation of phosphorus, iron, and manganese and lower ammonium content and increase pH. Artificial water circulation by pumps, jets, and bubbled air or other gases destratifies the water strata, making the lake isothermal and increasing water temperatures, particularly of the former hypolimnion of smaller volume. This destratification reduces the competitive advantages of cyanobacteria. In deep lakes, circulation may light-limit the phytoplankton. Hypolimnetic aeration with contained aeration and flow devices increases hypolimnetic oxygen content without destratifying the water column or warming the hypolimnion. Internal loading of phosphorus often declines from renewed aerobic conditions at the sediment–water interface if adequate iron is present. Otherwise, iron may be added to the hypolimnetic aeration devices.

8. *Sediment Removal.* Shallow eutrophic lakes can often be restored by removal of sediments. This technique simultaneously removes large quantities of nutrients stored in the sediments, increases the mean depth of the basin, and can remove sedimented toxic substances. Often, the habitat for nuisance development of macrophytes is reduced by the deepening of the basin, which can result in light limitations.

9. *Food-Web Manipulations.* The management of food-web structure by manipulation of animal herbivory, predation, and nutrient recycling by animals can influence the quantitative and qualitative composition of algae on a seasonal basis (see critical review in Chaps. 16 and 20). Nutrient concentrations and loading rates set general limits on the types of phytoplankton and their productivities. Alterations of zooplanktonic herbivore types and densities can alter algal biomass and species composition to levels below those anticipated by the nutrient loadings to the lake ecosystem. The phytoplankton productivity is usually rapidly replaced by smaller algal species that may be less obtrusive for human uses of the water bodies.

Browsing of littoral sediments of benthivorous fishes and their digestive activities can add to internal loading of nutrients in shallow lakes and reservoirs (LaMarra, 1975; Brabrand *et al.*, 1990). This enhancement can be suppressed if intensive fish bioturbation activities resuspend fine particled sediments sufficiently to maintain turbid conditions of the water (Hosper and Jagtman, 1990). Fish removal, coupled with reduced nutrient loading, may "switch" the lake to a clear state dominated by submersed macrophytes.

Natural factors or manipulative procedures that significantly increase and maintain strong populations of piscivorous fish should reduce populations of planktivorous fish. This reduction should lead to enhanced survival of large-bodied zooplankton species and to a reduction in phytoplankton biomass and improved water transparency. It should be emphasized that these animal community-induced changes in algal mass do not really alter nutrient content *within the ecosystem,* but rather displace nutrient availability temporarily to areas (tropholytic zone) where it is less immediately available photosynthetically. Downward-cascading (Paine, 1980) piscivore influences to lower trophic levels have less effect on algal biomass in productive lakes where nutrient regulation of phytoplanktonic biomass is large relative to influences of the feeding interactions

of piscivore through planktivore to zooplankton communities (McQueen *et al.*, 1989).

Food-web management to improve resulting algal community structure and biomass levels remains experimental (Crowder *et al.*, 1988). Many confounding interactions, such as variations in mixing events, climate, zooplanktonic refuges, and long-term fish reproductive successes, limit applications of fish manipulations as predictive management tools. Food-web manipulation, however, is not a control method but offers some potential as a supplementary procedure to manipulate the types of phytoplankton at certain times of the year in low to moderately productive lakes (see pp. 462–466).

3. Control of Macrophyte Biomass

Excessive growth of macrophytes, particularly of certain exotic nuisance species such as the water hyacinth (*Eichhornia crassipes*), hydrilla (*Hydrilla verticillata*), and the Eurasian watermilfoil (*Myriophyllum spicatum*), can curtail or eliminate the use of lakes, reservoirs, and river ecosystems by humans. Entire disciplines have emerged that are directed to the control and management of aquatic macrophytes (e.g., Gopal, 1987; Gangstad, 1988; Pieterse and Murphy, 1990). The ensuing few paragraphs summarize common approaches to the control and management of excessive development of aquatic macrophytes (see Cooke *et al.*, 1993).

1. *Drawdown of Water Level.* The drawdown of water level is a multipurpose restoration and management technique for ponds and reservoirs to control certain aquatic plants and to modify habitats for the management of fish populations. Exposure of aquatic macrophytes to dry or freezing conditions for adequate (i.e., species-specific and variable) periods of time can kill the plants. Negative effects also occur (e.g., losses of or damage to important adjacent wetlands and losses of important benthic communities).

2. *Mechanical Removal.* Aquatic macrophyte communities that have developed to nuisance densities have been controlled by numerous manual and mechanical methods. Mechanized devices effectively drag, dredge, and till the sediments by mowing and tillage machinery or by suction and diver-operated dredging equipment. Harvested plants are preferably removed from the water, thereby simultaneously removing appreciable amounts of nutrients.

3. *Plant and Sediment Shading.* Sediments and submersed macrophytes can be covered with opaque sheeting or dense screen materials that are impenetrable by plants growing from root systems. These methods are limited to small areas of intensive uses where macrophytes are not desired.

4. *Biological Controls.* Introduction of phytophagous insects and fish or plant pathogens such as fungi and viruses have been used as species-specific control agents to reduce the success and biomass of targeted macrophytes. The objectives are to establish an equilibrium between the control organism and its target plant at an acceptable level of plant biomass (reviewed in Cooke *et al.*, 1993).

5. *Chemical Controls.* A number of general and moderately selective herbicides have been effectively applied to the control of aquatic macrophytes (Gangstad, 1988a,b; Westerdahl and Getsinger, 1988). Such compounds are often used in concert with other control methods.

B. River Management and Restoration

A fundamental aspect of both river management and restoration is to protect or restore the riparian floodplain areas of streams and rivers. In many cases, streams and rivers have been channelized by straightening and deepening the channel, particularly in lowland agricultural areas to increase drainage. Accompanying the loss of stream length is a loss of riffles and pools, a loss of riparian flood plains and wetlands and a loss of riparian vegetation. As a result, hydraulic head is increased when energy dissipation is lost. Increased flows reduce habitat diversity, particularly in the sediments and adjacent wetland, with a catastrophic reduction in habitat diversity and biodiversity (e.g., Petersen *et al.*, 1992). Loss of riparian flood plains and wetlands decreases water tables, increases rates of water runoff, enhances nutrient losses from adjacent land, and increases scouring and sediment yield to the channel. Water retention capacities are greatly reduced, and as a result, during high precipitation events, flooding is very common and much more severe than would be the case if portions of the riparian and floodplain environments were retained. It is estimated that drainage basins comprised of 5–10% wetlands are capable of providing a 50% reduction in peak flood period compared to those drainage basins that have none.

The relative stability of flowing water ecosystems and communities living within them is indicated by their resistance to disturbance as well as their rate of recovery from disturbance (Webster *et al.*, 1983; Yount and Niemi, 1990). After a disturbance, such as a flooding event, a poisoning phenomenon, or alteration of channel stability, lotic communities and ecosystems recovered relatively rapidly because (a) life histories of communities are commonly adapted for rapid recolonization and reestablishment of the disturbed areas, (b) unaffected internal refugia as well as unaffected upstream and downstream populations can serve as seed

inocula for reestablishment, (c) flushing characteristics assist in dilution and replacement of polluted regions, and (d) streams and rivers have frequent natural disturbances and are adapted to human-induced perturbations. Major alterations, such as channelization, that severely alter sediment and flow characteristics will result in much longer recovery times.

Several management and restoration measures for streams and rivers are commonly used (see Gore, 1985; Peterson *et al.*, 1990, 1992; Osborne and Kovacic, 1993; Large and Petts, 1994; Eiseltová and Biggs, 1995; Muhar *et al.*, 1995; Boon *et al.*, 2000; Petts *et al.*, 2000). A means of river restoration is to allow the river channel to migrate laterally with periodic inundation of the flood plain above river bankfull.

1. Buffer Strips

Plant and microbial communities on a buffer strip of land, ca. 10- to 30-m wide, along each side of the river channel function to stabilize banks and as a metabolic filter for nutrients and other substances potentially released from land. These narrow strips of vegetated riparian land can retain and reduce nutrient loadings to the channel by 65–100%. Hence, buffer zones and riparian strips function as barriers to eutrophication of streams, aid in channel stability, and have great ecological influence by provision of habitat patch variability. Variations in natural revegetation of the buffer strips are advantageous to enhance biodiversity and habitat differences. Restoration methods are also used to encourage development of wetlands at juncture points of small tributaries or drainage ditches to the main channel.

2. Reduction of Channel Slide–Slope

Reduction of the slope gradient at the edge of the channel, particularly when dredging is periodically required, will encourage channel meandering and floodplain revegetation.

3. Channel Migration and Floodplain Development

Reversion of the channel to natural migrations and meandering morphology increases channel length, alters path morphology, and greatly increases habitat diversity. The erosional and depositional process (see pp. 97–102) will seek a meander frequency of about five to seven channel widths, dissipates flow energy, and allows for greatest habitat variability. Because of the greater time that water spends in contact with sediment surfaces, nutrient retention and spiraling properties are optimized.

C. Acidification

Mitigation of the acidification of lakes and rivers requires long-term reductions in atmospheric pollution and involves complex socioeconomic issues. Reduction at the sources of acidic precipitation is clearly the best alternative strategy for restoration of acidified lakes and streams (Schindler *et al.*, 1991; Schindler, 1997). Acidified lakes and streams begin to recover rather quickly once acid inputs are reduced, assisted by alkalinity producing anaerobic bacterial processes in the systems (see earlier discussion, p. 197). Depletion of base cations in soils impairs the ability of catchment soils to neutralize acid (Likens *et al.*, 1996). Short-term restoration of acidified surface waters has been accomplished by the addition of alkaline materials to the affected lake, stream, or drainage basin (Olem, 1991). Although several substances have been used, additions of limestone ($CaCO_3$) are most common and generally increase nutrient cycling, decomposition, and productivity of phytoplankton and other biota. These restoration procedures are never ideal in their effectiveness for recovery, often of very short duration before repetition of treatment is needed, and are extraordinarily expensive.

V. EPILOGUE

In the comparative approach taken in the foregoing pages, a concerted attempt was made to integrate the massive number of dynamic variables that govern and effect the resultant biotic productivity and conditions. Dominant factors regulating the differing productivity of the ecosystems of lakes, reservoirs, and rivers were contrasted. The underlying rationale was to emphasize the basic control mechanisms that operate on the progressive changes that lead to enrichment and increases in productivity per given quantity of water and why the resulting medley of organisms function together. Only by understanding these regulatory mechanisms can we understand what is likely to happen as aquatic ecosystems are variously disturbed by human activities.

Our understanding of the operation of freshwater ecosystems has come a great distance in the last century. However, if we really scrutinize the existing information in an unbiased way, the only possible conclusion is that we remain quite ignorant of this beautifully complex integration in aquatic ecosystems. The accrual of needed information must be greatly accelerated in order to understand how these systems function before they are irreversibly altered by human activities. As has been demonstrated so well in the human medical profession, there is no alternative to devoting a greater percentage of our intellectual and financial resources to understanding biotic regulation, in this case of freshwater quality. Everything allocated to this critical resource, the foremost resource of our survival, thus far

has been utter tokenism. We have passed the point at which we can continue to take unabatedly without casting back some comprehensive understanding and wise use in return. Nature is remarkably resilient to human insults. Yet, humans must learn what are nature's dynamic capacities, because excessive violation without harmony will only unleash her intolerable vengeance. The very survival of humankind depends on our understanding and wise use of our finite freshwater resources.

VI. SUMMARY

1. Water quality is biologically mediated and is the result of a complex integration of biological components within environmental variability. Understanding that mediation is essential to effective water management.
2. Species diversity of lakes, streams, and wetlands is poorly understood but is certainly equal to or greater than that in terrestrial environments. Biodiversity is highest in the land–water interface regions where habitat diversity is remarkably large.
3. Biodiversity decreases precipitously as salinity increases. Saline lakes are species-poor, although reduced competition often allows exploitation of resources with reduced competition and extensive development and high productivity of a few species.
4. Biodiversity within freshwater ecosystems is examined in relation to a gradient of loadings of nutrients and of the chemical composition of organic matter to these ecosystems (Fig. 26-1). These changes are also examined in relation to hypothesized shifts in ecosystem resilience or relative stability—that is, the rate at which a property or the ecosystem returns to a quasi-steady state following a perturbation. Increased rates of nutrient recycling tend to decrease resilience.
5. Regulation of biotic regeneration and recycling of nutrients, and thus resilience to disturbances, is markedly influenced by the sources of organic substrates.
   a. From an entire ecosystem perspective, much of the organic carbon entering aquatic ecosystems is respired by microbial heterotrophs without entering the metazoan food web.
   b. Dissolved organic carbon emanating from decomposing higher plant tissues buffers the rates of nutrient recycling and increases resilience of the ecosystem. Shifts in the ratios of higher vegetation vs. algal dominance in the development of aquatic ecosystems therefore alter relative stability.
6. Maximum metabolic stability of aquatic ecosystems occurs where dissolved organic matter loadings derived from higher plant tissues from land–water interface and terrestrial sources are high. As a result, a concordance of biodiversity and relative stability occur.
7. Major disruptions of river ecosystems occur by regulation of flows, particularly by impoundment in reservoirs and channelization.
   a. Periodic disturbance by flooding and inundation of the flood plain is critical to functions of nutrient retention and cycling, maintenance of habitat diversity and productivity, and high biodiversity.
   b. Nearly all major rivers and many tributaries are impounded with dams, and the channels are often constrained by levees or dikes to retain water for agricultural, industrial, and domestic purposes, hydroelectricity, and for flood protection.
   c. Regulation of river flows by dams and controlled release of water and channelization reduce or eliminate the essential linkages between the river and its floodplain margins.
   d. Removal of the flooding and lateral channel migration effectively eliminates the resetting functions and degrades the rivers and eliminates most of their biological functions.
8. Five major types of degradation of surface waters have occurred in recent times. Various remediation methods are summarized.
   e. Eutrophication from nutrient enrichments, which causes excessive growth of algae and macrophytic plants. Thirteen common methods for remediation to reduce nutrient availability or habitat for photosynthesis of phytoplankton and macrophytes within the contaminated waters are summarized.
   f. Siltation as a result of soil erosion, particularly from agriculture.
   g. Acidification of waters from excessive loading of hydrogen ions from strong acids from ions in acidic atmospheric precipitation derived from human combustion products of petroleum. Remediation of acidified waters is difficult and expensive.
   h. Diffuse introduction of toxic materials (e.g., heavy metals, chlorinated hydrocarbons, and radioisotopes). Remediation, if possible at all once contaminants are dispersed, is often ineffective and manifoldly (at least 10 times) more expensive than removing the contamination at the sources where they are concentrated.

Note: A few discrepancies occur in the transliteration of Slavic languages. When the work of an author is translated into another language and I have cited only one of his or her works, that citation is recorded as printed even if the transliteration is incorrect. When more than one work of the same author is cited but some are from the mother language, the name is cited consistently as it should be transliterated. An exception is Vinberg in the Russian, because of his European ancestry, the author used Winberg in several important writings in the English. Conforming to the transliteration in this case could lead to confusion if the references were sought.

Further discrepancies appear as abbreviations for certain journal names have evolved over time. The original definitions and abbreviations of journals have been retained, but are later cited to what they have been changed (e.g., Amer. is now Am., Mich. is now MI, Water is now Wat., etc.).

Placing some names in alphabetical order can be confusing. The surname (family) name should of course have priority, and usually does (e.g., de Angelis is under A). Where the foreign article de or preposition van, among others, is part of the name, it is organized under the first letter (e.g., DeAngelis is under D).

	1 Btu ft/ft² h °F	=	1.73073 W/m K
Gas constant	1 ft lbf/lb °R	=	0.00538032 kJ/kg K
Plane angle	1 rad (radian)	=	57.2958°
	1 degree	=	0.0174533 rad = 1.1111 grade
	1 min	=	2.90888×10^{-4} rad = 0.0185 grade
	1 sec	=	4.84814×10^{-6} rad = 0.0003 grade
Radioactivity	1 Ci (curie)	=	37 GBq (becquerel)
	1 μCi	=	37 kBq

Interrelationships of Selected Units of Irradiance and Illuminance

	μmol quanta/m²-s	*J/m²-s*	*erg/cm²-s*	*gcal/cm²-min*	*lux[a] (illuminance unit)*
μmol quanta/m²-s	1	1.20×10^{-1}	1.20×10^{2}	1.72×10^{-4}	$\sim 5.12 \times 10^{1}$
J/m²-s (= W/m²)	5.03	1	10^{3}	1.43×10^{-3}	$\sim 2.5 \times 10^{2}$
gcal/cm²-min	5.83×10^{3}	6.98×10^{2}	6.98×10^{5}	1	$\sim 1.8 \times 10^{5}$
lux[a] or m-candle (= 1 lumen/m² or 0.0929 ft-candle)	$\sim 1.953 \times 10^{-2}$	$\sim 4.0 \times 10^{-3}$	~4.0	$\sim 5.7 \times 10^{-6}$	1

[a] Energy equivalents are given in terms of visible range in daylight (380–720 nm). 1 W/m² ≈ 4.6 μmol quanta/m²-s; 1 lux × 0.01953 μmol quanta/m²-s; 1 lux = 4.1×10^{-7} W/cm² = 6.0×10^{-6} gcal/cm²-min; 1 lumen = 4.17×10^{-3} W (1 W = 240 lumens); 1 ft-candle = 4.6×10^{-6} W/cm² = 6.5×10^{-5} gcal/cm²-min; 1 W/cm² = 2.4×10^{6} lux = 2.2×10^{5} ft-candles; and 1 gcal/cm²-min = 1.6×10^{5} lux = 1.5×10^{4} ft-candles.
